Haldane’s formula in Cannings models: The case of moderately weak selection

Florin Boenkost, Adrián González Casanova,
Cornelia Pokalyuk, Anton Wakolbinger

July 24, 2019

Abstract

We introduce a Cannings model with directional selection via a paintbox construction and establish a strong duality with the line counting process of a new Cannings ancestral selection graph in discrete time. This duality also yields a formula for the fixation probability of the beneficial type. Haldane’s formula states that for a single beneficial ancestor the probability of fixation is asymptotically equal to the selective advantage \( s \) divided by half of the offspring variance. For a class of offspring distributions within Kingman attraction we prove this asymptotics for sequences \( s_N \) with \( N^{-2/3} \gg s_N \gg N^{-1} \). It turns out that in this regime of “moderately weak selection” the Cannings ancestral selection graph is so close to the ancestral selection graph of a Moran model that a suitable coupling argument works. In a companion paper we treat the case of moderately strong selection, \( N^{-2/3} \ll s_N \ll 1 \), which, other than the case considered in the present paper, admits a more classical approach to Haldane’s formula via branching process approximations.

1 Introduction

The calculation of fixation probabilities is a prominent task in mathematical population genetics; for a historical overview see Patwa and Wahl [1]. A classical idea going back to Haldane, Fisher and Wright is to approximate the probability of fixation of a beneficial allele with small selective advantage \( s \) by the survival probability of a supercritical, near-critical Galton-Watson branching process. This results in Haldane’s formula for the fixation probability \( \pi \),

\[ \pi \sim \frac{s}{\rho^2/2}, \tag{1} \]

where \( \rho^2 \) is the offspring variance. In [2] the asymptotics \( \tag{1} \) was proved for a class of Cannings models that arise in the modeling of experimental evolution. This was achieved under the assumption that \( s = s_N \sim N^{-b} \) with \( 0 < b < 1/2 \), i.e. for a moderate selection that is more on the side of strong selection (\( s = \text{const} \)) than on the side of weak selection (\( s \sim \text{const}/N \)). In [2] the question remained open if \( \tag{1} \) also holds for \( s = s_N \sim N^{-b} \) with \( 1/2 \leq b < 1 \). This is one of the motivations of the present paper.

The purpose of our paper is twofold. First, for Cannings models admitting a paintbox representation, we introduce a graphical representation which allows for a natural generalization to the case with directional selection, and leads to a time discrete version of the ancestral selection graph that was developed by Krone and Neuhauser [3] for the (continuous time) Moran model. A discrete ancestral selection graph recently been constructed by González Casanova and Spanó [4] for a special class of Cannings models. While their construction relies on analytic arguments, we provide here a probabilistic construction which works for a wider class of models and also gives a clear interpretation of the role of the geometric distribution of the number of potential parents in
this context. This construction will be explained in Section 5. We will prove a sampling duality between the Cannings frequency process and the line counting process of the discrete ASG (alias Cannings ancestral selection process or CASP), see Theorem 1. This also allows to obtain an expressive and handsome representation of the fixation probability of the beneficial type in terms of the CASP in equilibrium, see Corollary 3.2.

Second, we show in Section 6 that for Cannings models that are in the domain of attraction of the Kingman coalescent, and for sequences $s_N$ with

$$CN^{-2/3-\eta} \geq s_N \geq cN^{-1+\eta}$$

for some positive $C$, $c$ and $\eta$ not depending on $N$, the CASP is very close to the ASG line counting process of a corresponding Moran model over a long period of time. This is our tool for proving Haldane's formula (Theorem 2) in this regime of moderately weak selection. Indeed, for a Moran model with directional selection, the analogue of the above mentioned representation of the fixation probability in terms of the CASP is valid, and the fixation probability can be calculated explicitly: this we explain in Section 5.

2 Cannings models with selection

2.1 A paintbox representation for the neutral reproduction

In a neutral Cannings model with population size $N$, the central concept is the exchangeable $N$-tuple $\nu = (\nu_1,\ldots,\nu_N)$ of offspring sizes, with non-negative integer-valued components summing to $N$. A reasonably large class of such random variables $\nu$ admits a paintbox construction, i.e. has a mixed multinomial distribution with parameters $N$ and $\nu$, where $\nu = (W_1,W_2,\ldots,W_N)$ is an exchangeable random $N$-tuple of probability weights taking its values in

$$\Delta_N = \left\{(x_1,x_2,\ldots,x_N) : x_i \geq 0, \sum_{i=1}^{N} x_i = 1 \right\}.$$ 

While this is clearly reminiscent of Kingman’s paintbox representation of exchangeable partitions of $N$, here we are dealing with a finite $N$. As such, obviously, not all exchangeable offspring sizes are mixed multinomial – consider e.g. a uniform permutation of the vector $(2,\ldots,2,0,\ldots,0)$. On the other hand, the exchangeable mixed multinomials cover a wide range of applications; e.g., they can be seen as approximations of the offspring sizes in a model of experimental evolution, where at the end of each reproduction cycle $N$ individuals are sampled without replacement from a union of $N$ families with large i.i.d. sizes; see [2] and [5], where the distribution of the family sizes was assumed to be geometric with expectation $\gamma = 100$. This leads to a mixed multi-hypergeometric offspring distribution, whose analogue for $\gamma = \infty$ would be a mixed multinomial offspring distribution with $L(\nu)$ the Dirichlet$(1,\ldots,1)$-distribution on $\Delta_N$.

Let us now briefly review the graph of genealogical relationships in a Cannings model. In each generation $g$, the individuals are numbered by $i \in [N]$ and denoted by $(g,i)$. A parental relation between individuals in generation $g$ and $g-1$ is defined in the following way. Let $\nu^{(g)}, g \in \mathbb{Z}$, be i.i.d. copies of $\nu$. Every individual $(g,j)$ is assigned a parent $(g-1,V_{(g,j)})$ in generation $g$ by means of an $[N]$-valued random variable $V_{(g,j)}$ with conditional distribution $P(V_{(g,j)} = i | \nu^{(g-1)}) = W_i^{(g-1)}$, $i \in \{1,\ldots,N\}$. The random variables $V_{(g,j)}$, $j = 1,\ldots,N$, are assumed to be independent given $\nu^{(g-1)}$. Due to the exchangeability of $(W_1^{(g-1)},\ldots,W_N^{(g-1)})$, the $V_{(g,1)},\ldots,V_{(g,N)}$ are uniformly distributed on $[N]$, and in general are correlated. With this construction of “one generation step backwards” we produce an exchangeable $N$-tuple of offspring sizes, i.e. the number of children for each individual $(g-1,i)$, $i = 1,\ldots,N$.

2.2 A paintbox representation incorporating selection

We now build directional selection with strength $s_N \in (0,1)$ into the model. Assume that each individual has one of two types, either the beneficial type or the wildtype. Let the chances
to be chosen as a parent be modified by decreasing the weight of each wildtype individual by the factor \(1 - s_N\). In other words, if individual \((g, i)\) has the wildtype the weight reduces to \(\tilde{W}_i := (1 - s_N)W_i\) and if the individual has the beneficial type the weight remains \(\tilde{W}_i := W_i\). Let \(\tilde{W}^{(g)} := (\tilde{W}_1^{(g)}, \ldots, \tilde{W}_N^{(g)})\). Given the type configuration in generation \(g - 1\), the parental relations are now generated in a two-step manner: First, assign the random weights \(\tilde{W}^{(g - 1)}\) to the individuals in generation \(g - 1\), then follow the rule

\[
P((g - 1, i) \text{ is parent of } (g, j) \mid \tilde{W}^{(g - 1)}) = \frac{\tilde{W}_i^{(g - 1)}}{\sum_{\ell=1}^{N} W_\ell^{(g - 1)}}.
\]

Individual \((g, j)\) then inherits the type from its (unique) parent. Note that \(\tilde{W}^{(g - 1)}\) is measurable with respect to \(\mathcal{W}^{(g - 1)}\) and the type configuration in generation \(g - 1\). Because of the assumed exchangeability of the \(W_i^{(g - 1)}\), \(i = 1, \ldots, N\), the distribution of the type configuration in generation \(g\) only depends on the number of individuals in generation \(g - 1\) that carry the beneficial type. Thus, formula (3) defines a Markovian dynamics for the type frequencies. We will denote the number of wildtype individuals in generation \(g\) by \(K_g\), and will call \((N - K_g, K_g)\) a Cannings frequency process with parameters \(N, \mathcal{L}(\mathcal{W})\) and \(s_N\).

### 2.3 The Cannings ancestral selection process

Again let \(N \in \mathbb{N}\), \(\mathcal{W}\) as in Section 2.1 and \(s_N \in (0, 1)\). As we will prove in Theorem 1, the process \((K_g)\) described in Section 2.2 is in sampling duality to the line counting process the Cannings ancestral selection graph which we will define in Section 5. For the moment, let us briefly state the essentials. Prior to any colouring, i.e. prior to any assignment of types to the individuals, we will define a random graph of potential ancestors of a sample \(J\) taken in generation \(g\). The evolution of this graph is Markovian backward in time, starting with the set of vertices \(\mathcal{A}_0 = J\) in generation \(g\). Given \(\mathcal{W}^{(g - m - 1)}\), every potential ancestor \((j, g - m)\) in generation \(g - m\) makes independently a \(\text{Geom}(1 - s_N)\)-distributed number of choices from the \(N\) individuals from generation \(g - m - 1\), where in each of the choices individual \((i, g - m - 1)\) is chosen with probability \(W_i^{(g - m - 1)}\). An individual \((i, g - m - 1)\) that is chosen at least once is a potential ancestor in generation \(g - m - 1\). (Here and below, we understand a \(\text{Geom}(p)\)-distributed random variable as describing the number of trials (and not only failures) up to and including the first success in a coin tossing with success probability \(p\).)

Writing \(A_m\) for the number of potential ancestors in generation \(g - m\), we thus see that the process \((A_m)_{m=0,1,\ldots}\) follows Markovian dynamics on \([N] = \{1, \ldots, N\}\) in discrete time which is composed by a branching and a coalescence step. Given \(A_m = a\), the branching step takes \(a\) into a sum \(H = \sum_{\ell=1}^{a} G^{(\ell)}\) of independent \(\text{Geom}(1 - s_N)\)-random variables; in other words, the random variable \(H\) has a negative binomial distribution with parameters \(a\) and \(1 - s_N\) (and thus takes its values in \(\{a, a + 1, \ldots\}\)). The coalescence step consists in putting \(H\) balls independently (given \(\mathcal{W}\)) into \(N\) boxes, where, conditional under \(\mathcal{W}\), \(\mathcal{W}_i\) is the probability that the first (second, \ldots, \(H\)-th) ball is put into the \(i\)-th box, \(i = 1, \ldots, N\). The random variable \(A_{m+1}\) is then distributed as the number of occupied boxes. We call \(A = (A_m)_{m=0,1,\ldots}\) a Cannings ancestral selection process (CASP) with parameters \(N, \mathcal{L}(\mathcal{W})\) and \(s_N\).

### 3 Main results

#### 3.1 Duality of Cannings frequency and ancestral selection process

For \(N \in \mathbb{N}\), \(\mathcal{W}\) as in Section 2.1 and \(s_N \in (0, 1)\), let \((K_g)_{g \geq 0}\) be the number of wildtype individuals in a Cannings model with parameters \(N, \mathcal{L}(\mathcal{W})\) and \(s_N\) as defined in Section 2.2, and let \((A_m)_{m \geq 0}\) be the Cannings ancestral selection process as defined in Section 2.3.
Theorem 1 (Sampling duality). Let \( g \geq 0 \), and \( k, n \in [N] \). Let \( J \) be uniformly chosen from all subsets of \([N]\) of size \( n \), and given \( A_g = a \), \( a = 1, \ldots, N \), let \( \mathcal{A}_g \) be uniformly chosen from all subsets of \([N]\) of size \( a \). Then we have the following duality relation

\[
\mathbb{P}(J \in [K_g] | K_0 = k) = \mathbb{P}(\mathcal{A}_g \in [k] | A_0 = n).
\]

Remark 3.1. Formula (17) in Section 3 will provide a strong (pathwise) version of the duality relation (4). Indeed, the set \( \mathcal{A}_g^{(J,g)} \) of potential ancestors of \( J \) which is specified in Definition 5.2 is of the form \( \mathcal{A}_g \times \{0\} \), with the set \( \mathcal{A}_g \) figuring in (4). Then (4) results as a consequence of the stronger statement “A sample from generation \( g \) is entirely of wildtype if and only if all of its potential ancestors in generation 0 are of wildtype”.

Expressed in terms of \( K_g \) and \( A_g \), the sampling duality relation (4) becomes

\[
\mathbb{E} \left[ \frac{K_g(K_g - 1) \cdots (K_g - n + 1)}{N(N - 1) \cdots (N - n + 1)} | K_0 = k \right] = \mathbb{E} \left[ \frac{k(k - 1) \cdots (k - A_g + 1)}{N(N - 1) \cdots (N - A_g + 1)} | A_0 = n \right].
\]

(5)

Specializing (5) to \( k = N - 1 \) and \( n = N \) gives

\[
\mathbb{P}(K_g = N | K_0 = N - 1) = 1 - \mathbb{E} \left[ \frac{A_g}{N} | A_0 = N \right]
\]

(6)

Taking the limit \( g \to \infty \) in (6) leads to

Corollary 3.2. Let \( A_{eq} \) be the equilibrium state of the Cannings ancestral selection process \((A_m)_{m \geq 0}\). The fixation probability of a single beneficial mutant is

\[
\pi_N := \lim_{g \to \infty} \mathbb{P}[K_g = 0 | K_0 = N - 1] = \mathbb{E} \left[ \frac{A_{eq}}{N} \right].
\]

(7)

Remark 3.3. In the light of Remark 3.1, the representation (4) can be interpreted as follows: With a single beneficial mutant in generation 0, the beneficial type goes to fixation if and only if the beneficial mutant is among the potential ancestors in generation 0 of the population at a late generation \( g \). In the limit \( g \to \infty \) the number of these potential ancestors is distributed as \( A_{eq} \), and given \( A_{eq} \), the probability that the beneficial mutant is among them is \( \frac{A_{eq}}{N} \).

3.2 Haldane’s formula for Cannings models with selection

Let \((s_N)\) be a sequence in \((0, 1)\) that satisfies (2). For each \( N \) let \( \mathcal{W}^{(N)} = (W_1^{(N)}, \ldots, W_N^{(N)}) \) be as in Section 2.1 and assume the following properties of the pair- and triple coalescence probabilities:

\[
\text{Condition C : } \mathbb{E} \left[ (W_1^{(N)})^2 \right] = \frac{\rho^2}{N^2} + O(N^{-3}), \quad \mathbb{E} \left[ (W_1^{(N)})^3 \right] = O(N^3),
\]

for some \( \rho^2 \geq 1 \) not depending on \( N \). (The requirement \( \rho^2 \geq 1 \) is natural because \( \mathbb{E} \left[ W_1^{(N)} \right] = \frac{1}{N} \).)

Note that Condition C implies

\[
\mathbb{E} \left[ (W_1^{(N)})^3 \right] = o \left( \mathbb{E} \left[ (W_1^{(N)})^2 \right] \right).
\]

(8)

Together with the assumption that the pair coalescence probability converges to 0 as \( N \to \infty \) (which is implicit in Condition C), (8) is equivalent to Möhle’s condition (9), which, in turn, is equivalent to the neutral Cannings coalescent being in the domain of attraction of a Kingman coalescent as \( N \to \infty \).

Our second main result says that under Condition C the probability of fixation of a single beneficial mutant is asymptotically given by Haldane’s formula, i.e., as the ratio of \( s_N/(v_N/2) \), where \( v_N \) is the offspring variance of a randomly chosen individual in the Cannings model.
Theorem 2 (Haldane’s formula).
Assume (2) and Condition C, and consider a sequence of Cannings frequency processes with parameters $N$, $\mathcal{L}(\mathcal{W})$ and $s_N$. Then the fixation probabilities $\pi_N$ of single beneficial mutant follow the asymptotics

$$\pi_N = \frac{2s_N}{\rho^2} + o(s_N) \quad \text{as } N \to \infty. \quad (9)$$

Here is a brief sketch of the proof. We know that the asymptotics (9) holds for the fixation probabilities $\pi_N^M$ (starting from a single beneficial mutant) in a sequence of Moran($N$)-models with neutral reproduction rate $\rho^2$/2 (or equivalently with pair coalescence probability $\rho^2$) and selection strength $s_N$. Indeed, in Section 4 we will argue that

$$\pi_N^M = \frac{E\left[B_{eq}^{(N)}\right]}{N}, \quad (10)$$

where $B_{eq}^{(N)}$ has the stationary distribution of the line counting process $(B_{eq}^{(N)})_{r \geq 0}$ in the ancestral selection graph belonging to the Moran model. As observed in [7], $B_{eq}^{(N)}$ is a binomially distributed random variable with parameters $N$ and $p_N := \frac{2s_N}{2s_N + \rho^2}$ that is conditioned not to vanish. In particular,

$$E\left[\frac{B_{eq}^{(N)}}{N}\right] = p_N \frac{1}{1 - (1 - p_N)^N}, \quad (11)$$

which because of (2) equals $\frac{2s_N}{\rho^2} + o(s_N)$.

We show in Section 5 that thanks to Condition C and again to assumption (2) we can couple $(A_m^{(N)})_{m \geq 0}$ and $(B_m^{(N)})_{m \geq 0}$ long enough to ensure $E\left[A_{eq}^{(N)}\right] = E\left[B_{eq}^{(N)}\right] (1 + o(1))$, which proves Theorem 2. In Corollary 5.9 we will show that this coupling is good enough to guarantee that $A_{eq}^{(N)}$ is asymptotically normal with asymptotic mean $Np_N$ and variance $Np_N(1 - p_N)$.

Remark 3.4.  

a) The relevance of condition (2) within the strategy of our proof can heuristically be seen as follows. Near the asymptotic mean $a_{eq}^{(N)} := N\frac{2s_N}{\rho^2}$ the number of pairs is of the order $(a_{eq}^{(N)})^2$. The number of pair coalescences per generation is of the order $(a_{eq}^{(N)})^2/N$, and the number of synchronous pair coalescences per generation is of the order $(a_{eq}^{(N)})^4/N^2$, or equivalently, of the order $N^2s_N^3$. The coupling of $A^{(N)}$ and $B^{(N)}$ over a time interval of length $s_N$ works if within this time interval the number of synchronous pair coalescences remains negligible. This amounts to the condition $N^2s_N^3 \ll 1$, which corresponds to the upper bound in (2).

b) An inspection of the jump probabilities described in Section 2.3 shows that in a regime of negligible multiple collisions the quantity $a_{eq}^{(N)}$ defined in part a) is indeed an asymptotic center of attraction for the dynamics. Using the technique of [3] it is not difficult to show that $(A^{(N)}_{rN}/a_{eq}^{(N)})_{r \geq 0}$ converges in distribution as $N \to \infty$ uniformly on compact time intervals to the solution of a dynamical system whose stable fixed point is 1. It would seem tempting to study, using results like [9, Theorem 8.2] or [10, Theorem 11.3.2], also the fluctuations of the sequence of these processes and in this way to ensure a suitable concentration of $\frac{A^{(N)}_{rN}}{N}$ as $N \to \infty$ which would then lead to an alternative proof of Theorem 7 (Let us mention in this context the work of [7], which contains a fluctuation result for the Moran frequency process under strong selection and two-way mutation that includes time infinity.) The assumptions of the just mentioned theorems, however, do not cover our situation and a suitable extension seems (at least) tedious. We therefore decided to go the way via the coupling with the Moran ancestral selection graph, also because this is interesting in its own right.
We are preparing a companion paper which for the regime $CN^{-n} \geq s_N \geq eN^{-2/3+n}$ provides a proof of Haldane’s formula by a comparison of the Cannings frequency processes with Galton-Watson processes in random environment. Together with the approach of the present paper, this does not yet cover the case $s_N \sim N^{-2/3}$; we conjecture that Haldane’s formula is valid also for this particular exponent.

4 Haldane’s formula in the Moran model

In a two-type Moran model with constant population size $N$ and directional selection (see e.g. [11] Chapter 6), each individual reproduces at a constant rate $\gamma/\eta > 0$. In addition beneficial individuals reproduce with an additional rate $s_N > 0$. Let $Y_t^N$ be the number of wildtype individuals at time $t$, and let $(B_t) = (B_t^N)_{t \geq 0}$ be the counting process of potential ancestors traced back from some fixed time. The process $(B_t)_{t \geq 0}$, which we call the Moran ancestral selection process (or MASP for short), is a Markov jump process with jumps from $k$ to $k+1$ at rate $ksN\frac{k-1}{N}$ for $1 \leq k \leq N-1$ and from $k$ to $k-1$ at rate $\frac{N}{N-1}(\frac{k}{N})$, see [3]. The well-known graphical representation of the Moran model yields a strong duality between $(Y_t^N)$ and $(B_t^N)$. Stated in words this says that a sample $J \subset [N]$ at time $t$ consists of solely of wildtype individuals if and only of all the potential ancestors of $J$ are wildtype. This immediately leads to the following sampling (or hypergeometric) duality

$$E\left(\frac{Y_t^N(Y_t^N-1)\cdots(Y_t^N-(N-1))}{N(N-1)\cdots(N-(n-1))} \bigg| Y_0^N = k\right) = E\left(\frac{k(k-1)\cdots(k-(B_0^N-1))}{N(N-1)\cdots(N-(B_0^N-1))} \bigg| B_0^N = n\right),$$

where $t > 0$ and $k, n \in [N]$. Specializing the latter to $n = N$ and $k = N-1$ we obtain as in Corollary [3.2] that the probability $\pi_M^N$ of fixation of a single beneficial mutant is given by [10]. Thus $\pi_M^N$ is given by the r.h.s. of (11) with $\rho^2$ replaced by $\gamma$.

In particular, for $s_N = \frac{n}{N}$, $\alpha > 0$ (the case of weak selection) this specializes to Kimura’s formula [12]

$$\pi_M^N = \frac{2sN}{\gamma} \frac{1}{1-e^{-\frac{n}{\gamma}}} (1+o(1)).$$

For $N^{-n} \geq s_N \geq N^{-1+n}$ (the case of moderate selection) we obtain Haldane’s formula

$$\pi_M^N = \frac{2sN}{\gamma} (1+o(s_N))$$

and for $s > 0$ (the case of strong selection) there results

$$\pi_M^N = \frac{2s}{2s+\gamma} (1+O(N^{-1})).$$

5 The Cannings ancestral selection graph

We now define the Cannings ancestral selection graph, i.e. the graph of potential ancestors in a Cannings model with directional selection as announced in Section 2.3. The final harvest of this section will be the proof of Theorem 1.

While the branching-coalescing structure of the Moran ancestral selection graph and the sampling duality stated in Section 3 serve as a conceptual guideline, the ingredients of the graphical construction turn out to be quite different from the Moran case, not least because of the discrete generation scheme. As a first step, we describe how, given $\#^g$-1, the set of potential ancestors of an individual $(j,g)$, which form a subset of $[N] \times \{g-1\}$ are constructed from a sequence of i.i.d. uniform picks from the unit square.
To this purpose, as illustrated in Figure 1, think of the two axes of the unit square as being partitioned in two respectively \( N \) subintervals. The two subintervals that partition the “horizontal” unit interval \([0, 1]\) are \([0, 1 - s_N]\) and \([1 - s_N, 1]\). The \( N \) subintervals of the “vertical” unit interval \([0, 1]\) have length \( W_1^{(g-1)}, \ldots, W_N^{(g-1)} \); we call these subintervals \( \mathcal{I}_i^{(g-1)}, \ldots, \mathcal{I}_N^{(g-1)} \). For \( j \in [N] \), let \( U^{(j,g,1)}, U^{(j,g,2)}, \ldots \) be a sequence of independent uniform picks from \([0, 1] \times [0, 1]\). We first define a transport of the type configuration in generation \( g - 1 \) to the type configuration in generation \( g \). Let \( \mathcal{B}^{(g-1)} := \{ i \in [N] : (i, g - 1) \text{ is of beneficial type} \} \) and \( \mathcal{C}^{(g-1)} := \{ i \in [N] : (i, g - 1) \text{ is of wildtype} \} \), and define

\[
\Gamma^{(g-1)} := \bigcup_{i \in \mathcal{B}^{(g-1)}} [0, 1] \times \mathcal{I}_i^{(g-1)} \cup \bigcup_{i \in \mathcal{C}^{(g-1)}} [0, 1 - s_N] \times \mathcal{I}_i^{(g-1)}.
\] (12)

**Definition 5.1.** For fixed \( j \in [N] \) and \( g \in \mathbb{Z} \), let \( \gamma \) be the smallest of the indices \( \ell \) for which \( U^{(j,g,\ell)} \) falls into \( \Gamma^{(g-1)} \). Given \( \mathcal{B}^{(g-1)}, \mathcal{C}^{(g-1)}, \mathcal{W}^{(g-1)} \) and \( U^{(j,g,1)}, U^{(j,g,2)}, \ldots \), there is a unique \( i \in [N] \) for which \( \tilde{U} := U^{(j,g,\gamma)} \in [0, 1] \times \mathcal{I}_i^{(g-1)} \). The individual \((i, g - 1)\) is defined to be the parent of \((j, g)\).

Since \( \tilde{U} \) is uniformly distributed on \( \Gamma^{(g-1)} \), this definition is fully compatible with the rule (3). In particular, Definition 5.1 implies

\[
\{ (j, g) \text{ is of wildtype } \} = \{ \tilde{U} \in [0, 1 - s_N] \times \mathcal{C}^{(g-1)} \}.
\] (13)

Next we define

\[
G^{(j,g)} := \min \{ \ell : U^{(j,g,\ell)} \in [0, 1 - s_N] \times [0, 1] \}.
\] (14)

Figure 1: This figure illustrates a case in which \( \mathcal{C}^{(g-1)} = \{1, \ldots, k\} \), \( \mathcal{B}^{(g-1)} = \{k + 1, \ldots, N\} \), \( \gamma = 2 \), \( G^{(j,g)} = 4 \). Consequently, \((j, g)\) is of beneficial type.

The following equality of events is both immediate and crucial:

\[
\{ \tilde{U} \in [0, 1 - s_N] \times \mathcal{C}^{(g-1)} \} = \{ U^{(j,g,1)}, \ldots, U^{(j,g,G^{(j,g)})} \in [0, 1] \times \mathcal{C}^{(g-1)} \}.
\] (15)
Definition 5.2.  
i) We call \((i,g-1)\) a potential parent of \((j,g)\) if \(U^{(i,g)} \in [0,1] \times A_{i}^{(g-1)}\) for some \(\ell \leq G^{(j,g)}\). Similarly, we call \((i,g-2)\) a potential grandparent of \((j,g)\) if \((i,g-2)\) is a potential parent of a potential parent of \((j,g)\). By iteration this extends to the definition of the set \(\mathcal{A}_{m}^{(j,g)}\) of potential ancestors of \((j,g)\) in generation \(g-m\), \(m \geq 1\), with \(\mathcal{A}_{0}^{(j,g)} := \{(j,g)\}\).

ii) For a set \(J \subset [N]\) and for \(m \geq 0\) let \(\mathcal{A}_{m}^{(J,g)} := \bigcup_{j \in J} \mathcal{A}_{m}^{(j,g)}\) be the set of potential ancestors of \(J \times \{g\}\) in generation \(g-m\). Moreover, let \(A_{m}^{(J,g)} := |\mathcal{A}_{m}^{(J,g)}|\) be the number of potential ancestors of \(J \times \{g\}\) in generation \(g-m\).

Combining (13) and (15) with Definition 5.2 we see that for all \(g \in \mathbb{N}\) and \(J \subset [N]\)
\[
\{J \subset \mathcal{C}^{(g)}\} = \{\mathcal{A}_{1}^{(J,g)} \subset \mathcal{C}^{(g-1)}\}
\]
(16)

Iterating (16) we arrive at
\[
\{J \subset \mathcal{C}^{(g)}\} = \{\mathcal{A}_{0}^{(J,g)} \subset \mathcal{C}^{(0)}\},
\]
(17)
which is the formal counterpart of the statement at the end of Remark 3.1.

It is obvious that the random variables \(G^{(j,g)}\) defined in (14) are independent of the \(\mathcal{W}^{(g')}\), \(g' \in \mathbb{Z}\), and have the property
\[
G^{(j,g)}, g \in \mathbb{Z}, j \in [N], \quad \text{are independent and Geom}(1 - s_{N}) \text{ distributed.}
\]
(18)
This leads directly to the following observation on the number of potential ancestors.

Remark 5.3.  
Let \(g \in \mathbb{Z}\) and \(J \subset [N]\) be fixed.

i) The dynamics of \(A_{m} := |A_{m}^{(J,g)}|\), \(m = 0, 1, \ldots\), is Markovian. Each transition consists of a branching and a coalescence step, where only the latter depends on the \(\mathcal{W}^{(g')}\), \(g' \in \mathbb{Z}\). Specifically, given \(A_{m} = a\), let \(H\) have a negative binomial distribution with parameters \(a\) and \(1 - s_{N}\). Given \(H = h\), \(A_{m+1}\) is distributed as the number of distinct outcomes in \(h\) trials, which given \(\mathcal{W}^{(g-m-1)}\) are independent and follow the probability weights \(\mathcal{W}^{(g-m-1)}\).

ii) For \(m \geq 1\) the exchangeability of the components of \(\mathcal{W}\) implies that, given \(A_{m}^{(J,g)} = a\), the set \(\mathcal{A}_{m}^{(J,g)}\) is a uniform pick of all subset of \([N]\) of cardinality \(a\).

Theorem 1 is now an immediate consequence of Remark 5.3 and the strong duality relation (17).

Another consequence of (17), together with Remark 5.3, is the following moment duality, which is interesting in its own right, not least because this was the route through which González Casanova and Spanò [4] discovered the “discrete ancestral selection graph” in the Wright-Fisher case, i.e. for \(W_{1} = \cdots = W_{N} = \frac{1}{N}\).

Corollary 5.4.  
Let \(k, n \in [N]\) and assume that the number of wildtype individuals in generation 0 is \(k\). Then the probability that a sample of \(n\) individuals taken in generation \(g \geq 1\) consists of wildtype individuals only is
\[
E \left[ \left( \sum_{i=1}^{K_{g-1}} W_{i} \right) \sum_{j=1}^{A_{g-1}} G^{(j)} \mid K_{0} = k \right] = E \left[ \left( \sum_{i=1}^{K_{g-1}} W_{i} \right) \sum_{j=1}^{A_{g-1}} G^{(j)} \mid A_{0} = n \right],
\]
where \(G^{(1)}, G^{(2)}, \ldots\) are independent and Geom\((1 - s_{N})\)-distributed.

6 Coupling of the Cannings and the Moran ancestral selection processes and the proof of Theorem 2

In this section we provide a few lemmata preparing the proof of Theorem 2 and conclude with the proof of that theorem. In particular, in Lemma 6.8 we give a coupling of the Cannings ancestral selection process (CASP) \((A_{m})_{m \geq 0}\) defined in Section 2.3 and the Moran ancestral selection
process (MASP) \((B_r)_{r \geq 0}\) whose jump rates we recalled in Section 3. Assume throughout that the \(\Delta N\)-valued random weights \(W(N) = (W_{N}^{(1)}, \ldots, W_{N}^{(N)})\) fulfill Conditions C from Section 3.2. Let \((s_{N})_{N \geq 0}\) be a sequence in \((0, 1)\) obeying (2). Frequently, we will switch to the notation \(s_{N} = \frac{-\ln s_{N}}{N}\) or equivalently to
\[
s_{N} = N^{-b_{N}},
\]
with (2) translating into
\[
\frac{2}{3} + \eta \leq b_{N} \leq 1 - \eta.
\]
For fixed \(N\), and \(j \in [N]\) let
\[
G^{(j)} \text{ be independent and Geom}(1 - s_{N})\text{-distributed};
\]
these will play the role of the random variables \(G^{(j,g)}\) defined in (12), see also (18). (Here and whenever there is no danger of confusion, we will suppress the superscripts \(N\) and \(g\).)

**Lemma 6.1** (Moran-like transition probabilities of the CASP).

Let \(\varepsilon \in (0, \frac{1}{2})\). The transition probabilities of the CASP \((A_{m}) = (A_{m}^{(N)})\) obey, uniformly in \(k \leq N^{1-b_{N}+\varepsilon}\),
\[
\Pr(A_{m+1} = k | A_{m} = k) = 1 - k s_{N} - \left(\frac{k}{2}\right) \frac{\rho_{N}^{2}}{N} + O(k^{4}N^{-2} + k^{2}s_{N}^{2}) \quad (20)
\]
\[
\Pr(A_{m+1} = k + 1 | A_{m} = k) = k s_{N} + O(k^{2}s_{N}^{2} + k^{4}N^{-2}) \quad (21)
\]
\[
\Pr(A_{m+1} = k - 1 | A_{m} = k) = \left(\frac{k}{2}\right) \frac{\rho_{N}^{2}}{N} + O(k^{4}N^{-2} + k^{2}s_{N}^{2}) \quad (22)
\]
\[
\Pr(|A_{m+1} - k| \geq 2 | A_{m} = k) = O(k^{4}N^{-2} + k^{2}s_{N}^{2}). \quad (23)
\]

**Remark 6.2.** For \(k = 2\) we have \(\Pr(A_{m+1} = k - 1 | A_{m} = k) = \frac{\rho_{N}^{2}}{N} + O(N^{-2})\), which is the pair coalescence probability. In the neutral Cannings model the pair coalescence probability is \(\frac{\Var(\nu_{1})}{N}\), where \(\nu = (\nu_{1}, \ldots, \nu_{N})\) is the vector of offspring sizes. The difference to this formula arises due to the fact that we sample with replacement, i.e.
\[
\frac{\rho_{N}^{2}}{N} + O(N^{-2}) = \mathbb{E} \left[ \sum_{i=1}^{N} \frac{W_{i}^{2}}{N} \right], \quad (24)
\]
whereas in the classical Cannings model
\[
\frac{\Var(\nu_{1})}{N - 1} = \mathbb{E} \left[ \sum_{i=1}^{N} \frac{\nu_{i}(\nu_{i} - 1)}{N(N - 1)} \right]. \quad (25)
\]

**Proof of Lemma 6.1.** Recall that each transition of the CASP consists of a branching and a coalescence step. To arrive at the transition probabilities (20) - (23) we first estimate the probabilities that \(k\) individuals give rise to a total \(k, k + 1\) or more than \(k + 1\) branches and then analyse the probabilities that a single individual is chosen multiple times as a parent. Since each individual has a Geom\((1 - s_{N})\)-distributed number of branches, the probability that \(k\) individuals give rise to a total of \(k\) branches in the branching step is
\[
\Pr \left( \sum_{j=1}^{k} G^{(j)} = k \right) = (1 - s_{N})^{k} = 1 - k s_{N} + O(k^{2}s_{N}^{2}) \quad (26)
\]
and the probability that the individuals give rise to \( k + 1 \) branches is
\[
\mathbb{P} \left( \sum_{j=1}^{k} G^{(j)} = k + 1 \right) = k (1 - s_N)^k s_N = ks_N + O \left( k^2 s_N^2 \right).
\] (27)

Adding the probabilities in (26) and (27) yields for all \( \ell \geq k + 2 \)
\[
\mathbb{P} \left( \sum_{j=1}^{k} G^{(j)} \geq \ell \right) = O \left( k^2 s_N^2 \right).
\]

Let us now calculate the probabilities of collisions in a coalescence step, that is the probability that an individual is chosen as a potential parent more than once. For two individuals the pair coalescence probability \( c_N \) is given by
\[
c_N = \mathbb{E} \left[ \sum_{i=1}^{N} W_i^2 \right] = \frac{\rho^2}{N} + O(N^{-2}).
\] (28)

In the same manner we obtain the probability for a triple collision as
\[
d_N = \mathbb{E} \left[ \sum_{i=1}^{N} W_i^3 \right] = O(N^{-2}).
\] (29)

Using (28) and (29) we control the probability of the event \( E \) that there are two or more collisions. There are two possibilities for this event to occur, either there is at least a triple collision or there are at least 2 pair collisions. This yields
\[
\mathbb{P} (E) \leq \left( \frac{k}{4} \right) \frac{\rho^4}{N^2} + O \left( \frac{k}{3} N^{-2} \right) + O \left( k^4 N^{-3} \right) = O \left( k^4 N^{-2} \right).
\] (30)

In order to estimate the probability of having exactly one collision we use the second moment method for the random variable \( X = \sum_{i=1}^{k} \sum_{j>i} X_{i,j} \), where \( X_{i,j} = 1 \) (\( i \) and \( j \) collide). With (28) we get
\[
\mathbb{E} [X] = \mathbb{E} \left[ \sum_{i=1}^{k} \sum_{j>i} X_{i,j} \right] = \left( \frac{k}{2} \right) \frac{\rho^2}{N} + O(k^2 N^{-2}).
\] (31)

Furthermore, the second moment of \( X \) can be written again due to (28) and (29) as
\[
\mathbb{E} [X^2] = \mathbb{E} \left[ \left( \sum_{i=1}^{k} \sum_{j>i} X_{i,j} \right)^2 \right] = \left( \frac{k}{2} \right) \frac{\rho^2}{N} + O(N^{-2}) + O \left( k^3 \mathbb{E} [X_{1,2} X_{2,3}] \right) + O \left( k^4 \mathbb{E} [X_{1,2} X_{2,3,4}] \right)
\]
\[
= \left( \frac{k}{2} \right) \frac{\rho^2}{N} + O(k^3 N^{-2}) + O(k^4 N^{-2}) = \left( \frac{k}{2} \right) \frac{\rho^2}{N} + O(k^4 N^{-2})
\] (32)

This yields plugging in (31) and (32)
\[
\mathbb{P} (X > 0) \geq \frac{\mathbb{E} [X]}{\mathbb{E} [X^2]} = \frac{\left( \frac{k}{2} \right) \frac{\rho^2}{N}}{\left( \frac{k}{2} \right) \frac{\rho^2}{N} + O(k^4 N^{-2})} = \left( \frac{k}{2} \right) \frac{\rho^2}{N} (1 - O(k^2 N^{-1})).
\] (33)

Together with (30) we obtain for the random variable \( X \) which counts the number of collisions
\[
\mathbb{P} (X = 0) = 1 - \left( \frac{k}{2} \right) \frac{\rho^2}{N} + O(k^4 N^{-2})
\] (34)
\[
\mathbb{P} (X = 1) = \left( \frac{k}{2} \right) \frac{\rho^2}{N} + O(k^4 N^{-2})
\] (35)
\[
\mathbb{P} (X \geq 2) = \mathbb{P} (E) = O(k^4 N^{-2})
\] (36)
Let $H := \sum_{j=1}^{A_m} G^{(j)}$. Then the above calculations allow us to derive \cite{20}:

$$
\mathbb{P}(A_{m+1} = k + 1|A_m = k) = \mathbb{P}(A_{m+1} = k + 1|A_m = k, H = k)\mathbb{P}(H = k|A_m = k)
+ \mathbb{P}(A_{m+1} = k + 1|A_m = k, H = k + 1)\mathbb{P}(H = k + 1|A_m = k)
+ \mathbb{P}(A_{m+1} = k + 1|A_m = k, H \geq k + 2)\mathbb{P}(H \geq k + 2|A_m = k)
= \left(1 - \frac{k + 1}{2}\right) \frac{\rho^2}{N} + O(k^4 N^{-2})
\left(k s_N + O(k^2 s_N^2)\right) + O(k^2 s_N^2)
= k s_N + O(k^2 s_N^2 + s_N k^2 N^{-2})
$$

The remaining transition probabilities \cite{21} - \cite{23} are derived analogously.

The next lemma controls the speed of convergence to 1 of the probability of the event that the CASP comes down from $N$ to (the still large) $N^{1-b+\varepsilon}$ within a time interval of length $o(N^b)$.

**Lemma 6.3** (CASP coming down from huge to large). Let $(A_m)_{m\in\mathbb{N}_0}$ be a CASP, $0 < \varepsilon < \frac{2}{7}$, $A_0 = N$ and denote by $\tau = \inf\{m \geq 0 : A_m \leq N^{1-b+\varepsilon}\}$ the first time the CASP crosses the level $N^{1-b+\varepsilon}$. Then there exists a $\delta > 0$, such that for any $c_2 > 0$

$$
\mathbb{P}\left(\frac{\tau}{N^b} > c_2\right) = O(\exp(-N^d)).
$$

**Proof.** The coalescence probabilities of the Wright-Fisher model are the smallest in our class of Cannings models with selection, since the variance of the weights $\mathscr{W} = (W_1, \ldots, W_N) = (\frac{1}{N}, \ldots, \frac{1}{N})$ is zero. This is a consequence of the general birthday problem as studied in \cite{13}, Corollary 1.1. The branching step of the CASP dynamics only depends on $s_N$ and neither on the distribution nor the realization of $\mathscr{W}$, see Remark 5.3 (i). Hence, the CASP of the Wright-Fisher model with selection is the slowest to come down from $N$ to $N^{1-b+\varepsilon}$ and therefore we use the stopping time corresponding to the Wright-Fisher model as a stochastic upper bound for $\tau$. Consequently, we assume in the following that $\mathscr{W} = (1/N, \ldots, 1/N)$.

To show \cite{37} we estimate $\mathbb{E}[A_{m+1}|A_m = k]$ for $1 \leq k \leq N$.

$A_{m+1}$ denotes the number of potential parents of $A_m$ individuals, that is

$$
A_{m+1} = \sum_{i=1}^{N} \mathbb{1}\{\text{Individual i is a potential parent of some of the } A_m \text{ individuals}\}.
$$

Let $H = \sum_{j=1}^{A_m} G^{(j)}$, with $G^{(j)} \sim \text{Geom}(1-s_N)$ and independent for $j \in \{1, \ldots, N\}$. Then

$$
\mathbb{P}(\text{Ind. i is chosen as a potential parent}|A_m) = 1 - \left(1 - \frac{1}{N}\right)^H
$$

for $i \in \{1, \ldots, N\}$.

Hence, for $k \geq 1$ and $x = \frac{1}{N(1-s_N)}$

$$
\mathbb{E}[A_{m+1}|A_m = k] = N \mathbb{E}\left[\left(1 - \left(1 - \frac{1}{N}\right)^H\right) \mid A_m = k\right]
= N \left(1 - \left(1 - \frac{1}{N(1-s_N + \frac{x}{N})}\right)^k\right)
\leq -N \left(k \log(1-x) + \frac{(k \log(1-x))^2}{2} + \frac{(k \log(1-x))^2 k \log(1-x)}{6}\right)
\leq N \left(kx - \frac{(kx)^2(1-2s_N)}{3}\right)
= \frac{k}{1-s_N} \cdot \frac{k^2(1-2s_N)}{3N},
$$

(38) (39) (40)
where for \((38)\) we use the probability generating function of a random variable which is negatively binomial distributed and for \((39)\) we use an estimate for the remainder of the corresponding Taylor expansion. Let \(0 < \varepsilon' < \varepsilon\), from \((40)\) follows

\[
\mathbb{E}[A_{m+1}|A_m] \leq \max\{ \frac{A_m}{1-s_N} - \frac{A_m N^{1-b+\varepsilon'} (1 - 2s_N)}{3N}, N^{1-b+\varepsilon'} \} = \max\{q_N A_m, N^{1-b+\varepsilon'} \},
\]

with \(q_N = \frac{1}{1-s_N} - \frac{N^{1-b+\varepsilon'} (1 - 2s_N)}{3N}\). This yields

\[
\mathbb{E}[A_m|A_0 = N] \leq \max\{q_N^m N, N^{1-b+\varepsilon'} \}. \quad (41)
\]

For any \(m \geq c N^{b-\varepsilon} \log N\), for some appropriate constant \(c > 0\), it follows \(\mathbb{E}[A_m|A_0 = N] \leq N^{1-b+\varepsilon'}\). By Markov’s inequality we obtain

\[
\mathbb{P}(A_{N^{c(1-\varepsilon') \log N}} > N^{1-b+\varepsilon'}) \leq N^{\varepsilon'-\varepsilon} \to 0 \quad (42)
\]
as \(N \to \infty\). If \((A_m)_{m \geq 0}\) did not reach \(N^{1-b+\varepsilon}\) after \(c N^{b-\varepsilon} \log N\) steps we can start the process in \(N\) again and wait another \(c N^{b-\varepsilon} \log N\) steps and check whether the process did reach the level \(N^{1-b+\varepsilon}\). This yields an upper bound for the probability to stay above \(N^{1-b+\varepsilon}\) by using this argument \(N^{\delta}\) times, \(0 < \delta < \varepsilon'\). Therefore,

\[
\mathbb{P}(A_m > N^{1-b+\varepsilon} \text{ for } m \in \{0, \ldots, c N^{b-\varepsilon+\delta_1} \log N\}) \leq \mathbb{P}(A_{N^{c(1-\varepsilon') \log N}} > N^{1-b+\varepsilon'}) N^{\delta_1} \leq (N^{\varepsilon'-\varepsilon})^{N^{\delta_1}}.
\]

Since \(\varepsilon > \varepsilon'\) and \(N^{b-\varepsilon+\delta_1} < N^b\), we have \((N^{\varepsilon'-\varepsilon})^{N^{\delta_1}} = O(\exp(-N^\delta))\) for some appropriate \(\delta > 0\) from which follows the assertion. \(\square\)

With this lemma we are able to obtain the following corollary

**Corollary 6.4.** Let \((A_m)_{m \geq 0}\) be a CASP. Then for any \(m_0 \geq 0\) and \(j \geq N^{1-b+\varepsilon}\)

\[
\mathbb{P}(A_{m_0+N^b} > j|A_0 = N) = O(N^{1-b+\varepsilon}/j), \\
\mathbb{E}[A_{m_0+N^b}|A_0 = N] = O(\ln(N)N^{1-b+\varepsilon}).
\]

**Proof.** For simplicity assume that \(m_0 = 0\), but the same proof works for any \(m_0 \in \mathbb{N}\) as \(\mathbb{P}(A_{m_0+N^b} > j|A_0 = N) \leq \mathbb{P}(A_{m_0+N^b} > j|A_0 = N)\). Due to Lemma 6.3 for the stopping time \(\tau = \inf\{m \geq 0 : A_m \leq N^{1-b+\varepsilon}\}\) it holds \(\mathbb{P}(\tau > N^b) \leq \exp(-N^{-c_1})\), with \(c_1\) as in Lemma 6.3. By Lemma 6.1 we can compare jump probabilities and obtain that there exists some \(x_0 \leq N^{1-b+\varepsilon/2}\) such that the probability to jump up is smaller than the probability to jump down. This yields that the process possesses the supermartingale property at least until the process reaches the point \(x_0\). Consequently since \(x_0 < N^{1-b+\varepsilon}\) for any \(m^* \in \mathbb{N}\) by the strong Markov property

\[
\mathbb{E}[A_{\tau+m^*}] \leq N^{1-b+\varepsilon}. \quad (43)
\]

Hence by Markov’s inequality we obtain

\[
\mathbb{P}(A_{N^b} > j|A_0 = N) \leq \mathbb{P}(A_{N^b} > j|A_0 = N, \tau \leq N^b) + \mathbb{P}(\tau > N^b) \\
\leq \frac{\mathbb{E}[A_{N^b}|A_0 = N, \tau \leq N^b]}{j} + O(\exp(-N^{c_1})) \leq \frac{\mathbb{E}[A_{\tau}]}{j} + O(\exp(-N^{c_1})) \\
= O\left(\frac{N^{1-b+\varepsilon}}{j}\right).
\]
For the second part observe that

$$
\mathbb{E}[A_{N^k}|A_0 = N] = \sum_{j=1}^{N^1} \mathbb{P}(A_{N^k} > j|A_0 = N) = \sum_{j=1}^{N^1} \mathbb{P}(A_{N^k} > j|A_0 = N) + \mathbb{P}(A_{N^k} > j|A_0 = N) = N^{1-b+\epsilon}\sum_{j=N^1+b-\epsilon}^{N^1} \frac{N^{1-b+\epsilon}}{j} = O(N^{1-b+\epsilon}\ln N).
$$

The following three lemmata provide some properties about the Moran process and the coupling of a Moran process to a Moran process in stationarity. For the remainder of this section we will fix three constants

$$
\delta_1 \in (0, 1), \ 0 < \delta_2 < \frac{\delta_2}{2}.
$$

The role of $\delta_1$ will be to specify a region $\left\{\frac{2sN}{2sN + \rho}N(1 - \delta_1), \frac{2sN}{2sN + \rho}N(1 + \delta_1)\right\}$ around MASP’s center of attraction. The constant $\delta_2$ will appear in factors $N^{\delta_2}$ that stretch some time intervals, and the constant $\delta_3$ will be an exponent in small probabilities $O(\exp(-N^{\delta_3}))$.

**Lemma 6.5** (MASP’s hitting time of the center). Let $(B_r)_{r \geq 0}$ be a MASP started in some state $n \in [N]$ and let $T = \inf\{r \geq 0 : B_r \in \left(\frac{2sN}{2sN + \rho}N(1 - \delta_1), \frac{2sN}{2sN + \rho}N(1 + \delta_1)\right)\}$. Then,

$$
\mathbb{P}(T \leq N^{b+\delta_2}|B_0 = n) = 1 - O(\exp(-N^{\delta_3})) \quad (44)
$$

for any $\delta_1, \delta_2 > 0$ and $\delta_3 < \delta_2/2$.

**Proof.** We proceed in a similar manner as [14] and separate the proof into two cases

i) $B_0 > \frac{2sN}{2sN + \rho}N(1 + \delta_1)$

ii) $B_0 < \frac{2sN}{2sN + \rho}N(1 - \delta_1)$.

For case i) the proof relies on a stochastic domination of the MASP by a birth-death process, in the same manner for case ii) a pure birth process is stochastically dominated by the MASP. We start by proving case i).

Assume the worst starting point $B_0 = N$. We couple the process $(B_r)_{r \geq 0}$ with a birth-death process $(\overline{B}_r)_{r \geq 0}$ which stochastically dominates $(B_r)_{r \geq 0}$ until $(B_r)_{r \geq 0}$ crosses the level $\frac{2sN}{2sN + \rho}N(1 + \delta_1)$. $(\overline{B}_r)_{r \geq 0}$ is defined as the Markov process with state space $\mathbb{N}_0$ and the following transition rates

- $k \to k + 1$ with rate $ksN =: \overline{k}$
- $k \to k - 1$ with rate $k\frac{2sN\rho^2}{2sN + \rho^2}(1 + \delta_1) =: \overline{\kappa}$.

Note that $\overline{k} \geq sNk(N - k)/N$ and $\overline{\kappa}k \leq \left(\frac{\overline{k}}{\kappa}\right)^\frac{1}{2N}$ for any $k \geq \frac{2sN}{2sN + \rho}N(1 + \delta_1)$. Hence, we can couple $(\overline{B}_r)_{r \geq 0}$ and $(B_r)_{r \geq 0}$ such that $B_r \leq \overline{B}_r$ a.s. as long as $B_r \geq \frac{2sN}{2sN + \rho}N(1 + \delta_1)$. In particular, we have

$$
\mathbb{P}(T \geq r|B_0 = k) \geq \mathbb{P}(\tau_0 \geq r|B_0 = k) \quad (45)
$$

when we set $\tau_0 := \inf\{r \geq 0 : B_r = 0\}$ and $k \geq \frac{2sN}{2sN + \rho}N(1 + \delta_1)$. For the birth-death process $\overline{B}_r$ we can estimate $\tau_0$. By a classical first step analysis we arrive at

$$
\mathbb{P}(\tau_0 \geq r|\overline{B}_0 = 1) = (1 - \overline{\kappa} - \overline{k})dr\mathbb{P}(\tau_0 \geq r - dr|\overline{B}_0 = 1) + \overline{k}dr(1 - (1 - \mathbb{P}(\tau_0 \geq r - dr|\overline{B}_0 = 1))^2)
$$

13
Setting \( f(r) = \mathbb{P}(\tau_0 \geq r | \mathcal{B}_0 = 1) \) we obtain
\[
f'(r) = (\overline{\beta} - \overline{\alpha}) f(r) - \overline{\beta} f(r)^2
\]
with \( f(0) = 1 \) which is solved by
\[
f(r) = \frac{\overline{\alpha} - \overline{\beta}}{\alpha e^{r(\overline{\alpha} - \overline{\beta})} - \overline{\beta}}.
\]
Observe that \( \overline{\alpha} - \overline{\beta} = \frac{s_N \rho^2}{\rho^2 + 2s_N} (1 + \delta_1) - s_N = \delta_1 s_N (1 + o(1)) \), hence,
\[
f(N^{b+\delta_k} r) = \frac{\delta_1 s_N (1 + o(1))}{\rho^2 N + s_N} (1 + \delta_1) \exp(N^{b+\delta_k} \delta_1 s_N (1 + o(1))) - s_N
\]
\[
= \frac{\delta_1 (1 + o(1))}{\rho^2 N + s_N} (1 + \delta_1) \exp(N^{\delta_1} (1 + o(1))) - 1.
\]

From (45) and (47) we finally estimate
\[
\mathbb{P}(T < N^{b+\delta_k} | B_0 = N) \geq \mathbb{P}(\tau_0 < N^{b+\delta_k} | \mathcal{B}_0 = N) \geq 1 - N f(N^{b+\delta_k})
\]
\[
= 1 - O(N \exp(-N^{\delta_2})) = 1 - O(\exp(-N^{\delta_2})).
\]
for any \( \delta_3 < \delta_2 \). This proves part i).

Now it remains to prove the case ii). Assume the worst case \( B_0 = 1 \). Let \((\mathcal{B}_r)_{r \geq 0}\) be a birth-death process which jumps

- from \( k \) to \( k + 1 \) at rate \( k s_N (1 - \frac{2s_N}{2s_N + \rho^2} (1 - \delta_1)) =: \beta_k \)
- from \( k \) to \( k - 1 \) at rate \( k \frac{s_N \rho^2}{2s_N + \rho^2} (1 - \delta_1) =: \alpha k \).

\( \beta_k \leq s_N k (N-k)/N \) and \( \alpha k \geq \delta_1 \frac{N}{N} \) as long as \( k \leq \frac{2s_N}{\rho^2 + 2s_N} N (1 - \delta_1) \). Hence, we can couple \( (\mathcal{B}_r)_{r \geq 0} \) and \( (\mathcal{B}_r)_{r \geq 0} \) such that \( B_r \geq B_r \) as long as \( B_r \leq \frac{2s_N}{\rho^2 + 2s_N} N (1 - \delta_1) \).

The extinction probability \( \xi_0 \) of \((\mathcal{B}_r)_{r \geq 0}\) is the smallest solution of
\[
\xi = \frac{\beta}{\beta + \alpha} \xi^2 + \frac{\alpha}{\beta + \alpha}
\]
that is \( \xi_0 = \frac{\alpha}{\beta} < 1 \). Let \((\mathcal{B}_r^I)_{r \geq 0}\) be the pure birth process consisting of the immortal lines of \((\mathcal{B}_r)_{r \geq 0}\), i.e. each line branches at rate \( (1 - \xi_0) \beta \).

Let \( \tau = \inf\{ r \geq 0 : B_r \geq N \} \) be the time when \((\mathcal{B}_r)_{r \geq 0}\) reaches the level \( \frac{2s_N}{\rho^2} N (1 - \delta_1) \) and define \( \tau^I \) and \( \tau^* \) in the same way for the processes \((\mathcal{B}_r^I)_{r \geq 0}\) and \((\mathcal{B}_r)_{r \geq 0}\) respectively in place of \((\mathcal{B}_r)_{r \geq 0}\), then \( \tau^I \geq \tau \geq \tau^* \) a.s. In order to prove ii) it remains to show \( \mathbb{P}(\tau^I \geq N^{b+\delta_2}) = O(\exp(-N^{\delta_3})) \) for \( \delta_3 > 0 \). It holds
\[
\mathbb{E}[\tau^I] = \mathbb{E} \left[ \sum_{i=1}^{\frac{2s_N}{\rho^2} N (1 - \delta_1)} \frac{1}{\beta i (1 - \xi_0)} \right] = \frac{1}{\beta (1 - \xi_0)} \left( \ln \left( \frac{2s_N (1 - \delta_1)}{2s_N + \rho^2} N \right) + O(1) \right)
\]
\[
= \frac{1}{\delta_1 s_N} \left( \ln \left( \frac{2s_N (1 - \delta_1)}{2s_N + \rho^2} N \right) + O(1) \right) = \frac{1}{\delta_1} N^b \ln \left( \frac{2(1 - \delta_1) N^{1-b}}{\rho^2} \right) (1 + O(s_N))
\]
\[
= \frac{1 - b}{\delta_1} N^b \ln (N) (1 + O((\ln N)^{-1})). \quad (48)
\]
We can estimate $\Pr(\tau \geq N^{b+\delta_2}) \leq \Pr(\tau > N^{b+\delta_2/2} | B_0^t = 1) \leq \Pr(\tau > N^{b+\delta_2/2}) = 1)^{N^{\delta_2/2}}$ for $\delta_2 > 0$ by separating the time interval of length $N^{b+\delta_2}$ into $N^{\delta_2/2}$ time intervals of length $N^{b+\delta_2/2}$ and realizing that if $(B_t^t)_{t \geq 0}$ did not reach the level $2^S N (1 - \delta_1)$ in a time interval of length $N^{b+\delta_2/2}$ then in the worst case $(B_t^t)_{t \geq 0}$ is 1 at the start of each time interval.

By Markov’s inequality we then arrive at

$$\Pr(\tau \geq N^{b+\delta_2}) \leq \Pr(\tau > N^{b+\delta_2/2}) \leq \left(\frac{1}{\delta_1} N^{-\delta_2/2} \ln N\right)^{N^{\delta_2/2}} \leq \exp\left(-\frac{\delta_2}{2} N^{\delta_2/2}\right) = O(\exp(-N^{\delta_2}))$$

for $\delta_2 < \delta_2/2$. From (49) we can directly conclude $\Pr(\tau \geq N^{b+\delta_2}) = O(\exp(-N^{\delta_2}))$, which together with part i) finishes the proof.

**Lemma 6.6 (MASP’s leaving time of the center).** Let $(B_r)_{r \geq 0}$ be a MASP started in $\left[\frac{2sN}{2sN + \rho^2} N(1 - \delta_1), \frac{2sN}{2sN + \rho^2} N(1 + \delta_1)\right]$ for some $0 < \delta_1 < \frac{1}{2}$ and let $S = \inf\{r \geq 0 : B_r \notin \left[\frac{2sN}{2sN + \rho^2} N(1 - 2\delta_1), \frac{2sN}{2sN + \rho^2} N(1 + 2\delta_1)\right]\}$ then it holds for $0 < \delta_2 < \frac{2}{3}$

$$\Pr(S > N^{b+\delta_2}) \geq 1 - o(\exp(-N^{1-b-2\delta_2})).$$

**Proof.** Assume we have $B_0 \in \left[\frac{2sN}{2sN + \rho^2} N(1 - \delta_1), \frac{2sN}{2sN + \rho^2} N(1 + \delta_1)\right]$. To prove (50) we couple $(B_r)_{r \geq 0}$ with a symmetric (discrete time) random walk $(S_n)_{n \geq 0}$ by ignoring the drift to $\frac{2sN}{2sN + \rho^2} N$. Using the same estimate as in (53) shows that $(B_r)_{r \geq 0}$ makes at most $N^{1-b-2\delta_2}$ many jumps in a time interval of length $N^{b+\delta_2}$ with probability $1 - O(\exp(-N^{1-b-2\delta_2}))$. Hence,

$$\Pr_x\left(B_r \notin \left[\frac{2sN}{2sN + \rho^2} N(1 - \delta_1), \frac{2sN}{2sN + \rho^2} N(1 + \delta_1)\right]\right) \leq P_0\left(S_n \notin \left[-\frac{2sN}{2sN + \rho^2} N, \frac{2sN}{2sN + \rho^2} N\right] \text{ for some } n \leq N^{1-b-2\delta_2}\right)$$

$$= 2P_0\left(\max_{1 \leq n \leq N^{1-b-2\delta_2}} S_n \notin \left[0, \frac{2sN}{2sN + \rho^2} N\right]\right)$$

$$= 4\exp\left(-cN^{1-b-2\delta_2}\right) = O(\exp(-N^{1-b-2\delta_2}))$$

for some $c > 0$. To obtain equation (51) and inequality (52) we used the reflection principle and Hoeffding’s inequality which finishes the proof.

**Lemma 6.7 (MASP close to stationarity).** Let $(B_r)_{r \geq 0}$ be a MASP started in $k$ individuals, with $1 \leq k \leq N$, then

$$d_{TV}(\mathcal{L}(B_{N^{b+\delta_2}}), \mathcal{L}(B^q)) = O(e^{-N^{\alpha_3}})$$

with $B^q \sim \text{Bin}(N, \frac{2sN}{2sN + \rho^2})$ conditioned to be strictly positive, and where the constant in $O$ is uniform in $k$.

**Proof.** We follow a similar strategy as has been used in the proof of Lemma 2.10 in [14]. Let $(B^q_r)_{r \geq 0}$ be a MASP started in the stationary distribution. Assume that in the graphical representation at time 0 either the lines of $B_0$ are contained in $B^q_0$ or vice versa. Then $B_r \leq B^q_r$, for
all \( r \geq 0 \), or vice versa \( B_{eq}^{r} \leq B_{r} \). Then \( \mathbb{P}(B_{N+\delta}^{r} = k) = \mathbb{P}(B^{eq} = k)(1 - O(e^{-N^{\delta_{1}}})) \) follows, once we show that at time \( N^{b+\delta_{2}} \) both processes are equal with probability \( (1 - O(e^{-N^{\delta_{1}}})) \).

The tuple \((B_{eq}^{r}, B_{r})_{r} \geq 0 \), and the tuple \((B_{r}, B_{eq}^{r})_{r} \geq 0 \) resp., have the following transition rate: jumps from \((k, \ell)\) to

- \((k + 1, \ell + 1)\) occur at rate \( s_{N}k(1 - \frac{\rho}{N}) \)
- \((k, \ell + 1)\) occur at rate \( s_{N}(\ell - k)(1 - \frac{\rho}{N}) \)
- \((k + 1, \ell)\) occur at rate \( ks_{N}\frac{k - \rho}{N} \)
- \((k, \ell - 1)\) at rate \( \frac{\rho^{2}}{N} \left( (\ell - k) + (\ell - k) \right) \)
- \((k - 1, \ell - 1)\) at rate \( \frac{\rho^{2}}{N}\frac{(k + 1)}{2} \).

To proceed further we consider the two cases

i) \( B_{0} > B_{eq}^{r} \)

ii) \( B_{0} < B_{eq}^{r} \)

separately.

We begin with Case i). Consider the process \((Z_{r}, r \geq 0)\) defined through \( Z_{r} := B_{r} - B_{eq}^{r} \) and condition on the two events that the process \( B_{0}^{eq} \) is started in a state in \([\frac{2s_{N}}{2s_{N} + \rho^{2}}N(1 - \delta_{1}), \frac{2s_{N}}{2s_{N} + \rho^{2}}N(1 + \delta_{1})]\) and stays in \([\frac{2s_{N}}{2s_{N} + \rho^{2}}N(1 - 2\delta_{1}), \frac{2s_{N}}{2s_{N} + \rho^{2}}N(1 + 2\delta_{1})]\) for some \( 0 < \delta_{1} < \frac{1}{2} \). The probability of each event can be estimated by \( 1 - \exp(-N^{\delta_{1}}) \), the former event by Hoeffding’s inequality and the latter with Lemma 6.6. The process \((Z_{r}, r \geq 0)\) jumps from \( z \) to \( z + 1 \) at most at rate \( s_{N}z \) and under the above condition \((Z_{r}, r \geq 0)\) jumps from \( z \) to \( z - 1 \) at least at rate \( \rho^{2}\frac{2s_{N}}{2s_{N} + \rho^{2}}(1 - 2\delta_{1})z \). If \((Z_{r}, B_{r}, B_{eq}^{r}) = (z, \ell, k)\) jumps to \((z - 1, \ell - 1, k)\) at rate \( \frac{\rho^{2}}{N}(\ell + z) \) and jumps to \((z - 1, \ell, k + 1)\) at rate \( ks_{N}\frac{z - k}{N} \). Therefore, the process \((Z_{r}, r \geq 0)\) jumps from \( z \to z - 1 \) at rate \( r_{z,z-1} = \frac{\rho^{2}}{N}(\ell + z) + ks_{N}\frac{z - k}{N} \). Due to the condition and the assumption that \( \ell \geq k \geq \frac{2s_{N}}{2s_{N} + \rho^{2}}N(1 - 2\delta_{1}) \) we can bound

\[
r_{z,z-1} = \frac{\rho^{2}}{N} \left( \frac{z}{2} + zk \right) + ks_{N}\frac{z - k}{N} \geq \frac{\rho^{2}}{2N}z(k + \ell - 1) + z\frac{2s_{N}}{2s_{N} + \rho^{2}}(1 - 2\delta_{1})
\]

\[
\geq \frac{\rho^{2}}{2N}z\frac{2s_{N}}{2s_{N} + \rho^{2}}N(1 - 2\delta_{1}) = \frac{\rho^{2}}{2s_{N} + \rho^{2}}N(1 - 2\delta_{1}).
\]

Hence, we can couple \((Z_{r}, r \geq 0)\) to a birth-death process \((Z_{r}', r \geq 0)\) with individual birth rate \( s_{N} := \beta' \) and individual death rate \( \rho^{2}\frac{2s_{N}}{2s_{N} + \rho^{2}}(1 - 2\delta_{1}) := \alpha' \), such that \( Z_{r} \leq Z_{r}' \) a.s. Let \( \xi := \inf\{r \geq 0 : Z_{r} = 0\} \) and \( \xi' := \inf\{r \geq 0 : Z_{r}' = 0\} \). Obviously it holds \( \mathbb{P}(\xi \geq r) \leq \mathbb{P}(\xi' \geq r) \) for all \( r \geq 0 \). As in the proof of Lemma 6.5 we estimate

\[
\mathbb{P}(\xi' \geq N^{b+\delta_{2}}|Z_{0}' = 1) = \frac{\frac{\rho^{2}}{2s_{N} + \rho^{2}}N(\frac{1}{2s_{N} + \rho^{2}} - 1) s_{N}}{\frac{2s_{N}}{2s_{N} + \rho^{2}}N(\frac{1}{2s_{N} + \rho^{2}} - 1) s_{N} \exp\left( \frac{\rho^{2}(1 - 2\delta_{1})}{2s_{N} + \rho^{2}} - 1 \right) N^{\delta_{2}} - s_{N}} = O(\exp(-c_{N}N^{\delta_{2}}))
\]

with \( c_{N} = \frac{\rho^{2}(1 - 2\delta_{1})}{2s_{N} + \rho^{2}} - 1 \rightarrow 2(1 - 2\delta_{1}) - 1 > 0 \). Since \( Z_{0} \leq N \) the probability that all lines go extinct before time \( N^{b+\delta_{2}} \) can be estimated by

\[
\mathbb{P}(Z_{N^{b+\delta_{2}}} = 0) \geq \left( 1 - \exp(-c_{N}N^{\delta_{2}}) \right)^{N} \geq 1 - O \left( \exp(-N^{\delta_{1}}) \right),
\]

which proves Lemma 6.7 in Case i).
In Case ii) we first wait until \( B_t \) reaches the level \( \frac{2}{3}\sigma s_N N(1 - \delta_1) \) within a time interval of length \( O(N^{b+\delta_2}) \) with probability \( 1 - O(\exp(-N^{\delta_1})) \) due to Lemma 6.5 and we assume that \( B_0^{eq} \) is started in at least \( \frac{2}{3}s_N N(1 - \delta_1) \), which happens with probability \( 1 - \exp(-\delta_1^2 N) \) due to Hoeffding’s inequality. Then due to Lemma 6.6 both processes remain bounded from below by \( \frac{2}{3}s_N N(1 - 2\delta_1) \).

When \( B_t \) has reached at least the level \( \frac{2}{3}s_N N(1 - \delta_1) \) consider \( Z_t = B_t - B_t^{eq} \). Then the same arguments as in Case i) show the claim. \( \square \)

As mentioned in the sketch of proof of Theorem 2 in Section 3 we aim to couple the CASP with the MASP. We have seen in the calculations before that in the regime where the number of potential ancestors is at most of order \( N^{1-b+\varepsilon} \) for \( \varepsilon \) sufficiently small the transition probabilities of these two processes are essentially the same for a time interval of length \( O(N^{b+\varepsilon}) \).

In particular in a time interval of length \( O(N^{b+\varepsilon}) \) we can exclude jumps of size 2 or bigger in the CASP with probability \( O(\varepsilon^{2\delta}) \).

Lemma 6.8 (Coupling of MASP and CASP). Let \( 0 < \varepsilon < \frac{3}{2}, \) and \( 0 < \delta = 3\eta - 6\varepsilon. \) There exists a coupling of the MASP \((B_t), t \geq 0 \) and the CASP \((A_m), m \geq 0 \) such that for all common initial values \( k_0 \) with \( 1 \leq k_0 \leq N^{1-b+\varepsilon} \)

\[
\mathbb{P} \left( |A_m - B_m| \leq 1, \forall m \in \{0, \ldots, N^{b+\varepsilon}\} \right) = 1 - O(N^{-\delta}).
\]

with the constant in \( O \) uniform in \( k_0. \)

Proof. Let \( A_0 = B_0 = k_0 \leq N^{1-b+\varepsilon}. \) We will show that the CASP and the MASP can be coupled such that the jump times of the CASP and the MASP occur consecutively with probability \( 1 - O(N^{-\delta}). \) Since the transition probabilities of the CASP and the MASP are essentially the same we can also couple the jump directions with high probability. To show that the jump times occur consecutively we first show the following claim:

Claim 1: The MASP makes for \( N^{b+\varepsilon} \) time intervals of length 1 at most one jump with probability \( 1 - O(N^{-\delta}). \)

By Lemma 6.5 and 6.6 the MASP stays below \( 2N^{1-b+\varepsilon} \) with probability \( 1 - O(\exp(-N^{\delta_1})). \)

Denote by \( r_{k,k+1} \) and \( r_{k,k-1} \) the jump rates for the MASP from \( k \) to \( k+1 \) and from \( k \) to \( k-1 \) respectively with \( \gamma = \rho^2. \) Then

- \( r_{k,k+1} = \frac{k}{N} \)
- \( r_{k,k-1} = \frac{k}{N} \)

Define \( r_k = r_{k,k+1} + r_{k,k-1} \) the total jump rate and

\[
r_k = r_{N^{1-b+\varepsilon}} = \max_{1 \leq k \leq N^{1-b+\varepsilon}} r_k = N^{1-2b+2\varepsilon}(1 + o(1))
\]

the maximal jump rate. We aim for the coupling to hold for an interval of length \( N^{b+\varepsilon}. \) The jump times of \((B_t), t \geq 0 \) are exponentially distributed with a parameter bounded form above by \( r_. \) To estimate the number of jumps falling into an interval of length \( N^{b+\varepsilon} \) we use Theorem 5.1 ii) in \( [15]. \) Let \( (X_i), i \geq 1 \) be a family of independent \( \exp(r.) \) distributed random variables. For \( c = 1-b+4\varepsilon \) Theorem 5.1 iii) yields

\[
\mathbb{P} \left( \sum_{i=1}^{N^c} X_i \leq N^{b+\varepsilon} \right) = O(\exp(-N^{1-b+4\varepsilon})),
\]

that is the number of jumps is bounded by \( N^{1-b+4\varepsilon} \) with probability \( 1 - O(\exp(-N^{1-b})). \)

Let \( E = \{ (B_t), 0 \leq t \leq N^b \} \) has at most one jump in the intervals \([j, j+1] \) for each \( 0 \leq j \leq N^b - 1 \),

\[
\mathbb{P}(E) \geq (1 - O(\exp(-N^{1-b}))) \prod_{i=1}^{N^c} \mathbb{P}(X_i > 1) \geq (1 - O(\exp(-N^{1-b})) e^{-r_.N^c}
\]

\[
= 1 - O(N^{-\delta})
\]

(57)
which yields Claim 1.
Let \( T_i^A = \inf \{ m \geq T_{i-1}^A : A_m \neq A_{T_{i-1}^A} \} \) be the \( i \)-th jump of the CASP with the convention \( T_{-1}^A = 0 \). In the same manner let \( T_i^B = \inf \{ r \geq T_{i-1}^B : B_r \neq B_{T_{i-1}^B} \} \) be the \( i \)-th jump of the MASP again with the convention that \( T_{-1}^B = 0 \).

\[
\mathbb{P}(B_{T_i^B} = k + 1 | B_{T_{i-1}^B} = k) = \frac{r_{k,k+1}}{r_{k,k+1} + r_{k,k-1}} = \mathbb{P}(A_{T_i^A} = k + 1 | A_{T_{i-1}^A} = k) + e_{k,N} \tag{58}
\]

and

\[
\mathbb{P}(B_{T_i^B} = k - 1 | B_{T_{i-1}^B} = k) = \frac{r_{k,k-1}}{r_{k,k+1} + r_{k,k-1}} = \mathbb{P}(A_{T_i^A} = k - 1 | A_{T_{i-1}^A} = k) + f_{k,N}, \tag{59}
\]

where \( e_{k,N}, f_{k,N} \in O(\max \{ k^2 A_k^2, k^4 N^{-2}, N^{-1} \}) \) these are the error terms from (21)-(22), that is \( e_{k,N}, f_{k,N} \geq 0 \) because the CASP can make jumps of size 2 or larger. Set \( d_{k,N} = e_{k,N} + f_{k,N} \).

We show that we can couple the times \( T_i^A \) and \( T_i^B \), such that \( T_{i+1}^B < T_i^A \) for \( i = 1, ..., N^{1-b+4c} \) with probability \( 1 - O(N^{-\delta}) \). From that follows the Assertion (55) of the Lemma by coupling the jump directions.

We couple the jump times \( T_i^A \) and \( T_i^B \) such that for all \( i \in \{1, ..., N^{1-b+3c}\} \)

\[
\mathbb{P}(T_{i+1}^B < T_i^A) = O(N^{1-2b+2c}) \tag{60}
\]

from which follows the assertion. We explicitly construct the coupling for \( i = 1 \), and the same holds for any \( i \in \{1, ..., N^{1-b+3c}\} \). To show (60) observe that, if \( A_0 = k = B_0 \) we can couple \( T_i^A \) and \( T_i^B \) by setting

\[
T_i^A \overset{d}{=} \left[ \frac{\ln U_1}{\ln(1 - r_k + d_{k,N})} \right], \quad T_i^B \overset{d}{=} -\frac{\ln U_1}{r_k} \tag{61}
\]

for \( U_1 \sim \text{Unif}([0,1]) \), since \( T_i^B \) is \( \text{Exp}(r_{k,k+1} + r_{k,k-1}) \) distributed and \( T_i^A \) is \( \text{Geo}(r_{k,k+1} + r_{k,k-1} + d_{k,N}) \) distributed. Note that \( T_i^A \geq T_i^B \) almost surely. The coupling holds due to a) if

\[
\mathbb{P}(T_{i+1}^B - T_i^A < T_i^A - T_i^B) = O(N^{1-2b+2c}). \tag{62}
\]

Furthermore observe

\[
T_i^A - T_i^B \geq \ln(U_1) \left( \frac{1}{\ln(1 - r_k + d_{k,N}) + \frac{1}{r_k}} \right) =: c_k \ln U_1
\]

We can upper bound the probability in (62) if we assume \( T_{i+1}^B - T_i^A \sim \text{Exp}(r_{k+1}) \), thus we obtain for \( E_2 \sim \text{Exp}(r_{k+1}) \)

\[
\mathbb{P}(T_{i+1}^B - T_i^A < T_i^A - T_i^B) \leq \mathbb{P}(E_2 \leq c_k \ln U_1) = 1 - \int_0^1 e^{-r_k+c_k \ln u} du = 1 - \int_0^1 u^{-r_k+c_k} du = 1 - \frac{1}{r_k+c_k+1}. \tag{63}
\]

Now we analyse (63) further and get

\[
1 - \frac{r_{k+1}}{\ln(1 - r_k + O(r_{k,N}))} + \frac{r_{k+1}}{r_k} + 1 = 1 - \frac{r_{k+1}}{r_k + d_{k,N} + O(r_{k,N})} + \frac{r_{k+1}}{r_k} + 1
\]

\[
= 1 - \frac{r_{k+1}}{r_k} (1 + O(d_{k,N}/r_k + O(r_k)) + \frac{r_{k+1}}{r_k} + 1
\]

\[
= O(d_{k,N}/r_k) + O(r_k) = O(N^{1-2b+2c}). \tag{64}
\]

which proves (60) and together with Claim 1 this proves the assertion of the lemma. \( \square \)
We are now able to complete the proof of Theorem 2.

**Proof of Theorem 2.** Let \((A_m)_{m \in \mathbb{Z}}\) be a stationary version of the CASP. By Corollary 6.3, it suffices to analyse \(\mathbb{E}[A_0]/N\) in order to obtain the probability of fixation of a single beneficial mutant. Let
\[
E = \{A_{-N^{b+\varepsilon}} \leq N^{1-b+\varepsilon}, |A_{-j} - B_{-j}| \leq 1, \; j \in \{0, 1, ..., N^{b+\varepsilon}\}\}
\]
be the event that the CASP \((A_m)_{m \in \mathbb{Z}}\) is not unusually big at time \(-N^{b+\varepsilon}\) and can then be coupled with a MASP for the remaining time such that \(|B_{-N^{b+\varepsilon}} - A_{-N^{b+\varepsilon}}| \leq 1\). Due to Lemma 6.3 and 6.8, we can estimate the probability of this event by
\[
P(E) = (1 - O(N^{-\delta}))(1 - O(\exp(-N^{c_1}))) = 1 - O(N^{-\delta})
\]
with \(c_1 > 0\) and a suitable \(\delta > 0\). This yields
\[
\frac{\mathbb{E}[A_0]}{N} = \frac{1}{N} \mathbb{E}[A_0|E]P(E) + \frac{1}{N} \mathbb{E}[A_0|E^c]P(E^c)
\]
where the second is an error term of order \(o(s_N)\). By Lemma 6.7, we get that with \(B^\infty \overset{d}{=} \text{Bin}(N, \frac{2s_N}{N^{b+\varepsilon} + \rho^2})\) conditioned to be strictly positive as in Lemma 6.7,
\[
\frac{1}{N} \mathbb{E}[A_0|E]P(E) = \frac{1}{N} \sum_{j=1}^{N} jP(A_0 = j|E)(1 - O(N^{-\delta}))
\]
\[
= \frac{1}{N} \sum_{j=1}^{N} jP(B^\infty = j)(1 - O(N^{-\delta})) = \frac{1}{N} \frac{N2s_N}{2s_N + \rho^2}(1 - O(N^{-\delta}))
\]
\[
= \frac{2s_N}{\rho^2}(1 + o(s_N)).
\]
It remains to bound the second expectation in (66), in the worst case \(A_{-N^{b+\varepsilon}} = N\) and now using the second part of Corollary 6.4 gives us
\[
\frac{1}{N} \mathbb{E}[A_0|E^c]P(E^c) = O\left(\frac{N^{1-b+\varepsilon}}{N}N^{-\delta}\right) = O(N^{-b+\varepsilon-\delta}) = o(s_N),
\]
since \(\varepsilon > 0\) can be chosen small enough such that \(\delta > \varepsilon\). This finishes the proof of Theorem 2. 

**Corollary 6.9.** Let \(A_{eq}^{(N)}\) have the stationary distribution of the CASP. Then, with \(p_N := \frac{2s_N}{\rho^2 + 2s_N}\), \(\mu_N := Np_N\) and \(\sigma_N^2 = Np_N(1 - p_N)\), the sequence of random variables
\[
Z_N := \frac{A_{eq}^{(N)} - \mu_N}{\sigma_N}
\]
converges in distribution to a standard normal \(N(0,1)\).

**Proof.** In (65) and (66), we have seen a decomposition of \(\mathbb{E}[A_{eq}^{(N)}]\). Analogously, the distribution \(\nu_N^Z\) of \(Z_N\) is the mixture of \(\nu_{2,E}^Z\) and \(\nu_{2,E^c}\) the distribution of \(Z^N\) conditioned on \(E, E^c\) respectively. Then we have for any \(f \in C_b(\mathbb{R})\) due to (65)
\[
\lim_{N \to \infty} \int f d\nu_N^Z = \lim_{N \to \infty} (1 - O(N^{-\delta})) \int f d\nu_{2,E}^Z + O(N^{-\delta}) \int f d\nu_{2,E^c}^Z
\]
\[
= \int f d\varphi,
\]
where \(\varphi\) is the standard normal density.
