Topological order on non-Hermitian Toric-code Model with Parity-time Symmetry

In this paper, based on a non-Hermitian Wen-plaquette (toric-code) model, we developed a theory for the non-Hermitian $Z_2$ topological order. The new topological theory is described by operation strings, phase strings, and dynamical strings for different topological excitations. The effective models for fermionic topological excitation becomes a non-Hermitian tight-binding lattice model. In particular, there exists spontaneous $\mathcal{PT}$ symmetry breaking for the topologically protected code subspace (the so-called topological qubits). At “exceptional points”, the degenerate topological ground states merge and the topological degeneracy turns into non-Hermitian degeneracy. In the end, the application of the non-Hermitian $Z_2$ topological order and its possible physics realization are discussed.

The non-Hermitian Hamiltonians obeying Parity-time($\mathcal{PT}$)-symmetry as a complex extension of the (Hermitian) quantum mechanics can exist purely real energy spectrum, which was proposed by Bender and Boettcher [1]. It can exhibit spontaneous $\mathcal{PT}$-symmetry breaking accompanied by transition from real to complex. The energy degeneracy points in non-Hermitian system are called “exceptional points” (EPs), at which energies coalesce and eigenvectors merge with each other. In physics, $\mathcal{PT}$-symmetric non-Hermitian systems are always obtained by appropriately engineered gain and loss that are steady systems out of equilibrium. There are a variety of suitable platforms to realize $\mathcal{PT}$-symmetric non-Hermitian systems, such as optical waveguide [2], electronics [3–5], microwaves [6], acoustics [7–9] and single-spin system [10]. Some applications associated with $\mathcal{PT}$-symmetric system have been explored including unidirectional transport [11, 12] and single-mode lasers [13, 14].

On the other hand, the $\mathcal{PT}$-symmetric non-Hermitian topological states of tight-binding models have been widely studied [15–20]. The classification of non-Hermitian topological phases in terms of symmetry has been developed including $\mathcal{PT}$-symmetry [21, 22]. However, there exists another type of topological states beyond Landau’s symmetry breaking paradigm – topological orders [23]. For the topological orders, all the excitations are gapped and have fractional statistics and the ground states have topological degeneracy, i.e., the quantum degeneracy for the ground states depends on the genus of the manifold of the background. The degenerate ground states of a topological order (on a torus) make up a protected code subspace (the topological qubit). It is possible to incorporate intrinsic fault tolerance into a quantum computer - topological quantum computation (TQC) which avoids decoherence and is free from errors [25].

A question is ”How about topological orders meet $\mathcal{PT}$-symmetric non-Hermitian?” In this paper, by taking the Wen-plaquette (toric-code) model as an example, we will study a $Z_2$ topological order on a $\mathcal{PT}$ symmetric non-Hermitian system and develop a theory for non-Hermitian ($Z_2$) topological order.

The non-Hermitian Wen-plaquette (toric-code) model: We introduce a non-Hermitian Wen-plaquette (toric-code) model [25–27], of which the Hamiltonian is

$$\hat{H}_{NTO} = \hat{H}_{TO} + \hat{H}_{PT}$$

where $\hat{H}_{TO} = -g \sum_i F_i$ with $F_i = \sigma_i^x \sigma_{i+\hat{e}_x}^y \sigma_{i+\hat{e}_y}^z + \sigma_i^y \sigma_{i+\hat{e}_y}^x \sigma_{i+\hat{e}_x}^z$ and $\hat{H}_{PT} = \sum_i (h_x \sigma_i^x + \text{ih}_z \sigma_i^y)$. $\sigma_i^{x,y,z}$ are Pauli matrices on sites $i$. In this paper, $g$ is set to be unit, $g = 1$. For this model, the Hamiltonian $\hat{H}_{NTO}$ is $\mathcal{PT}$ invariant, i.e., the time reversal operator $\mathcal{T}$ has the function $\mathcal{T} \hat{\sigma} \mathcal{T} = -\hat{\sigma}$ and the parity operator $\mathcal{P}$ has the function of rotating each spin by $\pi$ about the $x$-axis $\mathcal{P} = \prod_j \sigma_j^z$. As a result, we have $[\mathcal{P}, \hat{H}_{NTO}] \neq 0$ and $[\mathcal{T}, \hat{H}_{NTO}] \neq 0$, but $[\mathcal{PT}, \hat{H}_{NTO}] = 0$.

For the case of $g \gg h_x, h_z$, $\hat{H}_{NTO} \rightarrow \hat{H}_{TO}$, we have a $Z_2$ topological ordered state with a small non-Hermitian term. In this limit, the elementary excitations ($Z_2$-vortex/charge) are defined as $F_i = -1$ at odd/even sub-plaquette. The bound states of a $Z_2$-vortex and a $Z_2$-charge on the two nearest neighbor plaquettes obey fermionic statistics. For the case of $g \ll h_x, h_z$, $\hat{H}_{NTO} \rightarrow N_t \left( \begin{array}{cc} \text{ih}_z & h_x \\ h_z & -\text{ih}_z \end{array} \right)$ ($N_t$ is the number of lattice sites), we have a typical non-Hermitian Hamiltonian system with spontaneous $\mathcal{PT}$-symmetry breaking. In this paper, we focus on the case of $g \gg h_x, h_z$ and treat the non-Hermitian term $\hat{H}_{PT}$ as a perturbation. Now, the ground state becomes a non-Hermitian $Z_2$ topological ordered state.

Strings for non-Hermitian Wen-plaquette (toric-code) model: To characterize the quantum properties of the non-Hermitian topological order for $\hat{H}_{NTO}$, we introduce three types of strings along a $N$-step loop $C_N$: the operation strings $W_a(C_N)$, the (Hermitian and non-Hermitian) phase strings $P_a(C_N)$, and the (Hermitian

*Corresponding author; Electronic address: spkou@bnu.edu.cn
and non-Hermitian) dynamical strings \( D_a(C_N) \). The indices \( a = v, c, f \) correspond to three types of quasi-particles (Z2-vortex, Z2-charge, fermion).

Firstly, an operation string is defined as the product of spin operators \( W_a(C_N) = \prod_{i \in C} \sigma_i^z \), where \( \prod_{i \in C} \) is over all the sites on the string along a loop \( C \). A phase string is introduced as the product of phases along a loop \( C \), \( P_a(C_N) = \prod_{i \in C} e^{i \phi_i^a} \), where \( \phi_i^a \) is the phase of the quantum states at step \( i \) for \( a \)-type excitation. The dynamical string \( D_a(C_N) \) is introduced to characterize the hopping property, i.e., \( D_a(C_N) = \prod_{i \in C} \frac{\sigma_i^z}{|\tau_i^a|} \)

where \( \frac{\tau_i^a}{|\tau_i^a|} = e^{i \phi_i^a} \sigma_i^z \). For a given topological excitation (\( a = v, c, f \)), a dynamic string is a combination of an operation string and a phase string, according to the relationship of the three types of strings, i.e., \( D_a(C_N) = W_a(C_N) P_a(C_N) \).

We verify Hermitian/non-Hermitian dynamical string \( D_a(C_N) \) by verifying its conjugation. For the case of \( D_a(C_N) = D_v(C_N) \), a dynamical string is Hermitian; For the case of \( D_a(C_N) \neq D_v(C_N) \), a dynamical string is non-Hermitian. In particular, a dynamical string is \( PT \)-symmetric non-Hermitian when it satisfies the following conditions, \( [P, D_a(C_N)] \neq 0 \) and \( [T, D_a(C_N)] \neq 0 \), but \( [PT, D_a(C_N)] = 0 \).

For the non-Hermitian topological order described by \( \mathcal{H}_{5TO} \), we show the detailed definitions for different strings.

To create a Z2-vortex/Z2-charge, one define the operation string that connects the odd (even) sub-plaquettes \( W_{o/e}(C_N) = \prod_{i \in C} \sigma_i^z \). The product \( \prod_{i \in C} \) is over all the sites on the string along a loop \( C \) connecting odd-plaquettes (or even-plaquettes), \( s_i = x \) if \( i \) is odd and \( s_i = y \) if \( i \) is even. Under the perturbation \( h_z \sum_i |\tau_i^a| \),

\( Z2 \)-vortex/Z2-charge begins to hop along \( \hat{e}_x - \hat{e}_y \) direction. As a result, we have \( i \tau_i^{o/e} = h_z \sigma_i^z \). The phase string and dynamical string for \( Z2 \)-vortex/Z2-charge are obtained as \( P_v(C_N) = P_v(C_N) = 1, D_v(C_N) = D_v(C_N) = \prod_{i \in C} \sigma_i^z \), respectively.

The operation string for fermion is defined as \( W_f(C_N) = \prod_{i \in C} \sigma_i^z \) where \( s_i = z \) if the string does not turn at site \( i \), \( s_i = x \) if the turn forms a upper-left or lower-right corner, \( s_i = y \) if the turn forms a lower-left or upper-right corner. Under a perturbation \( h_z \sum_i |\tau_i^a| \)

(without considering the term \( h_z \sum_i |\tau_i^a| \), fermions begin to move. Now, we have \( i \tau_i^{o/e} = h_z \sigma_i^z \). The phase string and dynamical string for fermion are obtained as \( P_f(C_N) = \prod_{i \in C} e^{i \phi_i^f} \), \( D_f(C_N) = \prod_{i \in C} e^{i \phi_i^f} \sigma_i^z \) with \( \phi_i^f = \frac{\tau_i^a}{|\tau_i^a|} \). For the case of even number \( N \), the phase string is \( P_f(C_N) = \pm 1 \) and the dynamical string is \( D_f(C_N) = \pm \prod_{i \in C} \sigma_i^z = \pm W_f(C_N) \). The phase string and dynamical string for fermions are Hermitian. For the case of odd number \( N \), the phase string is \( P_f(C_N) = e^{i \phi_i^f} \) and the dynamical string is \( D_f(C_N) = e^{i \phi_i^f} \prod_{i \in C} \sigma_i^z = e^{i \phi_i^f} W_f(C_N) \). The phase string and dynamical string for fermions are \( PT \)-symmetric non-Hermitian according to \( [P, D_f(C_N)] \neq 0, [T, D_f(C_N)] \neq 0 \), and \( [PT, D_f(C_N)] = 0 \).

Effective Hamiltonian for quasi-particles - physics for one-step open dynamical strings: The open string creates two point-like objects that correspond to different types of quasi-particles (topological excitations) at its ends. In this part we use the perturbative method in Ref. [24] to describe the effective Hamiltonian of quasi-particles. These many-body Hamiltonians describe a hard-core boson/fermion system.

In the perturbative method, each hopping term \( \hat{t}_{i,j} \) for Z2-vortex/Z2-charge on \( I^a \)-lattice (\( a = v \) on lattice of odd sub-plaquettes and \( a = c \) on lattice of even sub-plaquettes) is proportional to to a one-step dynamical string \( i \tau_i^{o/e} \),

\[ i \tau_i^{o/e} \rightarrow i \tau_i^{o/e} = h_z (\phi_{a,i}^1, a_i^e, a_i^+ + e_{x_i}^a + e_{y_i}^a) + \phi_{a,i}^1 a_i^e, a_i^+ + e_{x_i}^a + e_{y_i}^a + h.c. \]  

(2)

where \( \phi_{a,i}^1 \) is the generation operator of the Z2-vortex/Z2-charge. Here, \( e_i^{x/a} \) is the unit vector along \( x/a \) direction on \( I^a \)-lattice, of which the lattice constant is \( \sqrt{2a_0} (a_0 \) is lattice constant of the original square lattice). For perturbative Hamiltonian on \( L_x \times L_y \) square lattice \( (L_x, L_y) \) are all even integers \( \mathcal{H}_{eff} = \sum_{i,j} (\phi_{a,i}^1, a_i^e, a_i^+ + 2g \sum_{i,j} \phi_{a,i}^1, a_i^e, a_i^+ (a = v, c) \), we obtain the dispersion of Z2-vortex/Z2-charge \( E_k = \sqrt{(\xi_k^a + 2g)^2 - \xi_k^a} \), where \( \xi_k^a = 2h_z \cos k_x^a + 2h_z \sin k_y^a \), \( k_x^a \) is the wave vector on momentum space for \( I^a \)-lattice. The mass gap is obtained as \( 2g \sqrt{1 - \frac{4h_z^2}{g^2}} \). When the term \( h_z \) becomes larger and larger, the energy gap for Z2-charge/Z2-vortex closes and quantum phase transition occurs.

In the perturbative method, the hopping term \( \hat{t}_{i,j}^{x/y} \) for two types of fermion on \( I^f \)-lattice (lattice of links) is proportional to to a one-step dynamical string \( i \tau_i^{x/y} \),

\[ i \tau_i^{x/y} \rightarrow i \tau_i^{x/y} = h_z (\phi_{f,i}^1, f_i^e, f_i^+ + e_{x_i}^f + e_{y_i}^f) + \phi_{f,i}^1 f_i^e, f_i^+ + e_{x_i}^f + e_{y_i}^f + h.c. \]  

\[ + \phi_{f,i}^1, f_i^e, f_i^+ + e_{x_i}^f - e_{y_i}^f + h.c. \]  

\[ + h_z (\phi_{f,i}^1, f_i^e, f_i^+ + e_{x_i}^f + e_{y_i}^f) + \phi_{f,i}^1 f_i^e, f_i^+ + e_{x_i}^f + h.c. \]  

\[ + \phi_{f,i}^1, f_i^e, f_i^+ + e_{x_i}^f - e_{y_i}^f + h.c. \]  

(3)

where \( \phi_{f,i}^1, f_i^e, f_i^+ \) are the generation operator of the fermionic quasi-particles on two sub-links, respectively. Here, \( e_i^{x/y} \) are the unit vector along \( x/y \) direction, respectively, with lattice constant to be \( \sqrt{2a_0} \). Then, the perturbative effective Hamiltonian of fermion is obtained as \( \mathcal{H}_{eff}^{f} = \sum_{i,j} (\hat{t}_{i,j}^{x/f} \hat{t}_{i,j}^{x/f} + \hat{t}_{i,j}^{y/f} \hat{t}_{i,j}^{y/f} \hat{t}_{i,j}^{x/f} + \hat{t}_{i,j}^{y/f} \hat{t}_{i,j}^{x/f} \hat{t}_{i,j}^{y/f} + \hat{t}_{i,j}^{x/f} \hat{t}_{i,j}^{y/f} \hat{t}_{i,j}^{x/f} + \hat{t}_{i,j}^{y/f} \hat{t}_{i,j}^{x/f} \hat{t}_{i,j}^{y/f} ) + h.c. \).
It is obvious that the energy spectra for fermions become complex with finite $h_z$.

**Effective pseudo-spin model for topologically degenerate ground states - physics for topological closed dynamical strings:** The ground state for $H_{\text{TO}}$ is a $Z_2$ topological order.\[23\] The ground states have topological degeneracy, i.e., different topologically degenerate ground states (TDGSs) are characterized by different topological closed operation strings (TCOSs) $W_a(C_N^{\text{close, topo}})$. Under the periodic boundary condition (on a torus) for $H_{\text{TO}}$, the degeneracy is dependent on lattice number, i.e., 4 on an even-by-even $(e \ast e)$ lattice, 2 on even-by-odd $(e \ast o)$, odd-by-even $(o \ast e)$ and odd-by-odd $(o \ast o)$ lattices. Thus we get a four-level (or two-level) system which can be mapped onto an effective pseudo-spin model for TDGSs.\[27\]

After considering a perturbative non-Hermitian term $H_{\text{PT}}$, the quantum tunneling processes occur that change one ground state to another. Then the transfer matrices between different TDGSs are characterized by the expectation values of topological closed dynamical strings (TCDSs) $D_a(C_N^{\text{close, topo}})$ around the torus. In the following parts we will derive the effective pseudo-spin model for TDGSs by calculating the expectation values for $D_a(C_N^{\text{close, topo}})$.

Firstly, we study the effective pseudo-spin model for TDGSs on an $e \ast o$ lattice that are characterized by TCOSs $W_a(C_L^e)$, $W_f(C_L^o)$ $(a = v$ or $c)$. Due to \{ $W_a(C_L^e)$, $W_f(C_L^o)$ \} = 0, we represent $W_a(C_L^e)$ and $W_f(C_L^o)$ by pseudo-spin operators $\tau_x$ and $\tau_z$, respectively. Now we map the two-fold TDGSs \{ $|m = 0\rangle$ \} and \{ $|m = 1\rangle$ \} onto quantum states of the pseudo-spin $\tau^z$ as $|\uparrow\rangle$ and $|\downarrow\rangle$, respectively. Here, $m$ is topological number of $\pi$-flux inside the holes of torus.

Under the perturbation, $H_{\text{PT}}$, there are two types of quantum tunneling processes - virtual $Z_2$-vortex/$Z_2$-charge propagating along $\hat{e}_x - \hat{e}_y$ directions around the torus and virtual fermion propagating along $\hat{e}_y$ direction around the torus.

For the virtual $Z_2$-vortex/$Z_2$-charge propagating along $\hat{e}_x - \hat{e}_y$ directions around the torus, the energy splitting $\Delta \sim \langle |D_o(C_L^{\text{close, topo}})| \downarrow\rangle = \langle |D_o(C_L^{\text{close, topo}})| \downarrow\rangle$ can be obtained by the high-order degenerate-state perturbation theory as $\Delta = 2L_xL_y\left(\frac{h_x}{L_x}\right)^{\frac{L_y}{L_x}}$ where the step number $L_0$ is equal to $\frac{L_xL_y}{1 - (\frac{h_x}{L_x})^{L_y}}$. Here $\xi$ is the maximum common divisor for $L_x$ and $L_y$. Because the TCDS $D_o(C_L^{\text{close, topo}})$ of $Z_2$-vortex (or $Z_2$-charge) plays a role of $\tau^x$ on the quantum states, we obtain the effective pseudo-spin Hamiltonian for TDGSs due to the contribution of $Z_2$-vortex (or $Z_2$-charge) as $\frac{\Delta}{\hbar^2} \tau^x$; For the tunneling process of fermion propagating around the torus along direction $\hat{e}_y$, we obtain the energy difference $\varepsilon \sim \langle |D_o(C_L^{\text{close, topo}})| \uparrow\rangle = \langle |D_o(C_L^{\text{close, topo}})| \downarrow\rangle$ of TDGSs as $\varepsilon = 16L_xL_y\left(\frac{h_x}{8}\right)\xi$. Because the TCDS $D_f(C_L^{\text{close, topo}})$ of fermions plays a role of $\tau^z$ on the quantum states, we obtain the effective pseudo-spin Hamiltonian for TDGSs due to the contribution of fermions as $\frac{\Delta}{\hbar^2} \tau^z$.

Finally, the two-level quantum system of the two TDGSs on an $e \ast o$ lattice is obtained as\[27\]

$$H_{\text{eff}}^{\text{close}} = \frac{\Delta}{4} \tau^x + \frac{\varepsilon}{2} \tau^z = \frac{1}{2} \left( H_{\text{eff}} \right)^{\text{close, topo}} = \begin{pmatrix} 0 & \alpha h_{\psi} \tau^y - \beta(\hat{h}_z) \tau^y \end{pmatrix}$$

where $\Delta = \alpha h_{\psi} \tau^y$ and $\varepsilon = \beta(\hat{h}_z) \tau^y$ (and $\beta$ are two real parameters). In thermodynamic limit, $L_0$, $L_y \rightarrow \infty$, we have $H_{\text{eff}}^{\text{close}} \rightarrow 0$ and the topological degeneracy becomes perfect and the $Z_2$ topological order is stable. According to odd number $L_y$, $Re \varepsilon \equiv 0$ and $\text{Im} \varepsilon = \pm 16L_xL_y\left(\frac{h_x}{L_x}\right)\xi \neq 0$, the effective pseudo-spin model turns into the typical $PT$ symmetric non-Hermitian ‘Hamiltonian’ that is invariant under a combined parity ($P$) and time-reversal ($T$) symmetry for $h_x$ and $g$, where $P \rightarrow \tau^y$ simply corresponds to an exchange of the two TDGSs and $T : i \rightarrow -i$. As a result, for odd number $L_y$, we have $\{ P, H_{\text{eff}}^{\text{close}} \} \neq 0$ and $\{ T, H_{\text{eff}}^{\text{close}} \} \neq 0$, but $\{ P, T, H_{\text{eff}}^{\text{close}} \} = 0$.

We may use similar approach to get the pseudo-spin model for TDGSs on an $o \ast e$ lattice ($H_{\text{eff}}^{\text{close}}$) and that on an $o \ast o$ lattice ($H_{\text{eff}}^{\text{close}}$). However, for the case of $e \ast e$ lattice, the situation changes. The TCDS $D_o(C_L^{\text{close}})$ $(a = v$ or $o$) that correspond to different quantum tunneling processes are all Hermitian and thus the effective pseudo-spin model $H_{\text{eff}}^{\text{close}}$ for TDGSs is Hermitian. See the detailed discussion in supplementary materials.

$PT$ spontaneous symmetry breaking for degenerate ground states: In this part, we focus on the TDGSs for a system on an $e \ast o$ lattice and show its $PT$ spontaneous symmetry breaking.

The effective pseudo-spin model for TDGSs is obtained as $H_{\text{eff}}^{\text{close}} = \frac{\Delta}{4} \tau^x + \frac{\varepsilon}{2} \tau^z$. The eigenvalues and (unnormalized) eigenvectors of $H_{\text{eff}}^{\text{close}}$ are $E_{\pm} = \pm \frac{1}{2} \sqrt{\Delta^2 - \varepsilon^2}$, $\psi_+ = e^{-i\frac{\varepsilon}{2}} |0\rangle + e^{i\frac{\varepsilon}{2}} |1\rangle$ and $\psi_- = ie^{-i\frac{\varepsilon}{2}} |0\rangle - ie^{i\frac{\varepsilon}{2}} |1\rangle$, where $\sin \Theta = |\varepsilon|/\Delta$. The energy splitting of two TDGSs is $\delta E = E_+ - E_-$. For the case of $\Delta \geq |\varepsilon|$ the system belongs to a phase with $PT$ symmetry, of which $E_+$ and $E_-$ are real and the eigenvectors are eigenstates of the symmetry operator, i.e., $PT \psi_\pm = \psi_\pm$. For the case of $\Delta < |\varepsilon|$, $E_+$ and $E_-$ are imaginary that correspond to a gain eigenstate and a loss eigenstate, respectively, i.e., $PT \psi_\pm \neq \psi_\pm$. A $PT$-symmetry-breaking transition occurs at the exceptional points $|\varepsilon| = \Delta$ that leads to the following relation $\alpha(h_x) \frac{L_y}{L_x} = \beta(h_x) \tau^y$.

In Fig.1, we plot the numerical results from the exact diagonalization technique of the Wen-plaquette model on $2 \ast 3$ lattice with periodic boundary conditions. Fig.1(a) shows the global phase diagram of $PT$-symmetry-breaking transition for TDGSs. The phase boundary are all exceptional points characterized by the relation $\alpha(h_x) \frac{L_y}{L_x} = \beta(h_x) \tau^y$. In Fig.1(b) and Fig.1(c), we
The phase boundary is exceptional points; (b) The absolute value of imaginary parts for energy splitting for the two degenerate ground states for the non-Hermitian toric-code model with $h_x = 0.2$ on $2\times 3$ lattice; (c) The absolute value of imaginary parts for energy splitting for the two degenerate ground states for the non-Hermitian toric-code model with $h_x = 0.2$ on $2\times 3$ lattice.

Application - initialization for quantum computation based on topological qubits: It was pointed out that the TDGSs for a $Z_2$ topological order make up a protected code subspace (the so-called toric-code) free from error\cite{25–27}. One can manipulate the protected code subspace by tune their quantum tunneling effect\cite{27}. However, due to the very tiny value of energy splitting for TDGSs, the initialization for quantum computation based on such topological qubits becomes very difficult.

We propose an alternative approach to initialize the system (for example, the TDGSs on an $e\ast o$ lattice) into a particular pure state. The basic idea is to drive the topological qubit to exceptional points by adding external field and then removal it slowly. This evolution will occur along the exceptional points according to the Hamiltonian $H_{\text{NTO}}(t) = H_{\text{TO}} + \sum_i [h_x(t)\sigma_i^x + ih_z(t)\sigma_i^z]$ where $h_x(t) = h_0(1 - e^{i\alpha t})$ and $h_z(t) = (\Delta t)^{1/2} (h_z(t))^{1/2}$. At the beginning, $t \rightarrow -\infty$, under the finite external field $h_x(t)$, $h_z(t)$, the system is at exceptional points. The effective Hamiltonian of the topological qubit in the external field becomes $H_{\text{eff}}^{e,o}(t) = \frac{\Delta t}{2} (\tau^x + i\tau^z)$. Due to the non-Hermitian term, the topological degeneracy is reduced into non-Hermitian degeneracy at the exceptional points. As a result, there doesn’t exist topological degeneracy and the two TDGSs merge into one quantum “steady” state, $\psi_+ \rightarrow |0\rangle - i|1\rangle \leftrightarrow \psi_- \rightarrow |0\rangle - i|1\rangle$.

At the time $t = 0$, when the external field disappears, $h_x(t) = 0$, $h_z(t) = 0$, a pure quantum state for quantum computation based on topological qubits is initialized as $|0\rangle - i|1\rangle$. This approach to initialization for topological qubits is much more efficiency than the traditional approach by adding a real external field in Ref.\cite{27}.

Conclusion: In this paper, the theory of non-Hermitian topological order is developed based on a non-Hermitian Wen-plaquette model. The effective models for bosonic topological excitations ($Z_2$ charge and $Z_2$ vortex) are Hermitian tight-binding lattice model; the effective model for fermionic topological excitation becomes a non-Hermitian tight-binding lattice model. In addition, the effective pseudo-spin model for TDGSs by calculating the expectation values for topological closed dynamical strings $D_\alpha(C^{\text{close},\text{top}})$. For the TDGSs of non-Hermitian Wen-plaquette model on an $e\ast o$, or $o\ast e$, or $o\ast o$ lattice, the effective pseudo-spin model turns into the typical $\mathcal{PT}$ symmetric non-Hermitian ‘Hamiltonian’. In particular, there exists spontaneous $\mathcal{PT}$ symmetry breaking for the TDGSs (topologically protected code subspace). At “exceptional points”, the TDGSs merge and the topological degeneracy turns into non-Hermitian degeneracy. By tuning the exceptional points, an efficiency approach to initialization for topological qubits is proposed.

In the end, we address the experimental realization of the non-Hermitian $Z_2$ topological order. It is still of challenge both to experimentally investigate $\mathcal{PT}$ symmetric Hamiltonian related physics in quantum systems and to realize the toric-code model. A possible approach is cold-atom experiments: On the one hand, non-Hermitian Hamiltonians arise in cold-atom experiments due to spontaneous decay\cite{24,31}; On the other hand, a small system for toric-code model has also been realized in cold atoms\cite{32}.
