Recent progress in matter-wave interferometry aims to directly probe the quantum properties of matter at ever increasing scales. However, in order to perform interferometric experiments with massive mesoscopic objects, taking into account the constraints on the experimental set-ups, the point-like particle approximation needs to be cast aside. In this work, we consider near-field interferometry based on the Talbot effects with a single optical grating for large spherical particles beyond the point-particle approximation. We account for the suppression of the coherent grating effect and, at the same time, the enhancement of the decoherence effects due to scattering and absorption of grating photons.

I. INTRODUCTION

The experimental observation of quantum superpositions at the macroscopic level has proven a tall order due mainly to quantum decoherence effects. In this context, matter-wave interferometry, which directly probes the superposition principle of quantum mechanics, offers the possibility to test quantum mechanics and modifications thereof with increasingly larger objects. This paves the way to the characterization of the quantum-classical transition and potentially the investigation of possible modifications of quantum mechanics. The assessment of quantum spacetime effects is the core of recent proposals for observing quantum superposition of increasingly large systems, most prominently macro-molecules and nano-spheres.

However, all the current proposals employing near-field interferometry with optical gratings work in a regime where the system of interest has a linear dimension much smaller than the grating laser’s wavelength, i.e., when Rayleigh approximation is not valid. Near-field interferometry with optical gratings, instead of material ones, is of particular interest for exploring the limits of quantum mechanics. In combination with current levitation and cooling techniques, it is the core of recent proposals for observing quantum superposition of increasingly large systems, most prominently macro-molecules and nano-spheres. However, all the current proposals employing near-field interferometry with optical gratings work in a regime where the system of interest has a linear dimension much smaller than the grating laser’s wavelength, i.e., when Rayleigh approximation holds true. Thus, in view of applying this technique to larger and larger objects it is crucial to sidestep the point-like approximation and account for the reduced coherent effect of the grating in combination with its enhanced decoherence effects.

In this work we make a step in this direction by applying the formalism developed in Ref. 15 to account for the decoherence effect due to scattered grating photons on spherical particles. The reduced coherent effect of the grating is also considered, and the effect of absorbed photons is touched upon. We give some examples of interference patterns and quantum visibilities when realistic experimental parameters are considered.

The remainder of this paper is organized as follow. In section II we briefly review the Talbot–Lau effect for optical grating and give the expressions for the interference pattern and Talbot coefficients which determine it. In Sec. III we discuss the reduced coherent effect of the grating when the Rayleigh approximation is not valid. In Sec. IV we introduce decoherence effects due to scattering of grating photons off spherical particles. Furthermore, we consider how to include the effect of absorption in the picture, whilst the fact that a fully fledged quantum formalism for this is currently not available. Finally, we discuss how to obtain the classical limit and its relevance to the problem at hand. In Sec. V some example of interference patterns are shown which highlight the effects of misusing Rayleigh approximation. We conclude this work in Sec. VI with a discussion of the results and future perspectives.

II. TALBOT–LAU EFFECT FOR OPTICAL GRATINGS

Here, we shall provide a concise review of the Talbot effect for matter-wave interferometry in the eikonal approximation. A more in-depth analysis can be found in Ref. 16–19.

The dynamics of a polarizable quantum particle interacting with an electromagnetic standing wave in the interaction picture is described by the master equation

$$\partial_t \rho_t = -\frac{i}{\hbar} [V(\hat{r}_t, t), \rho_t] + \mathcal{L}_t (\rho_t),$$

where $V(\hat{r}_t, t)$ is the interaction potential and $\mathcal{L}_t = \mathcal{L}_{\text{sca}} + \mathcal{L}_{\text{abs}}$ is the dissipative term taking into account the effects due to scattering ($\mathcal{L}_{\text{sca}}$) and absorption ($\mathcal{L}_{\text{abs}}$) of grating photons.

As a full quantum description of matter-light interaction encompassing both scattering and absorption mechanisms is currently lacking, we make use of the results in

*These authors contributed equally to this work
Ref. [15] to describe both the coherent effects of the grating and the decoherence due to photon scattering, while making use of semiclassical arguments [17, 18], to include decoherence effects due to absorption. This results in the interaction potential

$$V(\hat{r}_t, t) = -\frac{\varepsilon_0 e^2}{4} \int_{V_n(\hat{r}_t)} dr |E_{\text{ev}}(r)|^2,$$ (2)

where $\varepsilon_0$ is the vacuum permittivity, $\epsilon_n^r$ is the real part of $\epsilon_n = 3(\epsilon - 1)/(\epsilon + 2)$ with $\epsilon$ the relative permittivity, and $E_{\text{ev}}(r)$ is the electric field of the standing wave. The integral is extended over the volume $V_n(\hat{r})$ of the dielectric particle. We will give explicit forms for the scattering and absorption decoherence terms described by $L_{\text{scat}}(\rho)$, $L_{\text{abs}}(\rho)$ in Sec. [15] [cf. Eqs. (25) and (35), respectively].

The net effect of the optical grating on the matter-wave density matrix is then given by

$$\rho \rightarrow T e^{i \int_0^{\tau_{\text{int}}} d\tau L_r(\rho)},$$ (3)

where the super-operator $L_r$ is defined through $L_r(\rho) = -\frac{i}{\hbar}[V(\hat{r}_t, t), \rho_t] + L_i(\rho_t)$, $\tau_{\text{int}}$ is the interaction time, and $T$ denotes the time ordering operator. Note that, in the case of pulsed-light grating, the interaction time is determined by the duration of the pulse.

By assuming a waist of the standing wave that is much bigger than the matter-wave profile, and an interaction time $(\tau_{\text{int}})$ that is negligible compared to the characteristic time of spreading of the matter waves, we can rely on the longitudinal eikonal approximation [19] to reduce the problem to an effective one-dimensional dynamics along the direction of propagation of the standing-wave propagation [cf. Fig. 1 for the coordinates setting]. This approximation allows us to rewrite Eq. (3) as

$$\rho(z, z') \rightarrow R(z, z') T(z, z') \rho(z, z'),$$ (4)

where $\rho(z, z') = \langle z | \rho | z' \rangle$ is the matter-wave density matrix in position representation, and we have introduced the phase-modification mask

$$T(z, z') = t(z) t^*(z') = e^{-\frac{i}{\hbar} \int_0^z dr [V(z, \tau) - V(z', \tau)]}$$ (5)

with $V(z, t)$ the classical interaction potential, and a decoherence mask

$$R(z, z') = e^{i \int_0^{\tau_{\text{int}}} d\tau L_i(z, \tau')} = R_{\text{scat}}(z, z') R_{\text{abs}}(z, z').$$ (6)

In order to make the description more transparent, it is convenient to rewrite Eq. (1) in a phase-space picture. We thus introduce the Wigner function associated with $\rho$ defined as

$$w(z, p) = \frac{1}{2\pi\hbar} \int dz' e^{ipz'} (z - s/2) |\rho(z + s/2),$$ (7)

with $z$ and $p$ the position and momentum coordinates in phase space. The effect of the grating in Eq. (1) is then described by the action of a convolution kernel $\hat{T}(z, p - q)$ on the Wigner function of the system [16], that is

$$w'(z, p) = \int dq \hat{T}(z, p - q) w(z, q).$$ (8)

The convolution kernel can be written explicitly as

$$\hat{T}(z, p) = \int dq R(z, p - q) T(z, q),$$ (9)

where

$$T(z, q) = \frac{1}{2\pi\hbar} \int dz' e^{ipz'} R \left( z - s/2, z' + s/2 \right)$$ (10)

describes the coherent effect of the grating on the matter-wave, and

$$R(z, p) = \frac{1}{2\pi\hbar} \int dz' e^{ipz'} R \left( z - s/2, z' + s/2 \right)$$ (11)

accounts for the incoherent effects of the grating. Exploiting the periodicity of the grating, the transmission function [Eq. (5)] and decoherence mask [Eq. (6)] can be written in Fourier series as

$$t(z) = \sum_{n=-\infty}^{\infty} b_n e^{\frac{2\pi inz}{d}},$$

$$R \left( z - s/2, z' + s/2 \right) = \sum_{n=-\infty}^{\infty} R_n \left( \frac{s}{d} \right) e^{\frac{2\pi inz}{d}},$$ (12)

where $d$ is the grating period, $b_n = \frac{1}{d} \int_{-d}^d dz e^{\frac{2\pi inz}{d}} t(z)$, and

$$R_n \left( \frac{s}{d} \right) = \frac{1}{d} \int_{-d}^d dz e^{\frac{2\pi inz}{d}} R \left( z - s/2, z + s/2 \right).$$ (13)

Finally, using Eq. (12) the convolution kernel takes the form

$$\hat{T}(z, p) = \frac{1}{2\pi\hbar} \sum_n e^{\frac{2\pi inz}{d}} \int dz' e^{ipz'} B_n \left( \frac{s}{d} \right)$$ (14)

FIG. 1. Optical standing wave grating. The figure shows the coordinate convention that we are using, in which $z$ is the relevant direction in the longitudinal eikonal approximation. We consider a standing wave linearly polarized in the $x$ direction which gives rise to a grating of period $d = \lambda/2$. 
The $\tilde{B}_n$’s are known as Talbot coefficients and characterize the fringe pattern due to quantum matter-wave interference\[19\]. These coefficients are conveniently expressed in Eq. (15) in terms of the Fourier coefficients of the decoherence mask function $R_n$ and of the transmission function $b_n$. The latter are indeed contained in the Talbot coefficients $B_n$

$$B_n\left(\frac{s}{d}\right) = \sum_j B_{n-j}\left(\frac{s}{d}\right) R_j\left(\frac{s}{d}\right)\,.$$ (15)

which describe only the coherent grating effect.

### III. COHERENT GRATING FOR LARGE SPHERES

The periodic modulation of the phase of the matter-wave quantum state of a polarizable particle operated by the optical grating is at the basis of the Talbot effect. We consider the case in which the grating is realised by retro-reflection of a laser pulse off a mirror. This produces a linearly polarized standing wave field $E(r) = E_0 \hat{e}_r f(x, y) \cos(kz)$, where $f(x, y)$ is the transverse mode profile and $\hat{e}_r$ is the polarization unit vector. In the following, we assume that the dimension of the particle is much smaller than the waist of the laser in the transverse directions. This allows us to neglect the transverse mode profile, and thus take $f(x, y) \simeq 1$.

The use of short laser pulses to generate the optical grating\[18\] justifies the eikonal approximation used to determine the coherent phase modulation and allows us to neglect any transverse force. Thus, we concentrate only on the reduced one-dimensional state of the matter-wave along the standing-wave axis, i.e., we work in longitudinal eikonal approximation. It should be noted that, set-ups with laser pulses have been used in\[21\] and advocated for ground and space based experiments aiming to use massive objects\[5, 6\]. On the contrary, the use of a continuous laser for the grating introduces limitations on the speed of the particles which need to traverse the grating fast enough for the eikonal approximation to be valid. See\[19\] for how to go beyond the eikonal approximation.

1 In order to arrive at the full-fledged interference pattern, the evolution in phase space of the Wigner function from the source to the grating and from after the grating to the detection stage has to be obtained. Once the final Wigner function is given, the interference pattern can be straightforwardly derived noting that the position probability density function is just a marginal of the Wigner pseudo-probability. See e.g.\[20\].

### A. Polarizable point-like particles

Let us start by reviewing well-known results on the effect of the optical grating for particles in the Rayleigh regime. Given $k = 2\pi/\lambda$, the wave-number of the standing wave, and the radius $R$ of the particle, the condition for the particle to be in Rayleigh regime reads $kR \ll 1$. In this regime, the dipole interaction potential due to the standing wave $E$ is given by

$$V(z, t) = -\frac{1}{4} \text{Re}(\chi)|E(z, t)|^2,$$ (17)

where the polarizability \(\chi\) is

$$\chi = 4\pi\epsilon_0 R^3 \epsilon(\omega) - \frac{1}{\epsilon(\omega) + 2} = \epsilon_0\epsilon\chi V.$$ (18)

In the last expression the relative permittivity $\epsilon$ is the square of the complex refractive index $n(\omega)$ of the particle’s material, $V = 4\pi R^3/3$ is the volume of the particle, and we define $\epsilon_c = 3(\epsilon - 1)/(\epsilon + 2)$. When the polarizable-point-particle interacts with the standing wave grating, and ignoring for the moment incoherent effects, its quantum state (reduced on the longitudinal direction) evolves unitarily as $\langle z|\psi \rangle \rightarrow \exp(i\phi_0 \cos^2 kz)\langle z|\psi \rangle$, where the eikonal phase factor $\phi_0$ is obtained from integrating the dipole potential over the laser pulse duration\[5\]

$$\phi(z) = \frac{1}{\hbar} \int dV(z, t) = \phi_0 \cos^2 kz.$$ (19)

In particular, we have that $\phi_0$ can be expressed in terms of the material polarizability as well as the laser parameters as

$$\phi_0 = \frac{2\text{Re}(\chi) E_L}{\hbar \epsilon\epsilon_0 a_L},$$ (20)

where $E_L$ is the pulse energy and $a_L$ is the spot area of the laser.

### B. Coherent grating for large particles

Having briefly reviewed the point-particle case, we move now to consider spherical particles for which $kR \gtrsim 1$. We follow Ref.\[18\], where the coherent effect of optical standing-wave gratings on extended spherical particles is analyzed. The expressions that we obtain in the following will allow us to construct the Talbot coefficients in the general case where incoherent effects are relevant.

When the point-like particle approximation ceases to hold, a general treatment of light-matter interaction is in order since the particle can no longer be approximated by an electric dipole, and higher-order multi-poles ought to be considered. For homogeneous spherical particles, Mie scattering theory\[22, 24\] is appropriate. In fact, such theory offers exact solutions to Maxwell equations for light scattering from spherical objects. In order to derive
the optical potential we look at the longitudinal light-induced force on the dielectric sphere. Note that, as remarked in Ref. [18], transverse forces and corrections due to finite mode waist can be neglected owing to the short laser pulses that we are considering. The light-induced forces acting on the dielectric particle can be obtained by integrating the electromagnetic stress-energy tensor over a spherical surface surrounding the particle. We follow Ref. [23], where a series-expansion expression of the net radiation-force on a spherical particle of arbitrary size illuminated by a monochromatic light is obtained (see also Ref. [18]). We report here the expression for the longitudinal force on a dielectric sphere in vacuum in which we are interested

\[
\frac{F_z(z)}{I_0k^{-1}c^{-1}} = -(kR)^4 \sum_{\ell=1}^{\infty} \sum_{m=1,\pm1} \text{Im} \left[ \left( \ell + 2 \right) \frac{(\ell - m + 1)(\ell + m + 1)}{(2\ell + 3)(2\ell + 1)} (2a_{\ell+1,m}a_{\ell m}^* + a_{\ell+1,m}A_{\ell m}^* + A_{\ell+1,m}a_{\ell m}^* + 2b_{\ell+1,m}b_{\ell m}^* + b_{\ell+1,m}B_{\ell m}^* + B_{\ell+1,m}b_{\ell m}) \right]
\]

where \( I_0 = \alpha c_0 |E_0|^2 / 2 \) is the intensity parameter of the incident light. This series contains several coefficients \(-a_{\ell m}, b_{\ell m}, A_{\ell m}, B_{\ell m}−\) that are derived starting from Mie scattering theory and that we report in Appendix [A] for ease of exposition. As the longitudinal force due to linearly polarized standing-wave \( E \) is of the form \( F_z(z) = -F_0 \sin 2kz \), the eikonal phase \( \phi_0 \) can be written as

\[
\phi_0 = \frac{8F_0E_L}{\hbar c_0a_L k |E_0|^2}.
\]

In order to determine \( F_0 \), and thus \( \phi_0 \), we can just evaluate Eq. (21) at \( z = -\lambda/8 \). Fig. 2 shows an example of its behaviour for a Si sphere at \( \lambda = 354 \) nm with the bulk refractive index \( n = 5.656 + i2.952 \) (as tabulated in Ref. [28]). As expected, the Rayleigh prediction (red dashed line) stops being valid for \( kR > 1 \) and \( F_0 \) stops growing with the volume of the sphere, showcasing an oscillatory behaviour. While a physical intuition behind this behaviour is provided in Ref. [18], here we focus on the fact that, at the values of \( kR \) corresponding to the nodes of the oscillations, the phase grating will be completely absent. This suggests that care should be used when deciding the size of large particles, so as to maximize the grating effects and avoid regions where the grating effect disappears. Moreover, one should bear in mind that the grating effect of the optical standing wave is greatly reduced for large particles with respect to the prediction of Rayleigh theory.

Another interesting point to consider here is the sensitivity of \( F_0 \) to changes in the refractive index. Indeed, it appears that the behaviour of \( F_0 \) against \( kR \), can change significantly under variations of the refractive index. Fig. 3 shows the effect of a \( \pm 5\% \) variation in the value of the refractive index for fused silica at 200nm. Fluctuations in the real part of \( n \) can lead to quantitatively significant changes: the relative error in \( F_0 \) at the maxima can be as large as 10\% and even larger at the nodes. On the other hand, analogous inaccuracies on the imaginary part of \( n \) lead to less important effects.

We can conclude that, when doing Talbot-Lau interferometry with large spherical particles, the refractive index needs to be carefully estimated. Thus, the use of the bulk material refractive index could be too gross approximation to the sphere refractive index. This point deserves to be accounted for when planning for experimental realizations.

IV. INCOHERENT EFFECTS

A. Scattering

In order to describe the incoherent effects due to scattering of standing wave photons we rely on the theory developed in [27] for light-matter interaction in Mie regime. According to [27], the effect of the scattering is described,
under the assumption that the laser waist is much bigger than the size of the particle, by the action of the Lindblad super-operator

$$\mathcal{L}_{\text{sc}}(\rho) = |\alpha(t)|^2 \int d\mathbf{k}\delta(\omega_k - \omega_0) \times \left(2\mathcal{T}_{k,c}(\mathbf{r})\rho\mathcal{T}_{k,c}^*(\mathbf{r}) - \{\mathcal{T}_{k,c}(\mathbf{r}),\rho\}\right),$$

(23)

where the collisional operators are defined as

$$\mathcal{T}_{k,c}(\mathbf{r}) = \frac{i\hbar^2}{2\pi\omega} \int d\mathbf{k}' (\mathbf{k}'|c) f(\mathbf{k},\mathbf{k}') e^{-i(\mathbf{k}-\mathbf{k}') \cdot \mathbf{r}}$$

(24)

with $f(\mathbf{k},\mathbf{k}')$ the Mie scattering amplitude and $|c\rangle$ the mode function of the standing wave, i.e., $\langle r|c\rangle = 1/\sqrt{V_0} f(x,y)\cos(kz)$ ($V_0$ is the mode volume of the standing wave). Assuming the free evolution is negligible during the interaction time, and working in longitudinal eikonal approximation, the effect on the matter-wave due to the scattering of grating photons is described by the action of the scattering mask $R_{\text{sc}}(z,z') = e^{i\mathcal{L}_{\text{sc}}(z,z')}$ in position representation, where

$$\mathcal{L}_{\text{sc}}(z,z') = |\alpha(t)|^2 \int d\mathbf{k}\delta(\omega_k - \omega_0) \left[2\mathcal{T}_{k,c}(z)\mathcal{T}_{k,c}^*(z') - |\mathcal{T}_{k,c}(z)|^2 - |\mathcal{T}_{k,c}(z')|^2\right].$$

(25)

In our case, the standing wave is described in good approximation by $E(\mathbf{r}) \sim E_0\hat{\mathbf{e}}_z\cos(kz)$. Thus, using the mode function $\langle z|c\rangle = 1/\sqrt{V_0} \cos(kz)$, one can show that

$$\mathcal{T}_{k,c}(z) = \sqrt{\frac{2\pi^3}{V_0}} (\mathcal{T}_{k_0,c}(z) + \mathcal{T}_{k_0,c}^*(z)).$$

(26)

Substituting $z \to z_- = z - s/2$ and $z' \to z_+ = z + s/2$, and with the help of the above equation, we have

$$\mathcal{L}_{\text{sc}}(z_-,z_+) = |\alpha|^2 \frac{\pi c}{V_0} \left[\int d\Omega f(k,\mathbf{k}n)^2 e^{-i(1-n_z)ks} - 1\right]$$

$$+ \int d\Omega f^*(k,\mathbf{k}n) f(-k,\mathbf{k}n) e^{-iks} (e^{iks} - \cos(ks))$$

$$+ \int d\Omega f^*(-k,\mathbf{k}n) f(k,\mathbf{k}n) e^{iks} (e^{iks} - \cos(ks))$$

$$+ \int d\Omega f(-k,\mathbf{k}n)^2 e^{i(1+n_z)ks} - 1\right].$$

(27)

We notice that the spherical symmetry of the nanoparticle reflects in the following symmetry of the scattering amplitude

$$f(-k,\mathbf{k}n) = f(k,-\mathbf{k}n).$$

Exploiting the symmetry, and through lengthy but otherwise straightforward algebra, we finally get

$$R_{\text{sc}}(z_-,z_+) = \exp(F + a\cos(2kz) + ib\sin(2kz))$$

(28)

where

$$a = \frac{2\pi c}{V_0} \int d\tau |\alpha(\tau)|^2 d\Omega \text{Re}(f^*(k,\mathbf{k}n)f(-k,\mathbf{k}n)) [\cos(kn_zs) - \cos(ks)],$$

$$b = \frac{2\pi c}{V_0} \int d\tau |\alpha(\tau)|^2 d\Omega \text{Im}(f^*(k,\mathbf{k}n)f(-k,\mathbf{k}n)) \sin(kn_zs),$$

$$F = \frac{2\pi c}{V_0} \int d\tau |\alpha(\tau)|^2 d\Omega |f(k,\mathbf{k}n)|^2 [\cos((1-n_z)ks) - 1].$$

(29)

Note that $\int d\tau |\alpha(\tau)|^2$ can be expressed in terms of the laser pulse parameters as $\int d\tau |\alpha(\tau)|^2 = 4V_0E_L/(\hbar c\omega_a L)$. We can now compute the Fourier coefficients of the

\[\text{Note that } \int d\tau |\alpha(\tau)|^2 \text{ can be expressed in terms of the laser pulse parameters as } \int d\tau |\alpha(\tau)|^2 = 4V_0E_L/(\hbar c\omega_a L).\]
scattering mask $R_{\text{sc}}(z, z')$ which enters in the Talbot coefficients of Eq. (15)

$$R_n \left( \frac{s}{d} \right) = \frac{1}{d} \int_{-d/2}^{d/2} dz e^{i 2\pi n \frac{z}{d} a \cos (\frac{2\pi}{d} z) + i b \sin (\frac{2\pi}{d} z) + F} = e^F \left( \frac{a - b}{a + b} \right)^{n/2} I_n (a - b) \sqrt{a^2 - b^2}. \tag{30}$$

We can then use Graf addition theorem to rewrite the Fourier coefficients as

$$R_n \left( \frac{s}{d} \right) = e^F \sum_k I_{k+n}(a) J_n(b). \tag{31}$$

Exploiting this result we can conveniently write the Talbot coefficient, modified by the presence of scattering mechanisms, as

$$\tilde{B}_n \left( \frac{s}{d} \right) = e^F \sum_{k,m} J_{n-k}(\xi_{coh}) I_{k+m}(a) I_k(b), \tag{32}$$

where $\xi_{coh} = \phi_0 \sin (\frac{2\pi}{d} z)$, and using again Graf theorem obtain

$$\tilde{B} \left( \frac{s}{d} \right) = \sum_k \Lambda^{\frac{n+k}{2}} J_{k+n} \left( \frac{\xi_{coh} - a}{\sqrt{\xi_{coh} - a^2}} \right) J_n(b) \tag{33}$$

with $\Lambda = e^F (\xi_{coh} + a)/(\xi_{coh} - a)$.

### B. Absorption

Apart from the scattering of grating photons, also their absorption gives rise to an additional incoherent effect. This effect is relevant unless very low-absorbing material spheres are employed, and it is amplified by the size of the spheres. However, while a quantum formalism beyond the point-particle approximation exists for the description of scattering of grating photons, no such formalism is available for absorption.

In order to estimate the incoherent effect due to absorption, we follow here a semiclassical approach, fostered in Ref. [15], which is valid in the Rayleigh regime. Nonetheless, we will improve on it by considering the actual number of absorbed photons, which depends on the Mie absorption cross-section. The result coming from this analysis only embodies a rough estimate of the real effect of absorbed photons and, in general, results in a lower bound on the actual amount of decoherence. We comment on how to possibly extend this approach at the end of this Section.

In Ref. [15] a Lindblad (super-)operator describing the incoherent effect of photon absorption is obtained by treating absorption as a Poisson process and using the corresponding noise in a stochastic Schrödinger equation describing the evolution of the state of an absorbing particle. The end result, after averaging, is a Lindblad-like equation with jump operators describing the evolution of the state of the particle every time an absorption event happens. In order to determine the jump operator characterizing absorption, consider a spherical particle in the Rayleigh limit with complex polarizability, and the effect of absorbing a photon from the linearly polarized incident light with the mode function $f(r) e_i z$. As the mode function can be expanded on a basis of plane waves $f(r) = \sum f_k \exp(\mathbf{k} \cdot \mathbf{r})$, and the absorption of a plane wave photon amount to a shift in momentum space by $\hbar \mathbf{k}$, the effect of absorbing a photon from the incident light transforms a momentum state of the particle as

$$|p\rangle \rightarrow \sum f_k |p + \hbar k\rangle = f(r) |p\rangle. \tag{34}$$

Thus, the effect of the jump operator is given simply by the scalar mode function. The rate at which the absorption happens is related to the number of photons in the light field $|\alpha|^2$ times the single photon absorption rate $\sigma_{\text{abs}}/V_0$, where $\sigma_{\text{abs}}$ is the absorption cross-section and $V_0$ is the mode volume of the incident light.

For a standing wave, and neglecting the effect on the transverse motion of the particle, the action of the Lindblad operator on the particle’s density matrix reads

$$\mathcal{L}_{\text{abs}}(\rho) = \frac{c\sigma_{\text{abs}}}{V_0} |\alpha(t)|^2 \left[ \cos(kz) \rho \cos(kz) - \frac{1}{2} \left( \cos^2(kz), \rho \right) \right], \tag{35}$$

where the time dependence of $|\alpha|^2$ reflects the fact that we consider a pulse. In order to better estimate the effects of absorption for large particles, a first crude approximation is to consider the same Lindblad super-operator as in Eq. (35), whilst considering the right absorption cross section as given by Mie scattering theory. This is given by $\sigma_{\text{abs}} = \sigma_{\text{ext}} - \sigma_{\text{scat}}$, i.e. the difference between the total extinction cross-section and the scattering one. Explicitly

$$\sigma_{\text{abs}} = \frac{2\pi (2n + 1)}{k^2} \sum_{n=1}^{\infty} \left( \text{Re} \left( a_n + b_n \right) - |a_n|^2 - |b_n|^2 \right), \tag{36}$$

in terms of the Mie coefficients that can be found in Appendix A.

With these expressions at hand, we can follow again the steps in Sec. IV A while including also the absorption super-operator. The decoherence mask due to absorption is given by

$$R_{\text{abs}}(z, z') = \exp \left[ -2n_0 \sin^2 \left( k_0 \frac{z + z'}{2} \right) \sin^2 \left( k_0 \frac{z - z'}{2} \right) \right], \tag{37}$$

where $n_0$ is the mean number of absorbed photons at the anti-nodes $n_0 = \frac{\lambda \sigma_{\text{abs}}}{\hbar c} E_0 \lambda = \frac{\omega_0}{\omega} \sigma_{\text{abs}} \phi_0$. Note that, by substituting $z \rightarrow z_-$ and $z' \rightarrow z_+$ and including also the effect of scattering, Eq. (30) is modified to
where \( c_{abs} = n_0(1 - \cos(\pi s/d)) \). We can now follow exactly the same steps as for the scattering case and end up with new Talbot coefficients that include absorption

\[
\tilde{B}_n \left( \frac{s}{d} \right) = e^{F - c_{abs}/2} \sum_{k=-\infty}^{\infty} \left( \zeta_{coh} + a + c_{abs}/2 \right)^{\frac{-s}{2}} K_k(b) \times J_{n+k} \left( \text{sign} \left( \zeta_{coh} - a - c_{abs}/2 \right) \sqrt{c_{ph}^2 - (a + c_{abs}/2)^2} \right).
\]  

(39)

It should be noted that, the only difference between the expressions for absorption presented here and the ones in, e.g., [18] is in the use of the Mie absorption cross-section.

The treatment of the absorption decoherence is based on a semiclassical approach in the Rayleigh limit, i.e., treating the particle as point-like. While we have refined the result by using the Mie theory absorption cross section, the formalism does not properly account for the finite size of the particle and the variation of the light intensity across it. In order to extend the formalism beyond the Rayleigh approximation, we look at the non-conservative part of the classical force acting on a polarizable particle of finite size interacting with the electromagnetic field

\[
F_{nc}(r) = -\frac{e\epsilon'_0}{2} \int \frac{d\mathbf{r}}{V_{n}(r)} \text{Im}\{[\nabla \cdot E^*(r)]E(r)\},
\]  

(40)

where \( \epsilon'_0 \) is the imaginary part of \( \epsilon_c \). The appearance of a non-conservative force is an artifact of having ignored the dynamics of the internal degrees of freedom (d.o.f.s) of the particle. If the latter were to be included, the complete dynamics would be fully unitary and no non-conservative force would appear. As far as we know, a full model for dielectric particles is not present, for a single atom interacting with a single quantized field mode such a treatment is viable [28, 29] and leads indeed to the absorption and scattering of photons by the atom. Notwithstanding the technical details, from the form of the non-conservative classical force we could argue that, replacing \( \nabla \cdot E \) with the particle charge density \( \rho_q \) and including its dynamics, a potential term coupling the incident field with the internal phonons modes would arise. These terms will be analogous to the coupling between incident and scattered electric field used in [15], to derive Eq. (25), with now instead of the scattering amplitudes the absorption ones. This suggests that the right form of the absorption term should be similar to Eq. (27) with the appropriate amplitudes and phononic mode functions. However, as already mentioned, a microscopic model for the interaction between the internal d.o.f.s and light is currently missing.

C. Classical Limit

In near-field matter interferometry, a fringe pattern may also appear when a classical description of the particle – in terms of ballistic trajectories – is adopted. This is due to partial reflection by the light grating [10]. Therefore, a non-vanishing fringe contrast is not sufficient to prove genuine quantum interference and one would have to resort to a direct comparison between the quantum and classical models for the dynamics. The classical behaviour can be obtained as the limiting case of eqs. (10), (11) for \( \hbar \to 0 \) (applied to a classical probability distribution in phase space). Here, we do so for the coherent and incoherent convolution kernel, for both the scattering and the absorption case, as the \( \hbar \to 0 \) limit of the quantum expression.

To show how the limit is performed, it is convenient to consider first the coherent convolution kernel eq. (10)

\[
\mathcal{T}_{coh}(z, p) = \frac{1}{2\pi\hbar} \int ds e^{i\frac{z}{\hbar} s} e^{-\frac{i}{\hbar} \int_0^s d\tau [V(z-s/2, \tau) - V(z+s/2, \tau)]},
\]  

(41)

where we used Eq. (5). We first rescale the integration variable as \( s \to \hbar s \) to have \( \hbar \) appearing only in the argument of the exponential, and then Taylor expand the potential \( V(z \pm \hbar s) \) to first order in \( \hbar \). In this way, we get

\[
\mathcal{T}_{coh}(z, p) \simeq \frac{1}{2\pi} \int ds e^{i\frac{z}{\hbar} s} \left( p + \int d\tau \nabla V(z, \tau) \right) + O(\hbar),
\]  

(42)

which, upon taking the limit \( \hbar \to 0 \), gives us the classical convolution kernel

\[
\mathcal{T}_{class}(z, p) = \delta \left( p + \int d\tau \nabla V(z, \tau) \right).
\]  

(43)

Following the same logic, the classical limit of the decoherence convolution kernels can be obtained. It should be noted that, re-scaling \( s \) and then expanding around \( \hbar = 0 \) is equivalent to only performing an expansion around \( s = 0 \) of the argument of the exponential in the Fourier transform of the kernels.

Consider Eq. (11) with \( R_{coh}(z_-, z_+) \) given by Eq. (28). Rescaling the integration variable, the dependence on \( \hbar \) goes only in the functions \( a, b, F \) in Eq. (29). It is crucial to note at this stage that, for the electromagnetic field, the identification of \( |\alpha|^2 \) with the classical intensity \( I(\tau) \) over \( \hbar \) requires to expand the trigonometric functions in \( a, b, F \) to first order in \( \hbar \), in analogy with the coherent kernel. It is easy to see that the only non-vanishing contribution to the classical decoherence kernel arise from the
FIG. 4. (Color online) Effect of the optical grating, photon scattering, and absorption on the interference pattern in the classical limit. Here we use the parameters in Table I with $m = 10^6 \text{amu}$ and the corresponding $x = kR \sim 0.098$, where the use of the Rayleigh limit is well justified. Panel (a) shows the classical fringe pattern, when varying the maximum phase modulation $\phi_0$, without decoherence, i.e., what we obtain by taking the classical limit as discussed in the main text. In panel (b), the decoherence terms due to scattering and absorption are evaluated using the same integral kernels as for the quantum case. This is what has been advocated previously in the literature (cf. Ref. [17]). Panel (c) shows an instance of the interference patterns for $\phi_0 = 4$. The solid black curve corresponds to panel (a), the blue dashed curve to panel (b), and the red dotted curve is the quantum interference pattern including decoherence due to scattering and absorption of the grating photons. Due to different notations, the Rayleigh limit of the Lindblad super-operator in Eq. (27) differs from Eq. (2.24) in Ref. [18] by a factor of $1/4\pi$.

The same argument shows that, the classical limit of the absorption decoherence kernel in Eq. (27) vanishes, giving no contribution to the classical dynamics. However, a more refined treatment of absorption decoherence — along the lines depicted in Sec. [IVB] — should give a contribution similar to the one found for scattering. It is interesting to note that, treating the
FIG. 5. (Color online) Effect of the coherent grating and photon scattering on the interference pattern in the classical limit. Here we used the parameter in Table I with a mass \( m = 10^6 \text{amu} \) that corresponds to a value of \( x = kR \sim 0.46 \), for which the Rayleigh approximation is not well-justified. The figure shows an instance of the interference pattern for \( \phi_0 = 2 \), where only the decoherence due to scattering of grating photons is considered. The solid black curve corresponds to the classical limit as obtained in this work. The blue dashed curve corresponds to the classical limit obtained without modifying the incoherent kernels from the quantum case. The red dotted curve is for the quantum case. Notice the striking difference between the two classical interference patterns, which is larger with respect to the Rayleigh case given the greater effect of scattering decoherence in the Mie regime.

light-matter interaction in Rayleigh limit would lead to no decoherent effect for the classical dynamics\(^3\), whatever, in contrast to what has been argued in the existing literature. This observation could already be relevant for upcoming experiments working in the Rayleigh approximation, as it would help identify the working point at which the differences between classical and quantum interference patterns are maximum [cf. Figs. 4 and 5].

V. REALISTIC EXAMPLE

We now study the effects of scattering and absorption of grating photons on the interference pattern. The figure of merit embodied by the sinusoidal fringe visibility \( \mathcal{V}_{\text{sin}} \) is used here to complement the predictions coming from the sue of the interference pattern. As outlined in Ref. 5, 18, the interference pattern is often dominated by the first Fourier amplitude. Thus, the fringe contrast is well described by [cf. caption of Table I]

\[
\mathcal{V}_{\text{sin}} = 2 \left| \tilde{B}_1 \left( \frac{t_1 t_2}{t_T(t_1 + t_2)} \right) \right| \exp \left( -\frac{2\pi^2 \sigma_z^2 t_2^2}{d^2(t_1 + t_2)^2} \right). \tag{44}
\]

Here we focus on the fringe visibility of the quantum interference pattern. We follow a recent proposals for an experimental realization of matter-wave interferometry with nano-particles 5 from which the parameters in Table I have been drawn. There, silicon (Si) nano-particles with a mass of \( 10^6 \text{amu} \) have been considered. For such a mass, the scattering of grating photons is completely negligible, while the effect of absorption is not insignificant. Nevertheless, the results obtained from Mie and the Rayleigh theory for both scattering and absorption are in good agreement, as it should be expected given the value \( x = kR \sim 0.098 \) of the parameter controlling the validity of the point-like approximation.

\(^3\) In the Rayleigh approximation, the \( b \) term in Eq. 29, is identically zero due to the symmetry property of the scattering amplitude.
In particular, the interference pattern can be inferred from the table. In particular, \( \sigma_2 = \sqrt{\frac{k_B T}{(4\pi^2 m^2 \nu^2)}} \), \( D = d(t_1 + t_2)/t_1 \), \( t_T = d^2 m/\nu \). The mass \( m \) of the spheres enters also in the definition of the sphere radius via \( R^3 = \frac{(3/4\pi)}{(m/\rho_{Si})} \), greater the mass larger its radius.

However, a mass of \( 10^8 \text{amu} \) makes \( x = kR \sim 0.46 \). Although this is a modest increase with respect to the previous case, it turns out that the Rayleigh approximation is no longer well-justified. Fig. 6 shows the difference in the predictions obtained using the Rayleigh approximation versus those arising from Mie theory. It should be noted that, in Fig. 6 we consider only decoherence effects due to scattering of gratings photons, upon which we have full control. Thus, no decoherence effect due to black-body radiation, gas particle collisions, and, most importantly, absorption of grating photons is considered in this case. As can be easily seen, the visibility is strongly affected. Even more significantly, the form of the interference pattern is significantly modified, the deformation being even more important at higher values of the mass parameter.

Finally we note that, while we employ the sinusoidal visibility to show the results associated with the use of Mie theory, this is not a very useful indicator when it comes to comparing the quantum prediction for the interference pattern with the classical shadow pattern. Indeed, while the quantum visibility could be smaller than its counterpart corresponding to the classical pattern, the interference figures could still be clearly distinguishable due to the position and shape of the oscillatory peaks. We stress here that better figure of merit should be used in order to certify the quantumness of an observed interference pattern.

\[

\end{array}
\]

TABLE I. Parameters considered for Si spheres. The other parameters entering the generalized Talbot coefficients and the interference pattern can be inferred from the table. In particular, \( \sigma_2 = \sqrt{\frac{k_B T}{(4\pi^2 m^2 \nu^2)}} \), \( D = d(t_1 + t_2)/t_1 \), \( t_T = d^2 m/\nu \). The mass \( m \) of the spheres enters also in the definition of the sphere radius via \( R^3 = \frac{(3/4\pi)}{(m/\rho_{Si})} \), greater the mass larger its radius.

VI. CONCLUSION AND DISCUSSION

We have addressed the Talbot-Lau effect beyond the Rayleigh limit, accounting for the suppression of coherent grating effects due to large-size particleless, scattering and photon absorption.

We have only considered polarizable spherical particles and neglected their internal degrees of freedom. These approximations are the usual workhorse in many matter-wave experiments and allows to neglect decoherence effects due to coupling between the center-of-mass motion and other degrees of freedom.

The main results of this work are the expressions needed to describe the coherent and incoherent effects – beyond the Rayleigh approximation – due to optical grating. Nonetheless, the discussion of the classical limit provides some interesting insight. Indeed, we have shown that the classical limit of the decoherent effects due to scattering and absorption of gratings photons is qualitatively different from the results presents in the current literature. In particular, it appears that when the Rayleigh approximation is well justified then, in the classical limit, no effect due to scattering and absorption survives, leaving only the deflection of ballistic trajectories due to the standing wave. While relevant for current experimental proposals, this result has striking consequences also for future experiments aiming to study large particles superpositions as it significantly reduces the decoherence suppressing the would-be classical shadow effect from which the quantum interference pattern needs to be distinguishable.

Our study is motivated by the need to account for increasing sizes of particles in experiments aiming at probing the quantum-to-classical transition. However, a number of assumptions were necessary in order to develop our framework. Two of them are particularly relevant for future endeavours: spherical symmetry of the particles, and their homogeneity. While it could still be a very good approximation, Mie theory is not rigorously applicable when such assumptions are relaxed. Moreover, additional decoherence effects can arise due to the coupling between the center of mass and rotational degrees of freedom of a non-spherical and/or an-isotropic object, and by coupling with internal degrees of freedom. The assessment of such questions will be the focus of our future investigations.

VII. ACKNOWLEDGEMENTS

We would like to thank J. Bateman and S. Nimmrichter for useful discussions and suggestions. AB is grateful to Eric Lutz for hospitality in his group at Universität Stuttgart during completion of this work. The authors gratefully acknowledge support from the MSCA IEF project Perfecto (grant nr. 795782), the EU Collaborative project TEQ (grant nr. 766900), the DfE-SFI Investigator Programme (grant 15/IA/2864), COST Action CA15220, the Royal Society Wolfson Research Fellowship (RWSF\R3\183013), the Leverhulme Trust Research Project Grant (grant nr. RGP-2018-266).

FIG. 6. (Color online) Sinusoidal visibility of the interference pattern for a particle of mass $m = 10^8$amu, which corresponds to a value $x = kR \sim 0.46$ for the parameters reported in Table I. For this parameters, the use of the Rayleigh approximation is not fully justified. The blue-dashed curve represents the interference pattern visibility in the case in which Rayleigh approximation is used. The red-continuous curve represents the visibility when Mie theory is employed. In the inset, we report an instance of the interference pattern for $\phi_0 = 2$ showing a significant difference between the two situations.

Appendix A: Mie Scattering

In this appendix we collect the expressions used in the main text which derive from Mie scattering theory. We will not go into the detail of the derivation as we refer mostly to \[18-21\] for an exhaustive treatment. Nonetheless, we will spend some word on how we compute the scattering amplitudes used in section \[IV\].

Mie theory serves to obtain exact solution for the scattering of light off spherical homogeneous particles of arbitrary size. In a nutshell, consider a plane electromagnetic wave $E_0$ impinging on an homogeneous sphere. The latter will develop an internal field $E_{\text{int}}$ and modify the incident field adding a scattering component, in such a way that the external field is $E_{\text{ext}} = E_0 + E_s$. From the symmetry of the problem, both the internal, incident, and scattered field can be expanded in spherical harmonics.

Then, by imposing boundary condition on the transverse fields at the sphere surface (plus the fact that the internal field ought to be finite at $r = 0$), the scattered field can be related to the incident one thus obtaining scattering amplitudes and scattering — and absorption — cross-sections.

The scattering coefficients, characterizing the scattering of a plane wave moving along the $z$-axis and linearly polarized in the $x$-direction, are given by

$$a_n = \frac{\sqrt{\epsilon} \psi_n(\sqrt{\epsilon} r) \psi_n'(x) - \psi_n(x) \psi_n'(\sqrt{\epsilon} r)}{\sqrt{\epsilon} \psi_n(\sqrt{\epsilon} r) \psi_n'(x) - \xi_n(x) \psi_n'(\sqrt{\epsilon} r)}$$

$$b_n = \frac{\psi_n(\sqrt{\epsilon} r) \psi_n'(x) - \sqrt{\epsilon} \psi_n(x) \psi_n'(\sqrt{\epsilon} r)}{\psi_n(\sqrt{\epsilon} r) \psi_n'(x) - \sqrt{\epsilon} \xi_n(x) \psi_n'(\sqrt{\epsilon} r)}$$

where $x = kR$, and $\psi_n, \xi_n$ are Riccati–Bessel functions, which are often expressed in terms of spherical Bessel $j$ functions and spherical Henkel $h^{(1)}$ as

$$\psi_n(\rho) = \rho j_n(\rho)$$

$$\xi_n(\rho) = \rho h_n^{(1)}(\rho)$$

Here, as in the main text, $\epsilon$ is the relative permittivity of the sphere’s material.

As it should be clear from section \[IV\] in order to determine the scattering amplitudes to obtain the incoherent effect of scattering of grating photons, it is enough to consider the aforementioned case of an incident plane wave linearly polarized in the $x$-direction. The scattered field is related to the incident one via a vector scattering amplitudes $X$

$$E_s \sim \frac{e^{ikr}}{kr} X E_0.$$
The amplitude scattering matrix elements $S_{1,2}$ are given in terms of the scattering coefficients (A1) and the angular functions

\[ \pi_n = \frac{P_n}{\sin \theta} = -\frac{dP_n(\cos \theta)}{d\theta} \frac{1}{\sin \theta} \quad (A9) \]

\[ \tau_n = \frac{dP_n^1}{d\theta} = \frac{d}{d\theta} \left( -\frac{dP_n(\cos \theta)}{d\theta} \right) \quad (A10) \]

where $P_n(\cos \theta)$ are the Legendre polynomials of degree $n$.

Note that, in Rayleigh limit ($x \ll 1$) the scattering coefficients

\[ a_1 = -\frac{2x^3}{3} \frac{\epsilon - 1}{\epsilon + 2} + \mathcal{O}(x^5) \]

dominates and the scattering matrix elements become

\[ S_1^{(\text{Ray})} = \frac{3}{2} a_1, \quad S_2^{(\text{Ray})} = \frac{3}{2} a_1 \cos \theta \]

and we recover the Rayleigh scattering result

\[ f(k, k') = S_1^{(\text{Ray})} \sin \chi, \quad (A11) \]

where $\chi$ is the angle between the polarization direction of the incident light and the scattering direction.

For what concern Eq. (21), we need a slight extension of Mie theory to account for interaction with standing waves. The way to obtain the final solution is the same as depicted before. We refer the reader to [18, 25] for the details of the calculation. Here we limit ourselves to report the expressions which appears in Eq. (21). The coefficients $A_{\ell m=\pm 1}$, $B_{\ell m=\pm 1}$ are given by

\[ A_{\ell m} = \frac{i^{\ell+1}}{2\alpha^2 \sqrt{\Gamma(l+1)}} m \zeta(l+1) \quad (A12) \]

\[ B_{\ell m} = \frac{i^\ell}{2\alpha^2 \sqrt{\Gamma(l+1)}} \zeta(\ell), \quad (A13) \]

where $\zeta(\ell) = \frac{1}{2} \left[ (-1)^\ell \exp(-ikz) + \exp(ikz) \right]$ and $z$ represents the position of the center of mass of the sphere. The remaining coefficients $a_{\ell m}$, $b_{\ell m}$ appearing in Eq. (21) are obtained by combining $A_{\ell m=\pm 1}$, $B_{\ell m=\pm 1}$ with the scattering coefficients (A1)

\[ a_{\ell m} = a_\ell A_{\ell m} \quad (A14) \]

\[ b_{\ell m} = b_\ell B_{\ell m}. \quad (A15) \]
