Abstract
Various authors have invoked discretized fractional Brownian (fBm) motion as a model for chain polymers with long range interaction of monomers along the chain. We show that for these, in contrast to the Brownian case, linear forces are acting between all pairs of constituents, attractive for small Hurst index $H$ and mostly repulsive when $H$ is larger than $1/2$. In the second part of this paper we extend this study to periodic fBm and related models with a view to ring polymers with long range interactions.
1 Introduction

Fractional Brownian motion (fBm) has, among other applications, attracted some interest as a model for the conformation of chain polymers \[1\][2][3][5], as a generalization of the classical Brownian models (see e.g. \([9]\), and references therein). Mathematically this enlarged class involves non-Martingale, non-Markovian processes, physically on the other hand it is of interest because of its more general scaling properties and the long range interactions it describes.

Fractional Brownian motion $B^H$, conventionally starting at $B^H(0) = 0$, gives rise to a discrete, mean zero Gaussian process via

$$X_k = B^H(k), \quad k = 0, 1, 2, \ldots$$

We denote the increments as

$$Y_k = X_{k+1} - X_k, \quad k = 0, 1, 2, \ldots, n - 1$$

with finite dimensional probability densities $\rho_n$ given by

$$\int d^n y \rho_n(y) e^{i(y, \lambda)} = \mathbb{E} \left( e^{i(Y, \lambda)} \right) = \exp \left( -\frac{1}{2} \langle \lambda, R\lambda \rangle \right)$$

and the covariance matrix

$$R_{ik} = \mathbb{E}(Y_i Y_k) = \frac{1}{2} \left| k - l + 1 \right|^{2H} + \frac{1}{2} \left| k - l - 1 \right|^{2H} - \left| k - l \right|^{2H}.$$ 

Hence

$$\rho_n(y) = \text{const. exp} \left( -\frac{1}{2} \langle y, Ay \rangle \right) \text{ with } A = R^{-1},$$

which can be interpreted as a canonical density with regard to an energy given by $(y, Ay)$.

The first part of this paper intends to elucidate the nature of the corresponding interaction between monomers. We show that these (and more general Gaussian) models can be interpreted as equilibrium models for particles with attractive and repulsive elastic forces acting between any two of them, i.e.

$$(y, Ay) = \sum g_{kl} (x_k - x_l)^2$$

and we display the strength $g_{kl}$ of these forces for different Hurst indices $H$. 

Periodic fBm cannot be constructed in a direct analogy to the Brownian case as in (9) because of the non-Markovian nature of fBm. As pointed out by Istas [6], this problem can be solved by replacing the distance $D$ in

$$E \left( (B^H(t) - B^H(s))^2 \right) = D^{2H}(t - s) = |t - s|^{2H}$$

by the geodesic distance $d$ on the circle of length $L$:

$$d(t - s) = \min (|t - s|, L - |t - s|),$$

however with the limitation that this leads to a positive semi-definite covariance function, and hence a Gaussian process. This is only the case if $H \leq 1/2$. For this class of models we shall in particular compute the coupling constants $g_{kl}$ and the spectrum of the quadratic form $\sum g_{kl}(x_k - x_l)^2$ for different values of the Hurst parameter $H$.

Finally we propose a class of periodic models which, contrary to the non-admissible fBm with large Hurst index, admit long range repulsive forces between the constituents.

It is proper to note that as far as more realistic polymer models are concerned, these Gaussian models must be modified to suppress self-crossings, see e.g. [1][3].

2 The Nature of the Interactions along the Chain

For applications in physics it would be desirable to rewrite the energy form $E(y) = (y, Ay)$ as an expression in terms of the monomer position variables $x_k$. Indeed one has

**Lemma 1.** For $x = x_0, ..., x_n \in \mathbb{R}^{n+1}$ and $y_k = x_k - x_{k-1}$, $A$ a symmetric $n \times n$ matrix, the identity

$$ (y, Ay) = \sum_{k,l=1}^{n} a_{kl} y_k y_l = \sum_{k,l=0}^{n} g_{kl} (x_k - x_l)^2 $$

(1)

holds with

$$g_{kl} = -\frac{1}{2} (a_{kl} + a_{k+1,l+1} - a_{k,l+1} - a_{k+1,l}),$$
setting \( a_{kl} = 0 \) whenever \( k, l \notin \{1, \ldots, n\} \).

Conversely, for \( s \leq t \)

\[
a_{st} = 2 \sum_{i=0}^{s-1} \sum_{k=t}^{n} g_{ik}.
\]

Proof. By direct verification.

Remark 2. As indicated above, expressions such as \((y, Ay)\) occur in the probability densities of mean zero Gaussian processes. In physics they play the role of potential energies in canonical ensembles and the lemma shows that these energies can always be understood as the sum of harmonic oscillator potentials with strength \( g_{kl} \) acting on the monomer pairs \( k, l \), see e.g. \([9]\).

To understand the nature in particular of fBm models which were suggested for chain polymers it is interesting to compute those coupling constants. We show these for a chain of length \( n = 61 \); specifically we display the couplings of the center constituent to all the others. For small Hurst index \((H < 1/2)\), as one might expect from the more compact nature of the corresponding fBm trajectories, all of the interactions are attractive.

\[ g_{31,i} > 0 \text{ for all } i \neq 31. \]

The rise at both ends of the chain is a finite-length effect.

Conversely, for \( H > 1/2 \), nearest neighbors are again attracted, but constituents further away on the chain are repelled.

Finally, for \( H \approx 0.75964 \), a value obtained via a bisection method, the third-nearest neighbors are also attracted, in our example

\[ g_{31,i} > 0 \text{ for } i = 31 \pm 1 \text{ and for } i = 31 \pm 3. \]

3 The Energy E as a Quadratic Form in x

At times it can be useful to have the energy

\[
E(x) = \sum_{k>l=0}^{n} g_{kl}(x_k - x_l)^2
\] (2)
Figure 1: Coupling constants for a fBm chain with 61 monomers and Hurst index $H=0.3$. 
Figure 2: Coupling constants for a fBm chain with 61 monomers and Hurst index $H=0.8$. 
Figure 3: Coupling constants for a fBm chain with 61 monomers and Hurst index $H=0.75964$. The coupling constant of the third oscillators from the middle are zero.
as a quadratic form

$$E(x) = \langle x, \mathcal{H}x \rangle$$

with the matrix $\mathcal{H}$ to be determined. Setting

$$g_{kl} = g_{lk} \quad \text{and} \quad g_{kk} = 0$$

one finds directly

$$h_{ik} = \begin{cases} -g_{ki} & \text{if } k \neq i \\ \sum_j g_{jk} & \text{if } k = i \end{cases} \quad (3)$$

Note that the matrix $\mathcal{H}$ has $x = (1, ..., 1)$ as eigenvector with eigenvalue zero, in accordance with equation (2). This corresponds to the “increment” vector $y = (x_{k+1} - x_k)_{k=0}^{n-1}$ being zero. All the other eigenvalues of $\mathcal{H}$ are then those of the matrix $A$ in (1).

4 Cyclic Conformations

In an equidistant periodic placement of $n$ indices $k = 0, ..., n-1$ on a circle, there are $\left\lfloor \frac{n}{2} \right\rfloor$ distinct geodesic distances

$$d(i, k) = \min (|i - k|, n - |i - k|).$$

4.1 Periodic Fractional Brownian Motion

As pointed out by [6], periodic fBm on a circle of length $L$ is obtained by setting

$$\mathbb{E} \left( (b^H(s) - b^H(t))^2 \right) = \left( \min (|s - t|, L - |s - t|) \right)^{2H}$$

$$= \left( d(s, t) \right)^{2H},$$

which serves to define a periodic centered Gaussian process $b^H$ iff $H \leq 1/2$.

We put $b^H(0) = 0$ without loss of generality, and the covariance is

$$\mathbb{E} \left( b^H(s)b^H(t) \right) = \frac{\left( (d(s, t))^{2H} + (d(s, 0))^{2H} - (d(s, t))^{2H} \right)}{2} \quad (4)$$

As a discretized version we set $L = n + 1$

$$X_k = b^H(k), \quad k = 0, 1, \ldots, n$$
with increments

\[ Y_k = X_{k+1} - X_k, \quad k = 0, ..., n - 1 \]

and a joint density

\[ \rho(y) = \text{const.}\exp\left(-\frac{1}{2}(y, Ay)\right) \]

where the energy matrix

\[ A = R^{-1} \]

is obtained as the inverse of the correlation matrix

\[ R_{ik} = E(Y_i Y_k). \]

This covariance kernel is positive definite, if and only if the Hurst index \( H \) is smaller than \( 1/2 \); for \( H > 1/2 \) the matrices

\[
E(X_k X_l) = \frac{d^{2H}(k) + d^{2H}(l) - d^{2H}(k-l)}{2}
\]

\[
E(Y_k Y_l) = \frac{d^{2H}(k-l+1) + d^{2H}(k-l-1) - 2d^{2H}(k-l)}{2}
\]

will fail to be positive semi-definite.

The coupling constants \( g_k \) for discrete periodic fBm of the Hurst index \( H = 0.3 \) is given in Figure 4.

### 4.2 General Cyclic Models

For the \( n \) Gaussian variables \( y_k \) we define

\[ \rho(y) = \text{const.}\exp\left(-\frac{1}{2}(y, Ay)\right) \]

starting from \( \mathcal{H}(x) \) and the equation (1), assuming that the \( g_{ik} \) depend only on the "geodesic" distance between the indices \( i \) and \( k \) i.e.

\[ g_{ik} = g_{d(i,k)}. \]
Figure 4: Coupling constants for a periodic fBm ring with 61 monomers and Hurst index $H=0.3$. 
We introduce the symmetric \((n+1) \times (n+1)\) matrix \(G = circ(0, g_1, g_2, \ldots, g_n, g_1)\)
\[
G = \begin{pmatrix}
0 & g_1 & g_2 & \cdots & \cdots & \cdots & g_3 & g_2 & g_1 \\
g_1 & 0 & g_1 & \cdots & \cdots & \cdots & g_3 & g_2 & g_1 \\
g_2 & g_1 & 0 & \cdots & \cdots & \cdots & g_3 & g_2 & g_1 \\
\vdots & \vdots & \ddots & \ddots & \ddots & \ddots & \ddots & \ddots & \ddots \\
g_3 & 0 & g_2 & \cdots & \cdots & \cdots & 0 & g_2 & g_1 \\
g_2 & 0 & g_1 & \cdots & \cdots & \cdots & g_2 & 0 & g_1 \\
g_1 & g_2 & g_3 & \cdots & \cdots & \cdots & g_2 & g_1 & 0
\end{pmatrix}.
\]

In view of (3) \(H\) then is of the form
\[
H = g1 - G
\] (6)
where 1 is the \((n + 1) \times (n + 1)\) unit matrix, and \(g\) is the row sum of \(G\)
\[
g = \sum_{i=1}^{n} g_i \quad \text{with} \quad g_k := g_{n+1-k} \quad \text{if} \quad k > n/2.
\]

The energy spectrum is that of the matrix
\[
H = g1 - G = circ \left( \sum_{k=1}^{n} g_k, -g_1, \ldots, -g_n \right)
\]
with the exception of the eigenvalue zero. By formula (11) in the Appendix, one has an explicit form for these energy eigenvalues as a function of the coupling constants:
\[
\lambda_m = \sum_{k=1}^{n} g_k \left( 1 - \cos \left( \frac{2mk\pi}{n+1} \right) \right).
\] (7)

**Example 3.** Particular models of interest might be ones with a scaling behavior
\[
g_k \sim k^{-\gamma}
\]
and
(1) all couplings positive (generalizing \(H < 1/2\)), or
(2) all couplings except the nearest neighbor one repulsive (as an alternative to a periodic fBm with \(H > 1/2\)): \(g_1 > 0, \ g_k < 0 \quad \text{for} \quad k > 1\).

Models of this latter nature are expected to produce stiff polymers.
4.3 Stiff Cyclic Polymers

Stiff chain polymers might be modelled by fBm with Hurst parameter $H > 1/2$. For such models we saw that the next-to-nearest neighbor coupling constants are negative, the nearest neighbor is attracted, such as e.g. in [8]. As Istaś points out [6], there is no cyclic version for fBm with $H > 1/2$. But other cyclic models with attractive-repulsive dynamics can be constructed, e.g. as follows.

Example 4. Taking

$$G = \text{circ}(0, g_1, g_2, 0, \ldots, 0, g_2, g_1),$$

hence

$$H = \text{circ}(2(g_1 + g_2), -g_1, -g_2, 0, \ldots, 0, -g_2, -g_1),$$

for which, using the formula (11) in the Appendix, we obtain the energy eigenvalues

$$\lambda_m = 2g_1 \left( 1 - \cos \left( \frac{2m\pi}{n+1} \right) \right) + 2g_2 \left( 1 - \cos \left( \frac{4m\pi}{n+1} \right) \right).$$

Apart from the spurious eigenvalue $\lambda_0 = 0$, all eigenvalues are positive, i.e. this choice of coupling produces an admissible ring model if $g_2 \geq -\frac{1}{4}g_1$. The way to see this is to look at the function

$$f(x) = 1 - \cos (2\pi x) + c(1 - \cos (4\pi x))$$

between the endpoints $x = 0$ (and $x = 1$ symmetrically) where, for $x \gtrsim 0$, it is of the approximate form

$$f(x) \approx 2\pi^2 (1 + 4c)x^2$$

i.e. for positivity

$$4c = 4\frac{g_2}{g_1} \geq -1$$

is required.

Remark 5. Had we chosen $g_k$ instead of $g_2$ non-zero the corresponding restriction would be

$$k^2 \frac{g_k}{g_1} \geq -1,$$

meaning that longer range repulsion can only occur with even smaller coupling strength (recall that a Hooke’s law type force becomes stronger with increasing distance, hence could then more easily produce instability if negative).
To construct long range repulsive interactions one needs to ensure positivity (except for the spurious zero eigenvalue associated with the vector $x$ with $x_k = c$ for all $k$).

**Example 6.** In Example 4, setting $g_1 > 0$ and $g_k$ negative for $k > 1$ positivity holds for

$$g_1 > \pi^2 \sum_{k=2}^{n/2} k^2 |g_k|.$$  \hspace{1cm} (8)

For this estimate, one uses (7) for $n/2 \geq i > 0$

$$\lambda_i = 2g_1 \left(1 - \cos \left(\frac{2\pi i}{n+1}\right)\right) - 2 \sum_{k=1}^{n/2} g_k \left(1 - \cos \left(\frac{2\pi ik}{n+1}\right)\right)$$

and

$$\left(\frac{x}{\pi}\right)^2 \leq 1 - \cos x \text{ and } 1 - \cos x \leq \left(\frac{x}{2}\right)^2$$

as a lower bound for the first and an upper bound on the second term.

To ensure the estimate (8) e.g. for $g_k = -ck^{-\gamma}$ and arbitrary $n$, it is thus sufficient to choose $\gamma > 3$ and $c$ such that

$$g_1 > c\pi^2 \sum_{k=2}^{\infty} k^{-\gamma+2} = c\pi^2 (\zeta(\gamma + 2) - 1),$$

where $\zeta$ is Riemann’s zeta function.

### 5 A Remark on the Brownian Case

Contrary to the statement in [6], the construction of periodic (f)Bm is via a *semi*-positive definite covariance matrix for the Brownian case $H = 1/2$.

**Example 7.** Consider a Brownian ring with $n = 6$ steps: $X = (b(0), ..., b(6))$. One computes

$$\text{cov}_Y = \text{circ}(1, 0, 0, -1, 0, 0) = \begin{pmatrix} 1 & 0 & 0 & -1 & 0 & 0 \\ 0 & 1 & 0 & 0 & -1 & 0 \\ 0 & 0 & 1 & 0 & 0 & -1 \\ -1 & 0 & 0 & 1 & 0 & 0 \\ 0 & -1 & 0 & 0 & 1 & 0 \\ 0 & 0 & -1 & 0 & 0 & 1 \end{pmatrix}.$$
Eigenvectors are \((1, 0, 0, 1, 0, 0)\) with eigenvalue zero, and \((-1, 0, 0, 1, 0, 0)\) with eigenvalue 2, together with their cyclic permutations. I.e. contrary to the assertion of Istas, the covariance matrices are no more positive definite when \(H = 1/2\).

More generally, Istas \([6]\), p. 257, finds

\[
E \left( \left| \int_0^{2\pi} b^H(t) \exp(int) \, dt \right|^2 \right) = -\frac{4\pi^2}{n^{2H+1}} \int_0^{\pi} x^{2H} \cos(nx) \, dx,
\]

and in the Brownian case the rhs is positive for odd \(n\), but

\[
\int_0^{\pi} x \cos(nx) \, dx = 0 \quad \text{for even } n > 0,
\]

contrary to the assertion of Istas, nevertheless semi-positivity holds.

**Proposition 8.** For \(H = 1/2\) a version of the periodic Brownian motion \(b(\cdot)\) is obtained in terms of the Wiener process \(B(\cdot)\) if one sets

\[
b(t) := \begin{cases} 
B(t) & \text{for } 0 \leq t \leq \pi \\
B(\pi) - B(t - \pi) & \text{for } \pi \leq t \leq 2\pi.
\end{cases}
\]

**Proof.** Setting e.g. \(L = 2\pi\) and \(0 \leq s \leq t \leq 2\pi\) without loss of generality, the covariance function given in \([4]\) for \(H = 1/2\) is

\[
E \left( b^H(s)b^H(t) \right) = \begin{cases} 
s & \text{for } 0 \leq s \leq t \leq \pi \\
\pi + s - t & \text{for } 0 \leq s \leq \pi \leq t \text{ and } t - s \leq \pi \\
0 & \text{for } 0 \leq s \leq \pi \leq t \text{ and } t - s \geq \pi \\
2\pi - t & \text{for } \pi \leq s \leq t.
\end{cases}
\]

Since \(b(\cdot)\) as defined in the proposition is centered Gaussian, it is sufficient - and straightforward - to verify that it has this same covariance function.

It is worth pointing out that a Brownian bridge such as

\[
b(t) = B(t) - \frac{t}{2\pi} B(2\pi)
\]

would not lead to stationary increments on the circle.\([4]\)
6 Supplementary Material on Circulant Matrices

Note that Istas’ cyclic correlation matrix is circulant and symmetric, hence also its inverse.

Circulant matrices are of the general form

$$C = \begin{pmatrix}
  c_0 & c_1 & c_2 & \cdots & c_{n-1} \\
  c_{n-1} & c_0 & c_1 & \cdots & \\
  \vdots & c_{n-1} & c_0 & \cdots & \\
  \vdots & \vdots & \vdots & \ddots & \\
  c_1 & \cdots & \cdots & c_{n-1} & c_0
\end{pmatrix}.$$  

Note that a real circulant matrix is symmetric iff

$$c_k = c_{n-k} \text{ for } k > 0.$$  

Normalized eigenvectors for any $C$ are

$$e_m = \frac{1}{\sqrt{n}} (1, \varrho, \ldots, \varrho^{n-1}) \quad \text{with} \quad \varrho = e^{-\frac{2\pi i}{n}},$$

the corresponding eigenvalues are

$$\lambda_m = \sum_{k=0}^{n-1} c_k e^{-\frac{2\pi i k m}{n}} = \sum_{k=0}^{n-1} c_k \varrho^{km},$$

i.e. they are simply the discrete Fourier transform of the first row of $C$. For symmetric $C$ this formula gives

$$\lambda_m = c_0 + \sum_{k=1}^{n-1} c_k e^{-\frac{2\pi i k m}{n}} = c_0 + \sum_{k=1}^{n-1} c_{n-k} e^{-\frac{2\pi i k m}{n}} \quad \text{(10)}$$

$$= c_0 + \frac{1}{2} \left( \sum_{k=1}^{n-1} c_k e^{-\frac{2\pi i k m}{n}} + \sum_{k=1}^{n-1} c_k e^{\frac{2\pi i k m}{n}} \right)$$

$$= \sum_{k=0}^{n-1} c_k \cos \left( \frac{2\pi k m}{n} \right) \quad \text{for } m = 0, \ldots, n-1. \quad \text{(11)}$$
These are degenerate:

\[ \lambda_m = \lambda_{n-m} \quad \text{for } m > 0 \]

so that the corresponding eigenvectors can then be combined to be real-valued. These \( n \) eigenvectors are

\[
v^{(m)}_j = \cos \left( \frac{2\pi jm}{n} \right), \quad m = 0, \ldots, \left[ \frac{n}{2} \right]
\]

and

\[
v^{(m)}_j = \sin \left( \frac{2\pi jm}{n} \right), \quad m = 1, \ldots, \left[ \frac{n-1}{2} \right].
\]

7 Conclusions and Outlook

Having clarified the dynamical nature of fBm models for chains and rings, one will next implement excluded volume effects. Where fBm rings fail to exist we indicate how the control of energy eigenvalues allows for the construction of alternate stiff ring models with a short or long range interaction along the chain.
