Abstract

Changing the interlayer exchange coupling between magnetic layers in situ is a key issue for spintronic, as it allows for optimization of properties that are desirable for applications including magnetic sensing and memory. In this paper, we utilize the phase-change material VO₂ as the spacer layer to regulate the interlayer exchange coupling between the ferromagnetic layers with perpendicular magnetic anisotropy. Successful growth of ultra-thin (several nanometers) VO₂ films with metal-to-insulator transition features is realized by sputtering at room temperature, which further enables the fabrication of [Pt/Co]₂/VO₂/[Co/Pt]₂ systems with distinct interfaces. Such a magnetic multilayer system demonstrates an evolution from weak antiferromagnetic coupling to ferromagnetic coupling as the VO₂ undergoes a phase-change. The underlying mechanism originates from the electronic structure change of the spacer layer from insulation to metallicity. As a demonstration of phase-change spintronics, this work may reveal the great potential of materials innovation for next-generation spintronics.

Keywords: phase-change; interlayer exchange coupling; VO₂; spintronics
Introduction

Interlayer exchange coupling (IEC) is an indirect exchange interaction between magnetic layers mediated by the conduction electrons of the spacer layer. The discovery of IEC has given birth to the booming research in spintronics including giant magnetoresistance (GMR)\(^1,2\) and tunneling magnetoresistance (TMR) effects\(^3,4\), and has been extensively applied to the design of synthetic antiferromagnet (SAF) layers in magnetic tunnel junctions (MTJ). Comparing with direct manipulations of magnetizations in spintronic devices, transitions of IEC between ferromagnetic (FM) and antiferromagnetic (AFM) coupling states may provide a promising opportunity to realize low-power spintronic device applications in the post-Moore’s-law era\(^5-7\). Up to now, IEC has been systematically investigated in layered structures with different metallic spacer layers\(^8-11\), as well as some semiconducting, insulating, and organic spacers, \(e.g.,\) Si\(^12-14\), GaAs\(^15,16\), MgO\(^17,18\) and α-sexithiophene\(^19\). The periodically oscillated IEC strength with the thickness variation of metallic spacer layer\(^8-10,20\) has attracted a great deal of research interest in its physical mechanism. One of the most important theories is the Rudermann–Kittel–Kasuya–Yosida (RKKY) interaction\(^21-23\), which attributes the magnetic coupling to interactions between localized d- or f-shell electron spins through the conduction electrons. Another commonly accepted theory is based on the quantum well states (QWSs), which describes the discrete electronic states formed by electron confinement, and evolves periodically with the well width\(^24-26\). Pioneering theoretical researchers have also tried to develop a unified theory for both metallic and insulating spacer layers, by introducing the concept of a complex Fermi surface\(^27,28\), although further research is still needed to promote relevant developments.

In most experimental cases, the regulation of IEC is achieved through thickness changing of spacer layer\(^29,30\), or external engineering by stress and electrochemistry\(^31\). However, these methods are usually non-dynamic or even irreversible, which limits the application of IEC in innovative spintronic devices. One possible attempt to solve this problem is to substitute the traditional spacer layer with materials sensitive to external stimuli, utilizing their electronic property change to manipulate IEC directly\(^32-34\). From this point of view, phase-change material, such as VO\(_2\), can be a promising candidate
for the spacer layer, benefiting from its feature of near room temperature metal-to-insulator transition (MIT)\textsuperscript{35,36}. In fact, with characteristics of fast-response and high-stability, VO\textsubscript{2} has been extensively studied in the phase-change electronics\textsuperscript{37–39}. Therefore, a VO\textsubscript{2} phase-change based spintronic device may reform the magnetism modulation strategy and enable emerging phase-change spintronic device applications.

In this work, we successfully deposited ultra-thin (several nanometers) VO\textsubscript{2} films using magnetron sputtering at high vacuum, verified by X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS). Phase-change feature of such an ultra-thin film is further proved by electrical transport measurements. [Pt/Co\textsubscript{2}]\textsubscript{2}/VO\textsubscript{2}/[Co/Pt\textsubscript{2}] multilayer system with perpendicular magnetic anisotropy (PMA) feature is prepared to explore the phase-change induced IEC regulation. By characterizations at different temperatures, the switching from weak antiferromagnetic coupling to ferromagnetic coupling has been observed. The VO\textsubscript{2} thickness dependent switching process has been evaluated and explained by the effect of MIT induced Fermi surface modulations. This work, combining MIT with IEC modulation, shows a fairly groundbreaking and promising approach to take joint advantages of phase-change electronics and spintronics.

Results

Characterization of ultra-thin VO\textsubscript{2} film and preparation of phase-change magnetic multilayer system

For the experiment of phase-change induced IEC regulation, the preparation of VO\textsubscript{2} films with nanometer thickness lies in the heart of all problems. Even though lots of methods have been used to deposit VO\textsubscript{2}, such as molecular beam epitaxy\textsuperscript{40}, pulsed laser deposition\textsuperscript{41–43} and chemical vapor deposition\textsuperscript{44}, strict growth requirements, \textit{e.g.}, high temperature, high oxygen pressure, and specific substrates, are usually needed\textsuperscript{45,46}, which however may oxidize or destroy the bottom layers in the preparing process. In addition, the desired thickness of the spacer layer for IEC investigations is usually less than 5 nm\textsuperscript{8,47}, which calls for high film quality of VO\textsubscript{2} to keep the MIT feature. Therefore, it remains a challenge to insert VO\textsubscript{2} into magnetic layers and guarantee perfect interfaces.
Utilizing the ability of multilayer depositions at ultra-high-vacuum (UHV) with sub-nanometer thickness control accuracy, we choose magnetron sputtering as the deposition method. Through careful adjustment of the target component and systematical study of the deposition condition, ultra-thin VO$_2$ films have been successfully prepared on different substrates in vacuum at room temperature. Fig. 1a shows the XRD results of 2-nm-thick VO$_2$ film grown on SiO$_2$/Si substrates. The red lines give the standard XRD pattern of VO$_2^{48}$, while the broad peak indicates an amorphous feature of the film. Further reducing the thickness of VO$_2$ would make the peak disappear owing to the weakened diffraction intensity, which has also been observed in single crystal samples. XPS measurement was also applied to check the valence states of vanadium. As shown in Fig. 1b, the proportion of VO$_2$ reaches more than 89.3%, which demonstrates the relatively pure composition of the film. To directly check the phase-change feature of the VO$_2$ film, the resistance of the vertical tunnel junction device fabricated based on Au/VO$_2$ (2 nm)/Au multilayers is measured at different temperatures. The I-V curves as the temperature rises have been shown in Fig. 1c, from which an evolution from tunneling contact to transparent contact can be detected. The results indicate that the resistance of VO$_2$ spacer layer experiences a significant drop after heating, i.e., MIT happens. Fig. 1d gives the resistance change ratio (calculated as the resistance divided by the minimum value) versus temperature with measuring current of 10 nA for the 2 nm sample and a 40 nm single crystal film sample. It’s noteworthy that the phase-change of the nanometer VO$_2$ takes place at a temperature around 310K. Such a value is much lower than that of the thicker one, which can be a result of strain effect. According to some reports, the MIT feature of ultra-thin VO$_2$ samples is usually suppressed due to impurity diffusions from the substrate$^{49}$. Nevertheless, our room temperature UHV deposition condition may restrain this negative effect. Although potential factors, like the amorphous nature and inevitable defects, still affect the MIT amplitude (~20 times resistance change), the hysteresis phenomenon proves the existence of the phase-change in the ultra-thin film.

The appreciable MIT effect, good-compatibility of the substrates, as well as UHV room temperature deposition condition of the ultra-thin VO$_2$ film, guarantee the
possibility of fabricating VO₂-related magnetic multilayer systems. To investigate the
effect of phase-change modulation on IEC, we prepared a series of
[Pt/Co]₂/VO₂/[Co/Pt]₂ heterostructures on SiO₂/Si substrates (see Fig. 2a for schematic
diagram of the multilayers). VO₂ with different thicknesses are used as the spacer layers
and Co/Pt systems are chosen as the perpendicular ferromagnetic layers in these
samples. The interface quality has been checked by high resolution transmission
electron microscopy (HRTEM), by which the thickness of the spacer layers has also
been respectively calibrated as 0.76, 1.48, 1.83 and 2.26 nm (see Supplementary Fig.
S1). Take the multilayer system with 2.26-nm-thick VO₂ being spacer layer as an
example (Fig. 2b), distinct interfaces and good continuity between the spacer and the
ferromagnetic layers can be observed. Inhomogeneous regions with microcrystalline
morphology can also be observed within the VO₂ layer, which may be caused by the
fluctuation of sputtering energy and non-annealing process. These inevitable defects
also explain the sluggish MIT curve and non-uniform phase change process mentioned
in the following discussion. Fig. 2c shows the energy dispersive X-ray spectroscopy
(EDX) line scan results of elements V, Co, and Pt. Different elements distribution across
the multilayered film has been checked, which is consistent with the layer structure.
The reason for the overlapping of the two Co peaks that connected to VO₂ layer is
called by the limitation of the electron beam spot (whose size is about 5nm). To further
determine the distribution of chemical elements in the multilayer system, EDX mapping
of V, Pt and Co are also performed. Fig. 2d-2f respectively present the mapping results
of different elements, which further verify the good quality of both spacer and
ferromagnetic layers.

Fig. 2g gives the schematic diagram of the modulation principle. In the VO₂-
related magnetic multilayer system, the magnetic electrons in top and bottom layers are
coupled indirectly through VO₂ whose Fermi surface drops on V-3d orbital. As the
space layer is insulating at room temperature and conducting at high temperature,
according to RKKY theory, the coupling strength or even coupling type would be
changed when the density of states near Fermi surface is enhanced. In the following
study of this work, we find that the coupling is AFM at room temperature, and evolves
into FM after VO$_2$ MIT happens. Detailed analysis about the electronic structure change will be discussed later in this article.

**Phase-Change induced IEC regulation**

The IEC coupling change of the phase-change magnetic multilayer systems is first investigated by magnetic property measurements. Vibrating sample magnetometer (VSM) and polar magneto-optic Kerr effect (p-MOKE) are used to characterize the [Pt/Co]$_2$/VO$_2$/[Co/Pt]$_2$ samples. As shown in Fig. 3a, obvious anisotropy is detected in the sample with 0.76-nm-thick VO$_2$ spacer layer. Similar PMA property can be found in all the other films (see Supplementary Fig. S2). The magnetization shows two reorientation process with out-of-plane magnetic field applied, which indicates that strong ferromagnetic coupling within both top and bottom Co/Pt bilayers. Thus, these bilayers can be assumed as two single ferromagnetic unites when the IEC modulation is investigated.

As illustrated in Fig. 3b-3f, hysteresis loops are also measured by p-MOKE before (300K, Monoclinic state) and after (360K, Rutile state) phase-change happens for samples with different thicknesses of VO$_2$. Interestingly, the two magnetization flips merge into one after the MIT happens in the results of 0.76, 1.48, 1.83 and 2.26-nm-thick VO$_2$ samples. This simultaneous switching phenomenon, implying a strong FM coupling between top and bottom Co/Pt bilayers through the metallic VO$_2$, gives a solid evidence that the IEC between magnetic layers has been changed. The experimental results of the control samples (with the structure of [Pt/Co]$_2$/VO$_2$/[Co/Pt]$_2$) show that a coercivity difference between the two magnetic layers exits in the whole process, which further exclude the possibility that this phenomenon is merely caused by the modulation on top or bottom magnetic layer (Supplementary Fig. S3). In contrast, when the thickness of the spacer layer reaches 3.22 nm (Fig. 3f), the two-flip phenomenon maintains even after the phase-change happens, which shows the modulation effect is also restricted by the thickness of the spacer layer. Additionally, the coercivity shrinking values of the two flips are consistent with that of the isolated magnetic layers in the control samples, which indicates a de-coupling state between top and bottom magnetic layers in this sample. These results confirm the possibility of
realizing the modulation of IEC via the MIT of VO$_2$, while leave more details to be investigated.

To further understand the phase-change induced IEC regulation effect, the first priority is to distinguish the magnetic coupling state at room temperature for the samples that regulation can be observed. Taking the sample with 0.76-nm-thick VO$_2$ as an example, as the coercive field of the first flip is fairly small (Fig. 4a), high-accuracy VSM with built-in Hall probe (accuracy reaches 0.01 Oe) is applied to collect the information of the minor loop. As shown in the inset of Fig. 4a, a negative exchange bias field $H_{ex}$ (~0.35 Oe) can be detected in multiple minor loop measurements, which indicates a weak AFM coupling at room temperature. Considering the insulator state of the spacer layer, the small value is reasonable if such a coupling truly exists. To further confirm this result, the magnetic domain switching behavior around the field region of minor loop are also investigated as shown in Fig. 4b. The results verify the domain switch fields of the top magnetic layer drop on -0.2 Oe and 1.88 Oe. Meanwhile, similar minor loop measurements are applied to samples with various thicknesses of VO$_2$ (see Supplementary Fig. S4), whose results suggest that the samples with VO$_2$ of 1.48, 1.83 and 2.26 nm also show weak AFM coupling ($H_{ex}$=0.64, 0.30, 0.15 Oe, respectively) while the sample with 3.22 nm VO$_2$ shows a decoupling feature ($H_{ex}$≈0 Oe).

To obtain more details of the regulation effect, we then focus on the dynamic changing process of IEC effect. Fig. 4c shows the hysteresis loops of samples under different temperatures. We find that the flip of the top ferromagnetic layer gradually becomes smoother and eventually coupled with the bottom ferromagnetic layer in all the four samples. Interestingly, the critical IEC type change temperature shows obvious difference in them. For the thinner two samples, the FM coupling change happens above room temperature (around 330 and 325 K), while for the thicker two it happens around 300 K. Considering all the samples are deposited at room temperature with same growth parameters, one possible explanation is that the interfacial strain affects the MIT temperature of VO$_2$. Similar strain induced transition temperature change has been extensively explored in single crystal VO$_2$ samples, while happens in thicker region. Considering the inhomogeneous feature of VO$_2$ in our samples, it is hard to give precise
analysis of the strain effect in the interfacial areas.

To make sure that the IEC modulation is phase change related, the loop evolution process during heating-up and cooling-down is investigated. Considering the phase-change of VO$_2$ exhibits obvious hysteresis characterization (Fig. 1d), it is reasonable to believe a phase-change induced IEC modulation should have the same feature. Therefore, we measured the hysteresis loops of the 0.76-nm-thick VO$_2$ sample at 305 and 315 K to check the relevance between them. As shown in Fig. 4d, the flip sharpness of the results shows clear difference, which proves the hysteresis speculation and further verifies that the coupling change is indeed caused by phase-change of VO$_2$.

**Discussion**

Based on the obtained results of [Pt/Co]$_2$/VO$_2$/[Co/Pt]$_2$ multilayer samples, the exchange bias field $H_{ex}$ between two ferromagnetic layers can be derived from the shift of the flip edges referring to control samples. For convenience, we use the flip edge of the bottom layer to calculate the value of $H_{ex}$. As plotted in Fig. 5a, the negative $H_{ex}$ values represent AFM coupling and positive ones represent FM coupling. Samples with various thicknesses of VO$_2$ all demonstrate a transition from weak AFM coupling at lower temperature (with insulating VO$_2$) to stronger FM coupling at higher temperature (with metallic VO$_2$). For each of the four samples, a critical temperature exists, specifying the coupling changing from AFM to FM.

As mentioned above, one possible explanation for the observed coupling change is caused by the electronic structure variation of VO$_2$ from insulation to metallicity which enhances the coupling between two ferromagnetic layers. To explain the mechanism behind it, the electronic structure and Fermi surface change of spacer layer should be taken into consideration. Abrikosov$^{50}$, as well as Narita and Kasuya$^{51,52}$, have studied the RKKY interaction mediated by valence conduction band excitations in intrinsic semiconductors in the 1980s. Later Litvinov and Dugaev$^{53}$ studied the one originated from impurity-valence band excitations in Mn-doped GaAs. As put forward by Goodenough$^{54}$ and elucidated in subsequent studies$^{55}$, d electrons participating in a Peierl-like phase-change exist a large spectral weight transfer from $\pi^*$ (d$_{xy}$) into the
valence $d_\gamma$ ($d_{xy, xz}$) orbitals. For the MIT of VO$_2$ induced by temperature change in our experiments, it means that more spin related conducting electrons would participate in the RKKY effect, and contribute to an enhanced coupling effect (Fig. 5a). In fact, there were calculation results based on Co-doped TiO$_2$/VO$_2$ diluted magnetic semiconductor multilayers reflecting that FM-AFM coupling change may happen accompanied by the phase-change of VO$_2$. The reason that coupling oscillation in VO$_2$ metallic state has not been observed, is probably caused by the restricted range of VO$_2$ thickness. As our film structure and spin orientation are much more complicated comparing to an ideal model, further calculation and simulations are desired to reveal more detailed physics in it.

Besides the transition from AFM to FM, the loop shape variation in the phase-change process also provides some clue to understand the dynamic spin evolution process. Generally speaking, if the phase-change of VO$_2$ is uniform across the whole spacer layer, the enhanced coupling would push the magnetization flip away from zero field, before the coupling changes into FM, as illustrated in Fig. 5b. While, for the evolution process in our results, the coupling varies accompanied by a smoothing instead of pushing behavior of the first magnetization flip. This phenomenon may be related to the inhomogeneous feature of the ultra-thin VO$_2$ film mentioned above, and can be explained by a non-uniform phase-change model. The existence of amorphous and microcrystalline VO$_2$ will result in some conduction boundaries around the inhomogeneous region during the MIT$^{56,57}$. Thus, the IEC strength increasement is also ununiform in the conducting and insulting areas. The smooth flip is the macroscopic presentation of the non-uniform switching behavior.

To check this speculation, Kerr microscope is then used to observe the domain switching under different temperature. As illustrated in Fig. 5c, a magnetic field of 2.6 Oe is applied to the film with 0.76-nm-thick VO$_2$ to induce a flipping critical state at room temperature. With temperature increase, the magnetic domain first evolves into maze morphology at 310K, then finely broken and becomes more smaller domains which beyond the resolution of the microscope at 315K. With the in-plane loop measurement under different temperature excluding the possibility of anisotropy
change (Supplementary Fig. S5), it is reasonable to believe that this domain type change is related to the non-uniform phase change of VO$_2$ which provides more nucleation points for spin switch. The domain evolution video can be found in Video S1.

In conclusion, we have succeeded in preparing the ultra-thin VO$_2$ film with appreciable metal-to-insulator transition feature by ultrahigh-vacuum magnetron-sputtering at room temperature. This nanometer-thick VO$_2$ has been adopted as a spacer layer to regulate the interlayer exchange coupling in a [Pt/Co]$_2$/VO$_2$/[Co/Pt]$_2$ system, whose coupling strength and type can be modulated reversibly and repeatably through the phase-change of VO$_2$. Further analyses indicate that change of valence band and shift of Fermi surface may answer for the interlayer exchange coupling change. The non-uniform phase-change induced local magnetic domain switching is used to explain the dynamic spin evolution during the transition process. The current result, which combines spintronics with phase-change electronics, offers a new strategy to regulate interlayer exchange coupling, and provides great possibilities for developing new types of electronic devices.
Methods

Film deposition and device fabrication

The Au/VO$_2$/Au and [Pt/Co]$_2$/VO$_2$/[Co/Pt]$_2$ multilayer systems were both grown on SiO$_2$/Si substrates by magnetron-sputtering at room temperature under high vacuum environment. Stoichiometric target was used to deposit VO$_2$ film during the experiments. The tunnel junctions were patterned by optical lithography (Micro Writer ML Baby, Durham Magneto Optics) followed by argon ion-beam etching into bottom electrodes and nanopillars. Then the samples were fully covered with SiO$_2$ for insulation. After the lift-off procedure, via holes were made over the bottom electrodes. Both the bottom electrodes and tunnel junctions were then connected to 90 nm Ti/Au electrodes to allow electrical contact for measurement using e-beam evaporation.

Characterization and measurement

The magnetic properties were measured by MOKE (NanoMOKE3, Durham Magneto optics ltd) with self-made heat source and VSM (7400, Lakeshore) at different temperatures. The Au/VO$_2$/Au tunnel junction were measured by normal 4-terminal methods with Keithley 6221 and Keithley 2182 sourcing and measuring units, respectively. The HRTEM was performed by Talos F200X. XPS results were measured by Rigaku D/max-2500PC and XRD measurement was performed by Delta-X.
