Abstract

X-ray diffraction and Raman scattering measurements, and first-principle calculations are performed to search for the formation of NaCl-hydrogen compound. When
NaCl and H\textsubscript{2} mixture is laser-heated to above 1500 K at pressures exceeding 40 GPa, we find the formation of NaCl(H\textsubscript{2}) with \textit{P6}_3/mmc structure which accommodates H\textsubscript{2} molecules in the interstitial sites of NaCl lattice that forms ABAC stacking. Upon the pressure decrease at 300 K, NaCl(H\textsubscript{2}) remains stable down to 17 GPa. In addition, our calculations predict that the hydrogen-richer phase, NaCl(H\textsubscript{2})\textsubscript{4}, is stabilized at 40 GPa. The present study demonstrates that the application of high temperature as well as high pressure is an effective technique to synthesize a new hydride from a material that is resistant to hydrogenation. Further, the obtained results suggest the possible development of a practical, low-cost, and eco-friendly hydrogen-storage system using salt.

**INTRODUCTION**

Compressed hydrides have been predicted to be potential candidates for high-temperature (\(T_c\)) superconductivity.\textsuperscript{1-3} Recent discoveries of SH\textsubscript{3} and LaH\textsubscript{10} exhibiting \(T_c\) above 200 K\textsuperscript{4-6} are attracting great interest in novel hydrides. Moreover, in the development of high-capacity hydrogen-storage, hydrogen-richer compounds have great importance. Therefore, the synthesis of new hydrogen compounds, including unconventional stoichiometries, is crucial for progress of these studies.

At ambient pressure, sodium chloride (NaCl) is the only known binary compound formed by Na and Cl. The large electronegativity difference between Na and Cl stabilizes the highly ionic compound (Na\textsuperscript{+} and Cl\textsuperscript{-}) which crystallizes in a rock-salt (B1) structure. Although it is not widely known, NaCl is one of the few materials\textsuperscript{7-9} that have been tested and revealed to be inert to hydrogen (H\textsubscript{2}). Even in a high-pressure H\textsubscript{2} atmosphere reaching 100 GPa, there is no chemistry.\textsuperscript{7,8} Even when heated to 500 K at 20 GPa, NaCl does not react with H\textsubscript{2}.\textsuperscript{8} Therefore, NaCl has been used to create an H\textsubscript{2}-sealing capsule in high-pressure experiments.\textsuperscript{7,8} However, we found the interstitial site in a B1 structure using the Pauling ionic radius\textsuperscript{10} is large enough to accommodate an H\textsubscript{2} molecule whose molecular
size is approximately 1.5 Å. Further, the recent experiments have revealed that alkali-metal polyhydrides (AH\textsubscript{x}, A = Li and Na, \(x > 1\)), containing H\textsubscript{2} molecules in their unit cells, can be synthesized by heating ionic compounds such as LiH or NaH in high-pressure H\textsubscript{2}.\textsuperscript{11-13} Research findings from the studies of AH\textsubscript{x} suggest that the formation of NaCl(H\textsubscript{2})\textsubscript{x} may be anticipated by heating NaCl and H\textsubscript{2} together at high pressures. NaCl is non-poisonous, inexpensive, and abundantly available in seas and on land. Achieving hydrogen-storing NaCl would allow the development of a practical, low-cost, and eco-friendly hydrogen-storage system. The aim of the present study is to search for NaCl(H\textsubscript{2})\textsubscript{x} under high pressures and to characterize its structural and physical properties.

In this study, we performed a structure search based on a genetic algorithm technique and first-principles calculations, and we predicted two stable NaCl(H\textsubscript{2}) compounds with different hexagonal crystal structures (\(P6_3/mmc\) and \(P6m2\)) at pressures above 20 GPa, and NaCl(H\textsubscript{2})\textsubscript{4} with monoclinic (\(Pm\)) structure at pressures above 40 GPa. By using Raman scattering and X-ray diffraction (XRD) measurements, when NaCl/H\textsubscript{2} mixture was heated to above 1500 K at pressures exceeding 40 GPa, we observed the formation of NaCl(H\textsubscript{2}) with \(P6_3/mmc\) structure having H\textsubscript{2} molecules in the interstitial sites of NaCl that formed ABAC stacking. Our analysis indicates that NaCl(H\textsubscript{2}) is formed by the penetration of H\textsubscript{2} molecules into the crystal lattice of NaCl which has CsCl-type structure and the resulting deformation of the crystal structure. Upon the pressure decrease at 300 K, NaCl(H\textsubscript{2}) remains stable down to 17 GPa. These results propose the possibility of developing salt-based hydrogen storage materials by using high-pressure and high-temperature conditions.

**METHODS**

**Computational Methods**

To investigate the possible formation of NaCl-hydrogen compounds, we performed a crystal structure search based on a genetic algorithm technique and first-principles calculations.
We developed a crystal structure prediction code based on a genetic algorithm and combined it with the Quantum ESPRESSO code\textsuperscript{14,15} which was previously used in the search for thermodynamically stable phases in a sulfur-hydrogen system\textsuperscript{16} and argon-hydrogen system.\textsuperscript{17} In our structure search, eight structures were created by ‘mating’, six by ‘distortion’, and six by ‘permutation’ in each generation. We searched for stable structures at pressures of 30, 50, and 100 GPa using supercells including two formula units for NaClH, NaClH\textsubscript{2}, NaClH\textsubscript{3}, NaClH\textsubscript{4} and NaClH\textsubscript{8}. We used the Perdew-Burke-Ernzerhof exchange-correlation functional\textsuperscript{18} and the Vanderbilt ultrasoft pseudopotential.\textsuperscript{19} The $k$-space integration over the Brillouin zone was performed on an $8 \times 8 \times 8$ grid, and the energy cut-off of the plane-wave basis was set to 80 Ry. For the phonon calculation of $P6_3/mmc$ NaCl(H\textsubscript{2}), we used an $8 \times 8 \times 4$ $k$-point grid and a $4 \times 4 \times 4$ $q$-point grid.

**Experimental Methods**

To detect the formation of NaCl-hydrogen compounds and reveal their crystal structure, we performed X-ray diffraction (XRD) and Raman scattering measurements on the mixture of NaCl and H\textsubscript{2} (NaCl/H\textsubscript{2} mixture) heated to above 1500 K at pressures between 25 GPa and 46 GPa. In this study, to applied high pressures using a diamond anvil cell (DAC) equipped with type Ia diamond anvils with culets between 0.2 and 0.3 mm. Figure 1 shows a schematic drawing of the sample chamber in a DAC. The 0.25 mm-thick gaskets made of Re (Aldrich, 99.98\%) were pre-indentened to 50-60 $\mu$m-thick, and a 150 $\mu$m-diameter hole (sample chamber) was drilled through the center of the gasket. In the sample chamber, we loaded two NaCl (Wako, 99.95\%+) thin plates, each of which has a thickness of about 10 $\mu$m, with fluid H\textsubscript{2}. we used IR-lasers (SPI laser, $\lambda = 1070$ nm and $\lambda = 1090$ nm) to heat the NaCl/H\textsubscript{2} mixture compressed in a DAC. Because NaCl does not absorb an IR laser, tiny chips of platinum (Pt, Nilaco, 99.95\%) in an experiment (Exp. 1) and gold (Au, Nilaco, 99.95\%) in other two experiments (Exp. 2 and 3) were supplied as laser absorbers, and the IR laser was focused on Pt or Au. Loading of H\textsubscript{2} fluid was performed by using a cryogenic gas-loading system.\textsuperscript{20}
We compressed the NaCl/H$_2$ mixture was first at room temperature to the desired pressure and heated the mixture to above 1500 K using an IR laser. We note that we obtained the same results using different laser absorbers.

During compression at room temperature, we confirmed that NaCl and H$_2$ did not react by observing the structural transformation via Raman scattering measurements. The heating temperature was estimated by collecting thermal radiation from the sample and analyzing it within a wavelength range of 600-800 nm to convert the radiation spectrum to a temperature in accordance with the Planck’s blackbody radiation law. Laser heating was performed at BL10XU/SPring-8 (SPI laser, $\lambda = 1070$ nm) and Nagoya University (SPI laser, $\lambda = 1090$ nm). During the laser heating at BL10XU/SPring-8, the reaction between NaCl and H$_2$ was detected by monitoring the crystal structure change of NaCl (B1 or B2) by in situ synchrotron XRD measurements using an X-ray flat panel detector (Perkin Elmer XRD0822 CP23, 1024 $\times$ 1024 pixels, pixel size: 0.20 mm). After heating for several minutes or after the reaction between NaCl and H$_2$ was confirmed by XRD, the sample was quenched to room temperature. After quenching, we performed Raman scattering and XRD measurements at room temperature. The XRD at 300 K were collected using an imaging plate (RIGAKU R-AXIS IV++, 300 $\times$ 300 mm$^2$, pixel size: 0.10 mm) in a forward scattering geometry. The Raman scattering measurements were performed in a backscattering geometry using a triple polychromator (JASCO NR1800) equipped with a liquid-nitrogen-cooled charge-coupled device. Radiation of 532 nm from a solid-state laser was used for excitation. The focused spot size of the radiation on the samples was approximately 10 $\mu$m in diameter. To estimate pressure, we used the shift of the first-order Raman band spectra of the diamond anvil facing the sample with a proposed calibration.
RESULTS AND DISCUSSION

Predicted stable phases of NaCl-hydrogen compounds: NaCl(H$_2$) and NaCl(H$_2$)$_4$ above 20 GPa

Figure 2a illustrates the formation enthalpy of NaCl-hydrogen compound ((NaCl)$_{1-x}$H$_x$) from NaCl and H$_2$. The convex hull diagram indicates that NaCl(H$_2$) emerges as the thermodynamically stable phase above 15 GPa and crystallizes in a hexagonal $P6_3/mmc$ structure at 30 GPa with lattice parameters $a = 3.515$ Å and $c = 6.465$ Å. The atomic positions are Na:2$c$(1/3, 2/3, 1/4), Cl:2$a$(0, 0, 0), and H:$4f$(1/3, 2/3, 0.808). Therefore, the Cl and Na layers stack in the ABAC manner along the c axis, and H$_2$ molecules occupy the center of mass in the Na triangles in the B (C) layer (Figure 2b). We also identified another hexagonal structure whose space group is a $P6m2$ with lattice parameters $a = 3.507$ Å and $c = 3.250$ Å. In the $P6m2$ structure, atoms are at Na:$1f$(2/3, 1/3, 1/2), Cl:$1a$(0, 0, 0), and H:$2h$(1/3, 2/3, 0.615) positions, and the layers of Na and Cl stack in AB manner (Figure 2c).

The hexagonal structure with AB stacking possesses a higher enthalpy by 0.15 mRy/atom than that of the ABAC stacking. In addition, we predicted that a hydrogen-richer phase, NaCl(H$_2$)$_4$, is stabilized at 40 GPa (Figure 2a and 2d). NaCl(H$_2$)$_4$ is obtained by deforming NaCl(H$_2$) with AB stacking. A NaCl(H$_2$) layer is formed by overlapping the B layer with A, and the hexagonal lattice is slightly distorted owing to the H$_2$ molecular axis orientation into the layer. Then, H$_2$ molecules are intercalated between the layers, and an (H$_2$)$_3$ layer
is created (Figure 2d). The space group of this structure is a monoclinic $Pm$ with lattice parameters $a = 4.155 \, \text{Å}$, $b = 3.146 \, \text{Å}$, $c = 4.197 \, \text{Å}$, $\beta = 118.91^\circ$. The detailed structural parameters for NaCl(H$_2$)$_4$ is shown in the Supporting Information.

In NaCl(H$_2$), if we assume that the H$_2$ molecules rotate freely, the shortest distance between the surface of a Na$^+$ cation and an H$_2$ molecule is 0.55 Å at 20 GPa. This distance is shorter than the H-H distance (0.74 Å at 1 bar) in an H$_2$ molecule. Therefore, the free rotation of H$_2$ can be blocked by a large energy barrier. H$_2$ molecules are considered to have rotational vibrations with limited angles (librons), and their molecular axes are roughly aligned along the $c$ axis.

Figure 2: Crystal structure search by a genetic algorithm technique and first-principles calculations. (a) Formation enthalpy per atom as a function of $x$ for (NaCl)$_{1-x}$H$_x$ at various pressures. The compounds whose enthalpies (cross marks) are above the convex hull are predicted to decompose. (b) The most stable structure of NaCl(H$_2$)$_4$, formed by ABAC stacking of a hexagonal layer. Na and Cl are depicted as a cation an anion, respectively. (c) Metastable structure of NaCl(H$_2$)$_4$, formed by AB stacking. (d) NaCl(H$_2$)$_4$, formed by the stacking of the (H$_2$)$_3$ layer and the NaCl(H$_2$) layer. The crystal structures were drawn using VESTA.

Figure 3 shows the calculated phonon dispersion of NaCl(H$_2$) with ABAC-stacking at pressures. Imaginary phonon frequency appears in $\Gamma$-M, M-K, K-$\Gamma$, $\Gamma$-A, and A-M lines at
10 GPa (Figure 3a), which indicates that this structure is unstable at the pressure. The imaginary phonon frequency disappears above 15 GPa (Figure 3b,d). The phonon at around 4250 cm\(^{-1}\) is the intramolecular stretching mode of H\(_2\) (H\(_2\) vibron) that occupies the 4\(f\) site in NaCl(H\(_2\))\(_2\). This H\(_2\) vibron is slightly dispersive at 50 GPa owing to the increases of the interaction between H\(_2\) molecules and the other atoms with compression (Figure 3d).

Figure 3: Phonon dispersion of NaCl(H\(_2\)) with ABAC stacking at pressures of (a) 10 GPa, (b) 20 GPa, (c) 40 GPa, and (d) 50 GPa.

**NaCl(H\(_2\)) synthesized above 17 GPa**

When the NaCl/H\(_2\) mixture was heated below 30 GPa, we detected no structural transformation of NaCl. On the other hand, at 46 GPa (Exp. 1) and 42 GPa (Exp. 2 and 3), where NaCl was in a cesium-chloride-type (B2) structure,\(^{24,25}\) the sample exhibited visible change after laser heating (Figure 4a,b). The laser-focused area was distinguishable from other areas, suggesting that some material was synthesized (Figure 4b). The visible difference became apparent at 33 GPa (Figure 4c,d) upon a pressure decrease and revealed the presence of a compound that had a refractive index different from that of either NaCl or H\(_2\). Hereafter, we refer the newly formed compound as NaClH\(_x\).
Figure 4: Visual observation of NaClH\textsubscript{x} synthesis in Experiment 1. (a) Microphotograph of the sample before laser heating at 46 GPa looking through a diamond anvil. Scale bar = 50 µm. Two pieces of PtH indicated by arrows were used for laser heating. (b) Sample after heating at 46 GPa. A dashed circle indicates the IR laser-focused area. The PtH laser absorbers moved and changed their shapes during laser heating. (c) Sample at 33 GPa upon pressure release. The bright line around the compound is the Becke line. (d) Schematic drawing of the components shown in (c).

Figure 5a and b present the synchrotron XRD profiles obtained in Exps. 1 and 2. The XRD peaks of the unheated area were indexed with NaCl (B2, \textit{Pm\overline{3}m}) and PtH (\textit{P6\textsubscript{3}/mmc}). We did not observe the formation of gold hydride (AuH\textsubscript{x}) in Exp. 2, which is in agreement with a previous report.\textsuperscript{9,26} In Exp. 1 at 46 GPa after the heating, six new XRD peaks appeared (Figure 5a and its inset) in the laser-focused area in addition to the unreacted NaCl and PtH peaks. At 42 GPa in Exp. 2, we confirmed three additional peaks at 2\textdegree = 7.9\textdegree, 13.8\textdegree, and 17.2\textdegree (inset to Figure 5b, upper panel). Using these nine XRD peaks, NaClH\textsubscript{x} was indexed with the hexagonal \textit{P6\textsubscript{3}/mmc} structure with ABAC stacking. The lattice parameters were \textit{a} = 3.410(7) Å and \textit{c} = 6.277(8) Å at 46 GPa. At 20 GPa in Exp. 1 (Figure 5b, bottom panel), the presence of 010, 110 and 013 diffractions from the \textit{P6\textsubscript{3}/mmc} structure becomes evident because the overlap between NaClH\textsubscript{x}, NaCl, and the laser absorber are canceled.

In Figure 5c, the volume per NaCl unit (\textit{V\textsubscript{f.u.}} (Å\textsuperscript{3}/NaCl)), which is calculated by dividing the unit cell volume by the number of NaCl units in a unit cell, is plotted for NaCl and
NaCl(H_x) as a function of pressure. The NaCl(H_x) exhibits apparent volume expansion from B1 and B2 NaCl. In addition, it shows good agreement with predicted \( V_{f.u.} \) for NaCl(H_2) via our first-principles calculations. These observations strongly suggest the formation of the predicted NaCl(H_2). Before experiments, there was a concern that the laser heating of NaCl/H_2 might result in the formation of Na_3Cl, NaCl_3, and NaH_x (\( x = 3, 7 \)). However, none of Na_3Cl, NaCl_3, and NaH_x have a \( P6_3/mmc \) lattice. Further, their Raman spectra do not match with the data of NaCl(H_x) (See the Supporting Information for the detailed comparisons of the Raman scattering data.).

Figure 6a shows the representative Raman scattering spectra measured in the heated area where we performed XRD measurements together with the data of unheated areas post laser heating at 46 GPa. As the heated area was a mixture of NaH_x, NaCl that had no Raman-active modes in the B2 structure, and excess solid H_2, the Raman scattering peaks from NaH_x and H_2 were observed. Across the heated area, in addition to the rotational mode (roton) and the vibron of H_2 in solid H_2, three new peaks appeared at the wavenumbers 272.8, 966.4, and 4323.5 cm\(^{-1}\) (hereafter referred to as \( \nu1, \nu2, \) and \( \nu3, \) respectively). Notably, no other new peaks appeared in the wavenumbers between 100 and 4400 cm\(^{-1}\). The high wavenumber of \( \nu3 \) suggests that \( \nu3 \) is the vibron of H_2. Furthermore, the shift of \( \nu3 \) from the vibron of solid H_2 indicates that \( \nu3 \) originates from the H_2 molecules placed in a potential field different from that of solid H_2. Thus, NaClH_x contains H_2 molecules in its crystal lattice. Figure 6b presents the Raman scattering spectra in Exp. 1 upon pressure release at 300 K. The Raman shift of \( \nu1-3 \) obtained in Exp. 1-3 are plotted together as a function of pressure in Figure 6c. Peaks \( \nu1-3 \) have positive pressure dependence. The pressure dependences of \( \nu1, \nu2, \) and \( \nu3 \) obtained in the three experiments are in excellent agreement, indicating that the presence of Pt (PtH) or Au does not affect the results. When pressure is released to 17 GPa, \( \nu1-3 \) disappear, and only the roton and vibron of the solid H_2 persist (Figure 6c). Because NaCl has no Raman-active phonon mode in the B1 structure, we conclude that NaClH_x decomposes into NaCl and H_2 below 17 GPa. This observation is in agreement with
Figure 5: XRD profiles of NaClH$_x$. (a) Integrated powder XRD profiles observed at the heated and unheated areas in the sample in Exp. 1. The wavelength of the X-ray was 0.4135 Å in all measurements. The asterisk (*) indicates peaks that appeared post laser heating. The inset graph presents a magnification of the XRD profile of the heated area. The solid and dashed circles in the microphotograph indicate the heated and unheated areas where the XRD measurements were performed. (b) Integrated XRD profiles at pressures of 42 GPa (Exp. 2, upper panel), 46 GPa (Exp. 1, middle panel) and 20 GPa (Exp. 1, bottom panel). PtH decomposed to Pt and H$_2$ below 20 GPa. The notation ‘h’ indicates the XRD peaks from solid H$_2$, and the ‘g’ is the gasket material rhenium hydride (ReH$_x$), which is produced by the hydrogenation of Re-metal gasket. (c) $V_f.u.$ for the observed NaCl(H$_x$), the predicted NaCl(H$_2$) with ABAC stacking, and NaCl.
our prediction that the imaginary frequency for several phonon modes appear below 15 GPa (Figure 2a and Figure 3a-d). We also note that the pressure dependence of the observed H₂ vibron shows an excellent agreement with the reported data of pure H₂\textsuperscript{28} supporting our conclusion that observed Raman peaks except for ν1-3 are from solid H₂.

Figure 6: Raman scattering measurements of NaClHₓ at pressures. (a) Typical Raman scattering spectra obtained at the heated area (solid circle) and H₂ (dotted circle). (b) Raman scattering spectra of NaClHₓ obtained from Exp. 1 at as the pressure decreased. (c) Pressure dependence of the Raman shifts for ν1-3 obtained in Exp. 1-3, and H₂ vibrons of solid H₂. The vertical dashed line indicates that NaClHₓ is unstable at the pressures below 17 GPa, and the dotted lines represent the data of the predicted Raman active phonon modes by our first-principles calculation: ‡1 (E\textsubscript{2g}), ‡2 (E\textsubscript{1g}), ‡3 (E\textsubscript{2g}), and ‡4 (A\textsubscript{1g}).

In Table 1, we display the predicted Raman-active zone-center phonon frequencies of NaCl(H₂) with ABAC stacking and the observed Raman shifts. See the Supporting Information for the phonons that are infrared active modes and silent modes. Mode ‡1 (E\textsubscript{2g}) is the translational oscillation of the B (C) layers in the a-b plane, and mode ‡2 (E\textsubscript{1g}) is the H₂ libron. Mode ‡3 originates from the translational oscillation of H₂ in the a-b plane, and mode ‡4 is the H₂ vibron. The predicted frequencies in modes ‡1, ‡2 and 3, and ‡4 emerge at frequencies similar to ν1, ν2, and ν3, respectively. In the Raman spectra, ν2 has a wider peak width than ν1, suggesting the presence of multiple peaks in a broad single
peak. Assuming that modes $\nu 2$ and 3 are broadened and overlap, $\nu 2$ can be assigned to the overlapped $\nu 2$ and 3 modes. In addition, the predicted positive pressure dependence of modes $\nu 1$-$3$ agrees with that of $\nu 1$-$3$ (Figure 6c).

Considering all theoretical and experimental data together, we conclude that hexagonal NaCl(H$_2$) with ABAC stacking is synthesized by heating a NaCl/H$_2$ mixture to approximately 1500 K above 40 GPa. While a pressure near 40 GPa is necessary for synthesis, NaCl(H$_2$) is stable down to 17 GPa. Such a large hysteresis in pressure at room temperature suggests the possibility of recovering NaCl(H$_2$) to ambient pressure at low temperatures because the mobility of hydrogen is significantly suppressed.

Here, we discuss the formation process of NaCl(H$_2$). The temperature used in the present study for laser heating was below the melting point of NaCl at 42-46 GPa and well above the melting point of H$_2$. Therefore, NaCl(H$_2$) is a product of the reaction between solid NaCl and fluid H$_2$. At 46 GPa, the shortest Cl-Cl distance in layer A of NaCl(H$_2$) was 15.5% longer than that of NaCl. Further, the shortest Cl-Cl distance between the layers ($c/2$) was 6.3% longer than that of NaCl. In contrast, the shortest Na-Cl distance of NaCl(H$_2$) was 1.5% shorter than that of NaCl. Based on these observations, the possible formation process is as follows: (i) Na-Cl bonding is weakened by high temperature. (ii) Fluid H$_2$ molecules penetrate the interstitial sites of NaCl owing to the high kinetic energy gained by heating and compression. (iii) Na atoms are displaced from a body-centered position, and the rectangular $a$-$b$ plane is deformed into a rhombic shape. The unit cell is expanded along with the $a$- and $c$-axes.
To obtain further insight concerning the formation criteria of salt (alkali-chlorides)-
hydride formation, at 2000 K, we laser-heated cesium chloride (CsCl) at 7 GPa and potassium-
chloride (KCl) at 17 GPa. Both of these compounds have a B2 structure. KCl at 17 GPa has
a larger interstitial site than NaCl at 46 GPa. In contrast, CsCl has inadequate interstitial
site volume to accommodate an H$_2$ molecule. Based on the formation process demonstrated
above, KCl appears to have the potential to form a KCl(H$_2$)$_x$ while CsCl does not. However,
no structural transformations were observed for both KCl and CsCl. Although further stud-
ies are necessary, it can be concluded that a B2 structure is not the necessary and sufficient
condition for the formation of salt-hydrogen compounds.

CONCLUSION

To summarize, we offer the following conclusion. The present study answers our initial
question, showing that NaCl can indeed form a compound with hydrogen in the form of
NaCl(H$_2$). The NaCl(H$_2$) has a $P6_3/mmc$ structure which accommodated two H$_2$ molecules
in the interstitial sites of the unit cell. Upon a pressure decrease at 300 K, NaCl(H$_2$)
remains stable as the pressure decreases down to 17 GPa. Our analysis indicates that
NaCl(H$_2$) is formed by the penetration of H$_2$ molecules into the crystal lattice of NaCl
which has CsCl-type structure and the resulting deformation of the structure. Furthermore,
our calculations predict that hydrogen-richer phase NaCl(H$_2$)$_4$ is stabilized at the pressures
above 40 GPa. Even if a material is resistant to hydrogenation at very high pressures
under ambient or high temperatures, pressurizing further as well as heating further can be
an effective technique to synthesize a new hydride. The remaining question concerns the
exact number of H$_2$ that are in NaCl(H$_2$) and whether non-stoichiometric NaCl(H$_2$)$_y$ ($y \neq 1$) is stable. Although a technological breakthrough is required, in-situ neutron diffraction
measurements could provide a more concrete answer. These measurements, which include
the recovery of materials at low temperature, are expected to contribute to the understanding
of the mechanical and thermodynamic stability of NaCl(H₂) and its application to hydrogen storage. Compared with known hydrogen storage materials, NaCl(H₂) has higher gravimetric hydrogen density (3.3 wt.%) than lanthanum-nickel alloy hydride (LaNi₅H₆) and a higher volumetric density (105 kgH₂/m³) than lithium alanate (LiAlH₄). The gravimetric hydrogen density of NaCl(H₂)₄ reaches 12.1 wt.%. Extending pressure and temperature range would be a particular interest because more hydrogen-rich phase may possibly be synthesized.

Comparison of Raman scattering data between NaCl(H$_2$), Na$_3$Cl and NaCl$_3$, and NaH$_x$ ($x = 3, 7$)

Here, we compare the Raman scattering spectra obtained for NaCl(H$_2$) with the data of Na$_3$Cl, NaCl$_3$ and NaH$_x$ ($x = 3, 7$). The Raman scattering spectrum and the pressure dependence of the observed Raman scattering peaks of NaCl(H$_2$) do not match the data of any of Na$_3$Cl, NaCl$_3$ and NaH$_x$ ($x = 3, 7$).

Figure S1: (a) Raman scattering spectra of NaCl(H$_2$), Na$_3$Cl, NaCl$_3$, and NaH$_x$ ($x = 3, 7$). The broad peak, which is seen in the spectra of NaCl(H$_2$) and NaH$_x$, centering at 600 cm$^{-1}$ is from the roton of excess pure H$_2$. The sharp peak centering at 4260 cm$^{-1}$ is the vibron of excess pure H$_2$. The data of Na$_3$Cl, NaCl$_3$, and NaH$_x$ were taken from refs. 1 and 2, and their supplementary materials. (b) Pressure dependence of the Raman shifts of $\nu 1$ and $\nu 3$ plotted together with the data of NaCl$_x$ and NaH$_x$. The data of NaCl$_x$ has been assigned to Na$_3$Cl in Figure S10 of ref. 1. The data of NaH$_x$ has been reported to contain the contributions from both NaH$_3$ and NaH$_7$.2
