We show that any commutative rationally ruled surface with a choice of anticanonical curve admits a 1-parameter family of noncommutative deformations parametrized by the Jacobian of the anticanonical curve, and show that many standard facts from commutative geometry (blowups commute, Quot schemes are projective, etc.) carry over. The key new tool in studying these deformations is a relatively simple description of their derived categories and the relevant t-structures; this also allows us to establish nontrivial derived equivalences for deformations of elliptic surfaces. We also establish that the category of line bundles (suitably defined) on such a surface has a faithful representation in which the morphisms are difference or differential operators, and thus find that difference/differential equations can be viewed as sheaves on such surfaces. In particular, we find that many moduli spaces of sheaves on such surfaces have natural interpretations as moduli spaces of equations with (partially) specified singularities, and in particular find that the “isomonodromy” interpretation of discrete Painlevé equations and their generalizations has a natural geometric interpretation (twisting sheaves by line bundles).
1 Introduction

The present work had its origin in the discovery of a connection between noncommutative geometry and discrete Painlevé equations: the latter can be interpreted as isomorphisms between moduli spaces coming from the former (see [34] for the case of sheaves on elliptic noncommutative planes). Since the continuous Painlevé equations and many of their discrete generalizations also have interpretations in terms of moduli spaces of differential (or difference) equations, this suggested both that there should be a connection between equations and noncommutative geometry and, since moduli spaces of sheaves on commutative surfaces are well-understood, that the latter could be a useful tool for understanding the former. This was carried out in the least degenerate level (relating noncommutative rational surfaces with elliptic anticanonical curve to symmetric elliptic difference equations) in [42], where it was shown that one could construct noncommutative Hirzebruch surfaces and their blowups via difference operators on the (assumed smooth) anticanonical curve. (More precisely, the category of line bundles on the generic commutative rational surface with chosen anticanonical curve has a flat extension to any rational surface with smooth anticanonical curve, and that category has a faithful representation in difference operators.) A major purpose of the present note is to extend this construction to cases in which the anticanonical curve becomes singular.

One side effect of developing the elliptic theory is that, in addition to the desired applications to difference equations and their moduli, the construction also led to new results in noncommutative geometry. For instance, it is a standard fact of commutative geometry that blowups in distinct points commute. The analogous fact was not known in the noncommutative setting, but in the elliptic case follows from the results of [42]. Thus another major purpose of the present note is to establish similar isomorphisms in general; not just commutativity of blowups, but other standard isomorphisms from the birational geometry of commutative surfaces (e.g., that a one-point blowup of \( \mathbb{P}^2 \) is a Hirzebruch surface, and that \( \mathbb{P}^1 \times \mathbb{P}^1 \) admits two different rulings).

One difficulty in generalizing the results from the elliptic case is that it relies on a very strong version of flatness: for any two line bundles on the surface, there is a natural subspace (generically everything) of the Hom space with dimension independent of the surface. Unfortunately, already in the commutative case, this construction fails (per [41]) if the surface contains a smooth rational curve of self-intersection \( < -2 \). Although this may not seem like a very significant restriction, this means the construction fails for any anticanonical surface with non-integral anticanonical curve of negative self-intersection. Although the surviving surfaces are quite interesting, the excluded cases include most of the generalizations of Painlevé equations in the literature. (Indeed, any continuous such generalization relates to a surface with nonreduced anticanonical curve!)

One could attempt to get around this by only establishing flatness for suitably ample divisor classes. This leads to other difficulties, however: there are already quite a few cases that needed to be dealt with in the elliptic case, and these would only get more complicated in the presence of \( \mathbb{P}^2 \)-curves or worse. Moreover, the arguments there required a number of statements about global sections of line bundles on the anticanonical curve, which naturally become much more delicate when the anticanonical curve becomes singular (or, worse, nonreduced). This could presumably be dealt with using the fact that a singular anticanonical curve is built out of smooth rational curves, but this would again risk combinatorial explosion, as well as introducing additional difficulties when dealing with families.

With this in mind, we take a rather different approach in the present work. The key insight is
that in the process of obtaining certain derived equivalences, [42] showed that the derived categories of the surfaces considered there had particularly nice descriptions: starting with a *commutative* projective rational surface, take the semiorthogonal decomposition arising from the fact that the structure sheaf is exceptional, and then deform the way in which the two subcategories are glued. It follows from this description that any isomorphism of commutative surfaces extends to a family of derived equivalences between corresponding noncommutative surfaces. Thus to show that the noncommutative surfaces are isomorphic, it suffices to show that these derived equivalences respect the $t$-structures. As stated, this is somewhat difficult to carry out, since the $t$-structure is not easily described when the derived category is viewed in this form. However, it turns out that each of the main constructions we need to consider (noncommutative planes, noncommutative ruled surfaces, and noncommutative blowups) comes with an inductive description of both the derived category and the $t$-structure that is simple enough to enable one to show exactness. This also has a number of nice consequences; e.g., one can read off the Grothendieck group, the Mukai pairing, and the existence of a Serre functor from the description of the derived category, and it is easily seen from the description of the $t$-structure that the Serre functor is exact up to a shift (the analogue of being Gorenstein). Moreover, having a nice description of the derived category makes it particularly simple to establish interesting derived equivalences (extending the derived autoequivalences of elliptic surfaces), and to deal with fairly general families.

We should note here that what we mean by a noncommutative scheme in general is actually an abelian category with marked object, corresponding to the category of quasicoherent sheaves with choice of structure sheaf. In particular, our description via $t$-structures on triangulated categories actually gives a new (and simpler!) construction of the noncommutative surfaces we are considering. Unfortunately, we as yet have been unable to show that the result is a $t$-structure, or that the triangulated category is the derived category of its heart, without reference to some more direct construction of the abelian category.

For planes and blowups, the requisite facts about the derived category have already been established in the literature, but we will need to establish them for ruled surfaces below. Moreover, in order to further the connection to special functions, we need to establish the connection between noncommutative ruled surfaces and difference equations. Another desideratum is to understand the “semincommutative” case; i.e., when the noncommutative surface can be represented as a finite sheaf of algebras on a commutative projective surface. It is somewhat difficult to work with the original construction of [53] for these purposes, and thus we introduce a new approach inspired by the construction of [40] for the elliptic case. The idea is to construct a Morita equivalent description of the underlying “algebra” as a variation of a twisted group algebra over the infinite dihedral group; this not only enables us to compute the center when the surface is semicommutative, but to show that in that case, the algebra is a maximal order in a central simple algebra on a related commutative ruled surface. (We also establish that this property survives birational transformations à la van den Bergh [51].)

One complication is that van den Bergh’s original construction of noncommutative $\mathbb{P}^1$-bundles involves two base schemes rather than only one. This makes it quite complicated to classify such surfaces in general, but it turns out that there is a very useful fact: if the two curves are not isomorphic (more precisely, if the corresponding curve on their product is not algebraically equivalent to twice the graph of an isomorphism), then the center is large! Thus the most complicated components of the moduli stack of noncommutative ruled surfaces as constructed in [53] consist entirely of maximal orders on commutative ruled surfaces, rendering most of the more basic questions trivial. The remaining components necessarily contain *commutative* ruled surfaces, and (with one mild exception in characteristic 2) are in fact naturally fibered over the corresponding stacks of commutative ruled surfaces. This leads us to define the result of van den Bergh’s construction
(over curves) as a “quasi-ruled” surface, reserving the word “ruled” to refer to those surfaces that can be deformed to truly noncommutative surfaces.

Another complication is that, although van den Bergh gave a construction of blowups of points on noncommutative surfaces (subject to some technical assumptions that need to be established in the cases of interest), there is not as yet a satisfying discussion of blowdowns. In particular, there is no analogue of Castelnuovo’s criterion for when a surface can be blown down. However, it turns out that when the surface in question is an iterated blowup of a quasi-ruled surface (or noncommutative plane), then the isomorphisms mentioned above can make any “-1-curve” (suitably defined) into the exceptional curve of the last blowup in one of its (possibly many) descriptions as such an iterated blowup. One thus finds that if some iterated blowup of a noncommutative surface is “rationally quasi-ruled”, then the surface is itself either rationally quasi-ruled or a noncommutative plane. (Note that this means that when considering how birational transformations affect the semicommutative case, we need only consider blowups...)

In [15], Chan and Nyman proposed a definition of “proper” noncommutative surfaces and established that noncommutative ruled surfaces satisfied their definition. It should not be too surprising, therefore, that we can show that their axioms are satisfied by any rationally quasi-ruled surface. In fact, some of the axioms hold in stronger forms. The most significant strengthening involves Quot schemes: we show that given any coherent sheaf on a Noetherian family of such surfaces, the corresponding Quot scheme (classifying quotients with specified Hilbert polynomial) is projective. This is somewhat tricky to establish, as the usual construction of Quot schemes uses the flattening stratification, which is far more delicate in noncommutative geometry. In fact, although we establish below that the flattening stratification is well-behaved for our surfaces, the proof in general actually requires first showing that the Quot schemes are projective! Luckily, there are approaches ([8, 4]) to controlling the flattening stratification over sufficiently nice (“admissible”) base, and this is good enough (given our understanding of the moduli of noncommutative surfaces) to deal with Quot schemes of powers of the structure sheaf, to which the general case can be reduced.

Since part of the strengthening of the Quot scheme result involves the notion of a Hilbert polynomial, we need an understanding of ample divisors. Although it would suffice for such purposes to restrict to any reasonable set of such divisors, we in fact establish below that ample divisors behave in much the same way as in the commutative case. In particular, we show that for a suitable notion of an “effective” divisor, the ample divisors are precisely those that lie in the interior of the corresponding “nef” cone. Here we make significant use of the above dichotomy: for strictly (rationally) quasi-ruled surfaces, this follows immediately from the corresponding statement on the center, while for (rationally) ruled surfaces, we need to argue directly. Luckily, it turns out that the latter case is actually simpler in a number of respects, in that we can give a relatively explicit combinatorial description of the effective and nef cones, which is not available in the quasi-ruled case. In fact, in the rational case, we can give an essentially combinatorial algorithm for computing the Betti numbers of $R \text{Hom}(L, L')$ for any pair of “line bundles” (i.e., the unique sheaves that arise by deforming line bundles from the commutative case).

Since the motivating objective was to understand moduli spaces of equations by relating them to moduli spaces of sheaves, we still need to understand the latter. This could, of course, be asked in several different ways. If one only asks for an algebraic space, then the moduli spaces are well-behaved for any “simple” sheaf (i.e., with no non-scalar endomorphisms), and in fact for simple objects in the derived category in general. Moreover, at least for sheaves, we establish that the moduli space has a natural Poisson structure with well-behaved (and modular) symplectic leaves. (More generally, there is always a natural biderivation with nice weakly symplectic (i.e., with nondegenerate 2-forms) leaves; what remains to be established is the Jacobi identity.)
argument here involves reducing to the case of “reflexive” (relative to a suitable contravariant derived equivalence) sheaves on a semicommutative surface, where it follows from a more general fact (of independent interest) about Poisson structures on moduli spaces of $G$-torsors.

If one wishes the moduli space to be a scheme, the situation is less satisfying: there is an obvious analogue of the semistable moduli space, but we can only show that it is projective when the rank is either 0 or 1. (The latter is particularly interesting, as those moduli spaces are deformations of the Hilbert scheme of points on a commutative surface; we in fact had to control these in order to establish sufficient boundedness to make the Quot scheme construction work.) Luckily, the rank 0 case turns out to be precisely the case of greatest interest in the application to equations, and allows us to establish that there is indeed a quasi-projective Poisson moduli space classifying difference/differential equations. Moreover, we show that the symplectic leaves are not only naturally described in terms of noncommutative geometry, but in terms of equations: they control the singularities of the equation.

Note that although the applications to special functions are via noncommutative surfaces over $\mathbb{C}$, the theory is developed in much greater generality: most results apply either over algebraically closed fields of arbitrary characteristic or over general (usually Noetherian) base schemes, with non-closed fields being viewed as a special case of the latter. Note that several results (in particular, the Poisson structure on the moduli space of sheaves and the existence of irreducible 1-dimensional sheaves with specified invariants) are proved below by reduction to the case of semicommutative surfaces. In particular, it turns out that even if one were only interested in the characteristic 0 instances of those results, one would still need to consider the finite characteristic case, since a higher genus noncommutative ruled surface is semicommutative precisely when its field of definition has finite characteristic.

The plan of the paper is as follows. In section 2, we give the “double affine Hecke algebra” construction of noncommutative quasi-ruled surfaces, and show that the corresponding “spherical” algebra essentially agrees with van den Bergh’s construction. In section 3, we consider the semi-commutative case in detail, showing that when a certain automorphism has finite order, then the noncommutative quasi-ruled surface is a maximal order in a central simple algebra on a commutative ruled surface, as well as showing that this property survives blowing up.

Section 4 begins the discussion of derived categories, showing that the well-known semiorthogonal decomposition of commutative ruled surfaces survives to the noncommutative case; it also recalls corresponding semiorthogonal decompositions for the other two constructions, and describes in each case how to obtain the $t$-structure, and how the various isomorphisms from birational geometry extend as derived equivalences. (This section also sketches the proofs that these equivalences are exact, with details in some cases left to section 8.) Section 5 discusses some additional derived equivalences, both deformations of autoequivalences of elliptic surfaces and an analogue of the usual Cohen-Macaulay duality of commutative smooth projective schemes. Section 6 considers families of surfaces, both in a relatively naïve sense (families described as explicit iterated blowups) and in a somewhat more sophisticated version (those which are étale-locally expressible as iterated blowups).

Section 7 then turns to the underlying abelian category, with an aim towards establishing most of the Chan-Nyman axioms, most notably that there is a well-behaved notion of the “dimension” of a sheaf; in the process, it also studies the Mukai pairing on the Grothendieck group and uses it to establish a reasonable notion of (first) Chern class. Section 8 uses this control of Chern classes to establish that the derived equivalences constructed in section 4 preserve the $t$-structure (by giving an alternate description of the $t$-structure which is clearly preserved and showing that it agrees with the original description). This section in addition shows that an exceptional sheaf with no cohomology can be blown down iff its Chern class looks like the class of a $-1$-curve, and if so,
the blowdown is again a noncommutative surface of the type we are considering. Section 9 defines effective divisors (Chern classes of rank 0 sheaves) and establishes sufficient conditions for one “line bundle” to be acyclically globally generated by another; this is then used to show that any divisor in the interior of the nef cone satisfies all the properties one might wish of an ample divisor.

Section 10 turns to moduli problems, showing that coherent sheaves on Noetherian families are globally bounded, and using this to show that Quot schemes are projective. Part of the argument requires controlling the invariants of globally generated sheaves, which in turn requires controlling subsheaves of the structure sheaf; as a result, the proof for Quot schemes includes most of a proof that moduli spaces of torsion-free sheaves of rank 1 are projective, also included in this section.

Section 11 considers more general moduli problems, not just of sheaves, but of objects in the derived category, showing that the moduli space of “simple” objects is an algebraic space with a natural bivector, that the symplectic leaves are not only algebraic but (modulo one case which may be empty!) smooth, and that the Jacobi identity holds on the open subspace classifying sheaves. This section also discusses the relatively minimal changes needed to the arguments of [42] to extend the results of that paper on semistable moduli spaces to more general cases.

Section 12 discusses applications of the above results to moduli spaces of difference and differential equations. In particular, the discussion from [11] of how the structure of the anticanonical curve relates to singularities is shown to hold in the noncommutative case, so that in combination with the results on moduli spaces of sheaves, one finds that any moduli space of difference or differential equations with specified singularities is a smooth quasiprojective scheme. Moreover, the noncommutative analogue of twisting by a line bundle extends to isomorphisms between such moduli spaces that act as isomonodromy (or gauge) transformations on the equations. In particular, one recovers all of the discrete Painlevé equations in Sakai’s hierarchy [45] in this way. (For continuous isomonodromy deformations, the situation is not entirely satisfactory: it is shown that one has the expected number of such deformations, and that they survive the various isomorphisms coming from birational geometry, but a geometric interpretation is still lacking.) In addition, it is shown that one can use one of the derived equivalences of section 5 to construct many other such interpretations of discrete Painlevé equations: for any point \( d/r \in \mathbb{P}^1(\mathbb{Q}) \) and any discrete Painlevé equation, there is an isomonodromy interpretation in terms of (discrete) connections on a vector bundle of rank \( 2r \) and degree \( d \). This section also discusses how certain constructions on equations (e.g., viewing a \( q \)-difference equation as a \( q^r \)-difference equation) suggest that there should be related morphisms of noncommutative surfaces, as well as a theory of difference equations for structure groups other than \( \text{GL}_n \).

Finally, in an appendix, we consider, both due to direct interest and as an example of the sort of combinatorial explosion that justifies the derived category approach, the explicit isomorphisms between algebras of difference/differential operators that arise from the fact that \( \mathbb{P}^1 \times \mathbb{P}^1 \) has two distinct rulings. In the most degenerate case, this is the quite familiar (Fourier!) automorphism of the Weyl algebra that swaps multiplication and differentiation, and the more general versions are qualitatively similar (interchanging certain multiplication and difference/differential operators). We thus in this way obtain 16 different generalizations of the Fourier transform, which in addition to several known cases (Fourier, Mellin and its inverse, middle convolution) include a number of less familiar instances (e.g., a transformation between nonsymmetric \( q \)-difference equations and symmetric \( q \)-difference equations).

**Acknowledgements.** The author would like to thank D. Chan for some helpful discussion about orders on surfaces, B. Pym for helpful discussions about derived stacks and Poisson structures, and A. Nakamura for pointing out some interesting examples of equations with non-GL structure group. This work was partially supported by a grant from the National Science Foundation, DMS-1500806.
2 Noncommutative quasi-ruled surfaces

Among the noncommutative projective surfaces we consider, the analogues of ruled surfaces are particularly fundamental; every surface we consider will be obtainable from such a surface via a sequence of blowups and blowdowns. The basic construction is due to Van den Bergh [53], but it will be helpful to give an alternate construction. In particular, we expect from [41, 42] that there should be a relation between sheaves on such surfaces and difference or differential equations, and thus would like to have a construction in which that relation is visible.

Since the fundamental object associated to a noncommutative projective surface is its category of coherent sheaves, there is a great deal of freedom in how we can obtain such a surface. For instance, if \( X \) is a commutative projective scheme with ample bundle \( O_X(1) \), then for any vector bundle \( V \) on \( X \), the (noncommutative) graded algebra \( \bigoplus_d \text{Hom}(V, V(d)) \) has the same category of graded modules as \( \bigoplus_d \Gamma(O_X(d)) \), and the same subcategory of “torsion” modules, and thus gives rise to the same category of coherent sheaves. Our first construction of noncommutative surfaces will be similarly Morita equivalent to Van den Bergh’s construction.

With this in mind, we begin by considering a special case of this construction. Let \( Y/S \) be a scheme and \( \pi: X \to Y \) a finite flat morphism of degree 2 such that \( \pi_* O_X \) is locally free. Then for any invertible sheaf \( L \) on \( X \), \( \pi_* L \) is a vector bundle of rank 2 on \( Y \), and thus we obtain an \( O_Y \)-algebra \( A_{L, \pi} := \text{End}_Y(\pi_* L) \).

This is Morita equivalent to \( O_Y \), with an explicit equivalence \( O_Y \text{-mod} \to A_{L, \pi} \text{-mod} \) given by

\[
M \mapsto M \otimes_{O_Y} \pi_* L,
\]

and the inverse given by

\[
M \mapsto \text{Hom}_{A_{L, \pi}}(\pi_* L, M).
\]

Moreover, since this algebra contains \( \pi_* O_X \), we may interpret it as a \( \pi_* O_X \)-bimodule, which we abbreviate to “\( O_X \)-bimodule” (as justified below).

**Lemma 2.1.** There are canonical isomorphisms \( A_{L \otimes O_X(\pi^* L')}, \pi \cong A_{L, \pi} \) for any line bundle \( L' \) on \( Y \), as well as a canonical involution \( A_{L, \pi}^{\text{op}} \cong A_{L, \pi} \).

**Proof.** For the first claim, we have

\[
\text{End}_Y(\pi_* (L \otimes O_X(\pi^* L'))) \cong \text{End}_Y(\pi_* (\pi^* O_Y \otimes L')) \cong \text{End}_Y(\pi_* (\pi^* L)),
\]

while for the second claim, we observe that for any rank 2 vector bundle \( V \) on \( Y \), we have isomorphisms

\[
\text{End}_Y(V)^{\text{op}} \cong \text{End}_Y(\text{Hom}(V, O_Y)) \cong \text{End}_Y(V \otimes \det(V)^{-1}) \cong \text{End}_Y(V),
\]

which in the case of the trivial bundle is the (adjoint) involution

\[
\left(\begin{array}{cc} a & b \\ c & d \end{array}\right) \mapsto \left(\begin{array}{cc} d & -b \\ -c & a \end{array}\right),
\]

so is an involution in general. \( \square \)

**Remark.** It is worth noting that although the algebra \( A_{L, \pi} \) only depends on \( L \) modulo \( \text{Pic}(Y) \), the explicit Morita equivalence depends on \( L \).

**Proposition 2.2.** There is a natural isomorphism \( \pi^! \cong \pi^* (\bigotimes \det(\pi_* O_X)^{-1}) \).
Proof. This reduces to showing that there is a natural isomorphism
\[ \text{Hom}_Y(\pi_*\mathcal{O}_X, N) \cong \pi_* \text{Hom}_X(\mathcal{O}_X, \pi^*(N \otimes_{\mathcal{O}_Y} \det(\pi_*\mathcal{O}_X)^{-1})), \]
which in turn reduces to the case \( N = \mathcal{O}_Y \), where it becomes
\[ \text{Hom}_Y(\pi_*\mathcal{O}_X, \mathcal{O}_Y) \cong \pi_*\mathcal{O}_X \otimes \det(\pi_*\mathcal{O}_X)^{-1}. \]

\[ \square \]

Remark. When \( Y \) is smooth and \( X \) is integral, this is essentially [16, Prop. 0.1.3].

There is an alternate form for the inverse Morita equivalence.

**Proposition 2.3.** The functors \( M \mapsto \pi_*\mathcal{L} \otimes_{\mathcal{O}_Y} M \) and \( M \mapsto \pi_*(\mathcal{L}^{-1} \otimes \pi^!\mathcal{O}_Y) \otimes_{\mathcal{A}_{\mathcal{L}, \pi}} M \) are inverse equivalences between \( \mathcal{O}_Y\text{-mod} \) and \( \mathcal{A}_{\mathcal{L}, \pi}\text{-mod} \).

Proof. This reduces to showing that
\[ \pi_*\mathcal{L} \otimes_{\mathcal{O}_Y} \pi_*(\mathcal{L}^{-1} \otimes \pi^!\mathcal{O}_Y) \cong \mathcal{A}_{\mathcal{L}, \pi}, \]
which follows from the (bimodule!) isomorphism
\[ \pi_*(\mathcal{L}^{-1} \otimes \pi^!\mathcal{O}_Y) \cong \text{Hom}_Y(\pi_*\mathcal{L}, \mathcal{O}_Y). \]

\[ \square \]

The adjoint involution can be written the form \( x \mapsto \text{Tr}(x) - x \), and thus in particular restricts to an involution \( s : \pi_*\mathcal{O}_X \to \pi_*\mathcal{O}_X \) of the same form. (This involution is nontrivial except when \( \text{char}(k) = 2 \) and either \( X \) is nonreduced or \( \pi \) is inseparable.) Given a coherent sheaf \( M \) on \( X \), let \( M_s \) denote the \( \mathcal{O}_X \)-bimodule with multiplication \( r_1mr_2 = r_1s(r_2)m \); we will also conflate \( \mathcal{O}_X\)-modules on \( X \) with the corresponding bimodules. (Recall that for the moment, an \( \mathcal{O}_X \)-bimodule means a \( \pi_*\mathcal{O}_X \)-bimodule on \( \mathcal{O}_Y \).) And as we have already mentioned, \( \mathcal{A}_{\mathcal{L}, \pi} \) has a natural \( \mathcal{O}_X \)-bimodule structure.

**Proposition 2.4.** There is a natural short exact sequence of \( \mathcal{O}_X \)-bimodules
\[ 0 \to \mathcal{O}_X \to \mathcal{A}_{\mathcal{L}, \pi} \to \mathcal{L} \otimes_{\mathcal{O}_X} (\pi^!\mathcal{O}_Y)s \otimes_{\mathcal{O}_X} \mathcal{L}^{-1} \to 0 \]

\[ (2.11) \]

Proof. Since \( \mathcal{A}_{\mathcal{L}, \pi} \cong \mathcal{L} \otimes_{\mathcal{O}_X} \mathcal{A}_{\mathcal{O}_X, \pi} \otimes_{\mathcal{O}_X} \mathcal{L}^{-1}, \) it suffices to prove this in the case \( \mathcal{L} = \mathcal{O}_X \). If we forget about the right module structure, then not only do we have such an exact sequence, but it splits. Indeed, the natural inclusion \( \mathcal{O}_X \to \mathcal{A}_{\mathcal{O}_X, \pi} \) is naturally split by the evaluate-at-1 map, so it remains to identify the other direct summand (the endomorphisms that annihilate 1) and show that the right action is triangular.

There is a natural short exact sequence
\[ 0 \to \mathcal{O}_Y \to \pi_*\mathcal{O}_X \to \det(\pi_*\mathcal{O}_X) \to 0; \]

\[ (2.12) \]

that the quotient is invertible follows as in [16, §0.1], and can then be identified by comparing determinants. An endomorphism that annihilates 1 annihilates \( \mathcal{O}_Y \) and is thus determined by its action on \( \det(\pi_*\mathcal{O}_X) \), so that we have the left \( \mathcal{O}_X \)-module decomposition
\[ \mathcal{A}_{\mathcal{O}_X, \pi} \cong \mathcal{O}_X \oplus \text{Hom}_Y(\det(\pi_*\mathcal{O}_X), \pi_*\mathcal{O}_X) \cong \mathcal{O}_X \oplus \text{Hom}_Y(\pi_*\mathcal{O}_X, \mathcal{O}_Y) \cong \mathcal{O}_X \oplus \pi^!\mathcal{O}_Y. \]

\[ (2.13) \]

Since the adjoint involution acts as \( x \mapsto \text{Tr}(x) - x \), it is clearly triangular with respect to this decomposition, and thus takes the diagonal left action of \( \mathcal{O}_X \) to a triangular right action. Moreover, the induced action on the quotient is itself induced by the adjoint, or in other words by \( s \).

\[ \square \]
Note that the other (left) direct summand of $\mathcal{A}_{O_X,\pi}$ consists (locally) of s-derivations, i.e. $O_Y$-linear endomorphisms that satisfy

$$\phi(r_1 r_2) = s(r_2)\phi(r_1) + r_1\phi(r_2).$$  \hspace{1cm} (2.14)

If $\pi_\ast O_X$ is actually free over $O_Y$, with generator $\xi$, then the morphism $\nu : a + b\xi \mapsto b$ is such an s-derivation, and any other s-derivation has the form $f \mapsto g\nu(f)$. If $\xi - s(\xi)$ is not a zero divisor, then we can write this in the form

$$\nu(f) = \frac{f - s(f)}{\xi - s(\xi)}. \hspace{1cm} (2.15)$$

The $O_Y$-module it generates is self-adjoint (the adjoint has eigenvalue $-1$) and may be characterized as the space of nilpotent endomorphisms that annihilate $O_Y$, which makes sense even when $O_X$ is only locally free over $O_Y$. This module is locally free of rank 1, and is easily seen to be isomorphic to $\pi^\ast O_Y \cong \pi^\ast \det(\pi_\ast O_X)^{-1}$.

Although it is most natural to view $\mathcal{A}_{\mathcal{L},\pi}$ as a sheaf of $O_Y$-modules, we will need a slightly different perspective coming from the bimodule structure. Indeed, the $\pi_\ast O_X$-bimodule structure on $\mathcal{A}_{\mathcal{L},\pi}$ induces a $\pi_\ast O_X \otimes_{O_Y} \pi_\ast O_X$-module structure, which in turn allows us to interpret it as a coherent sheaf on $X \times_Y X = \text{Spec}(\pi_\ast O_X \otimes_{O_Y} \pi_\ast O_X)$. The embedding $X \times_Y X \to X \times X$ then makes it a coherent sheaf on $X \times X$ supported on the union of the diagonal and the graph of $s$, so finite over either projection. In other words, $\mathcal{A}_{\mathcal{L},\pi}$ is a sheaf bimodule over $X \times X$ (in the sense of [52,7]). Moreover, the algebra structure on $\mathcal{A}_{\mathcal{L},\pi}$ is compatible with this bimodule structure, in that the multiplication induces a morphism

$$\mathcal{A}_{\mathcal{L},\pi} \otimes_X \mathcal{A}_{\mathcal{L},\pi} := \pi_2^\ast (\pi_3^\ast \mathcal{A}_{\mathcal{L},\pi} \otimes_{O_X \times X \times X} \pi_1^\ast \mathcal{A}_{\mathcal{L},\pi}) \to \mathcal{A}_{\mathcal{L},\pi},$$ \hspace{1cm} (2.16)

and thus $\mathcal{A}_{\mathcal{L},\pi}$ is a sheaf algebra. (Indeed, this is immediate from the corresponding fact for the fiber product.)

The Morita equivalences are also naturally expressed in terms of sheaf bimodules; the sheaf $(1 \times \pi)_\ast \mathcal{L}$ is a sheaf bimodule on $X \times Y$, and the action of $\mathcal{A}_{\mathcal{L},\pi}$ induces a morphism

$$\mathcal{A}_{\mathcal{L},\pi} \otimes_X (1 \times \pi)_\ast \mathcal{L} = \pi_2^\ast (\pi_3^\ast \mathcal{A}_{\mathcal{L},\pi} \otimes_{O_X \times X \times Y} \pi_1^\ast (1 \times \pi)_\ast \mathcal{L}) \to (1 \times \pi)_\ast \mathcal{L}$$ \hspace{1cm} (2.17)

making $(1 \times \pi)_\ast \mathcal{L}$ a $(\mathcal{A}_{\mathcal{L},\pi}, O_Y)$-sheaf bimodule. Similarly, there is a $(O_Y, \mathcal{A}_{\mathcal{L},\pi})$-sheaf bimodule given by

$$(\pi \times 1)_\ast (\mathcal{L} \otimes \pi^\ast \det \pi_\ast \mathcal{L}^{-1}),$$ \hspace{1cm} (2.18)

and these induce Morita equivalences.

One caution is that the natural adjoint involution does not in general respect the sheaf bimodule structure, since it acts as $s$ on $O_X$. Luckily, there is a variant that works more generally, at the cost of changing $\mathcal{L}$.

**Proposition 2.5.** There is a natural sheaf algebra isomorphism $\mathcal{A}_{\mathcal{L},\pi}^{op} \cong \mathcal{A}_{\mathcal{L}^{-1},\pi}$.

**Proof.** Consider the composition

$$\pi_\ast \mathcal{L} \otimes_{O_Y} \pi_\ast (\mathcal{L}^{-1}) \to \pi_\ast O_X \to \det(\pi_\ast O_X),$$ \hspace{1cm} (2.19)

where the first map is multiplication and the second is the quotient by the subbundle $O_Y$. The corresponding pairing respects multiplication by $O_X$, and thus will induce a sheaf algebra isomorphism as required so long as it is perfect, i.e., the induced map

$$\pi_\ast \mathcal{L} \to \mathcal{H}om_{O_Y}(\pi_\ast (\mathcal{L}^{-1}), \det(\pi_\ast O_X))$$ \hspace{1cm} (2.20)
is an isomorphism. It suffices to check this locally, so that we may assume \( \mathcal{L} = \mathcal{O}_X \). In that case, the (now symmetric) pairing vanishes on \( \mathcal{O}_Y \otimes \mathcal{O}_Y \), and thus induces a pairing \( \mathcal{O}_Y \otimes \det(\pi_*\mathcal{O}_X) \to \det(\pi_*\mathcal{O}_X) \); since this is an isomorphism, the original pairing is perfect. \( \square \)

**Remark.** If \( \mathcal{L} = \mathcal{O}_X \), then \( r \) and \( s(r) \) always pair to 0, and thus this involution is the composition of the adjoint with conjugation by \( s \). If also \( \pi_*\mathcal{O}_X \) is free, with basis \( (1, \xi) \), then the pairing is given by \[
\begin{pmatrix}
0 & 1 \\
1 & \text{Tr}(\xi)
\end{pmatrix}.
\]

Since this isomorphism is also an adjoint (albeit with respect to a different pairing), and much more important for our purposes, we will refer to the original involution on \( \mathcal{A}_{\mathcal{L}_i,\pi} \) as the “intrinsic” adjoint, reserving the unadorned term for this involution.

Now, suppose we are given two finite flat degree 2 morphisms \( \pi_i : X \to Y_i, \ i \in \{0,1\} \), as well as two invertible sheaves \( L_i \) on \( X \). This gives rise to a pair \( \mathcal{A}_{\mathcal{L}_0,\pi_0}, \mathcal{A}_{\mathcal{L}_1,\pi_1} \) of sheaf algebras on \( X \), and we define the (quasicoherent) sheaf algebra \( \mathcal{H}_{\mathcal{L}_0,\mathcal{L}_1,\pi_0,\pi_1} \) on \( X \) to be their pushforward over \( \mathcal{O}_X \). That is, \( \mathcal{H}_{\mathcal{L}_0,\mathcal{L}_1,\pi_0,\pi_1} \) is generated by \( \mathcal{A}_{\mathcal{L}_0,\pi_0} \) and \( \mathcal{A}_{\mathcal{L}_1,\pi_1} \) subject only to the relation that the common subalgebras \( \mathcal{O}_X \) should be identical. Since the respective adjoints act trivially on \( \mathcal{O}_X \), they combine to form an automorphism

\[
\mathcal{H}_{\mathcal{L}_0,\mathcal{L}_1,\pi_0,\pi_1}^{op} \cong \mathcal{H}_{\mathcal{L}_0^{-1},\mathcal{L}_1^{-1},\pi_0,\pi_1}.
\]

(2.21)

Note that when \( Y_0 \cong Y_1 \cong \mathbb{P}^1 \) and \( X \) is a smooth genus 1 curve, the resulting sheaf algebra is an instance of the “type \( C \) elliptic double affine Hecke algebra” construction of [40] (with the Morita-equivalent algebra \( \mathcal{S} \) being the spherical algebra in those terms). This suggests that there should be a multivariate version of this more general construction, possibly for general root systems, but at the very least for type \( C \).

To work with this sheaf algebra, it will be convenient to work locally. Localization is somewhat trickier with sheaf algebras than with sheaves of algebras, since the restriction to an open subset is usually not a sheaf algebra. In this case, however, there is not too much difficulty. If an open subset is invariant under the action of the two involutions \( s_0, s_1 \), then the restriction to that open subset will again be a sheaf algebra. This is still too restrictive (if \( s_0s_1 \) has infinite order, we cannot expect to have a covering by affine opens of that form), but a slight generalization will suffice in most cases. Define a localization of \( X \) to be a nonempty intersection of a nonempty (and possibly infinite) collection of affine opens. This is a fiber product of affine morphisms, so inherits a scheme structure, and is affine over each open set in the original collection, so affine, with coordinate ring given by the limit of \( \Gamma(U; \mathcal{O}_X) \) over all open subsets \( U \) containing the intersection. The significance of this notion is that although there are not in general any nontrivial \( \langle s_0, s_1 \rangle \)-invariant affine opens in \( X \), there are typically many invariant localizations. Moreover, \( \mathcal{H}_{\mathcal{L}_0,\mathcal{L}_1,\pi_0,\pi_1} \) induces a sheaf algebra on any invariant localization, which will be an honest algebra containing the structure sheaf of the localization.

If we not only have nontrivial invariant localizations but have a locally finite covering by such localizations with consistent algebras on each localization, then the theory of fpqc descent gives rise to an induced sheaf algebra. We assume that not only does such a covering exist, but that there is such a covering such that each bundle \( \mathcal{L}_0, \mathcal{L}_1, \pi_0, \pi_1, \mathcal{O}_X \) becomes trivial. Note that if \( Y_0 \) and \( Y_1 \) are smooth curves over a field (which is the case we care about for the present application), the existence of such a configuration is straightforward. Indeed, any actual configuration of curves and bundles is the pullback of a configuration over a field which is not algebraically closed, and any bundle can be trivialized by removing finitely many points which are not defined over that field (and thus such that no point of the orbit is in that field). It follows that any point of \( X \) is
contained in an invariant localization that trivializes the bundles. Moreover, each such localization only omits finitely many orbits, and thus there is a finite subcovering.

Thus let \( R \) be a ring which is free of rank 2 over its subalgebras \( S_0 \) and \( S_1 \), and consider the algebra \( H \) generated over \( R \) by \( \text{End}_{S_0}(R) \) and \( \text{End}_{S_1}(R) \). We can give a more explicit presentation of this algebra as follows. The subspace of \( \text{End}_{S_0}(R) \) consisting of nilpotent elements annihilating \( S_0 \) is a free \( S_0 \)-module, so that we may choose a generator \( \nu_0 \) of this module, and similarly for \( \nu_1 \). Then \( H \) has the presentation

\[
H = R/N_0, N_1)/(N_0^2, N_0r - s_0(r)N_0 - \nu_0(r), N_1r - s_1(r)N_1 - \nu_1(r)).
\] (2.22)

Note that since \( L_0 \) and \( L_1 \) are trivial, the adjoint becomes an involution of this algebra, acting trivially on \( R, N_0 \), and \( N_1 \); one has

\[
N_0r - s_0(r)N_0 = N_0r + rN_0 - \text{Tr}_0(r)N_0 = N_0r + rN_0 - N_0 \text{Tr}_0(r) = rN_0 - N_0s_0(r),
\] (2.23)

so that this is indeed a contravariant automorphism, and is clearly of order 2.

Let \( D_\infty \) denote the infinite dihedral group, with generating involutions denoted by \( s_0, s_1 \), acting in the obvious (not necessarily faithful) way on \( R \). Each element of \( D_\infty \) is represented by a unique reduced word \( s_{i_1}s_{i_2} \cdots \) in which \( i_j \neq i_{j+1} \) for all \( j \). (Thus there are two such words of each positive length, corresponding to the two possible values of \( i_1 \).) Given any such element \( w \), let \( N_w \) denote the corresponding product \( N_{i_1}N_{i_2} \cdots \). There is a natural partial ordering on \( D_\infty \) given by \( w < w' \) iff \( \ell(w) < \ell(w') \), where \( \ell(w) \) denotes the length of the reduced word.\footnote{This is the Bruhat ordering on the infinite dihedral group, viewed as the free Coxeter group on two generators.}

**Proposition 2.6.** As a left \( R \)-module, one has

\[
H \cong \bigoplus_{w \in D_\infty} RN_w,
\] (2.24)

and thus the partial ordering on \( D_\infty \) induces a left \( R \)-module filtration of \( H \). This is in fact a bimodule filtration, and the subquotient corresponding to \( w \) is the bimodule \( Rw \).

**Proof.** Define a left action of \( H \) on the free module \( \bigoplus_{w \in D_\infty} Re_w \) by extending the \( R \) action by

\[
N_i \cdot (re_w) = \begin{cases} 
    s_i(r)e_{s_iw} + \nu_0(r)e_w & \ell(s_iw) > \ell(w), \\
    \nu_0(r)e_{w} & \ell(s_iw) < \ell(w).
\end{cases}
\] (2.25)

This is easily seen to satisfy the relations, so indeed gives a module structure, and since \( rN_w \cdot e_1 = re_w \), may be identified with the regular representation, establishing the desired isomorphism. It remains to show that right multiplication by \( R \) respects the filtration and acts correctly on the associated graded: i.e., that for \( r \in R \), \( N_w r - w(r)N_w \in \bigoplus_{\ell(w') < \ell(w)} RN_{w'} \). Moving \( r \) to the left uses the relations \( N_0r = s_0(r)N_0 + \nu_0(r) \) and \( N_1r = s_1(r)N_1 + \nu_1(r) \), from which the result follows by induction in the length. \( \Box \)

**Remark.** The adjoint immediately implies that \( H \) is also free as a right \( R \)-module. Moreover, the adjoint respects the filtration by \( D_\infty \), modulo the (order-preserving) map \( w \mapsto w^{-1} \).

For the global version, we need to understand how the gluing interacts with the filtration; in other words, we need to show that the corresponding automorphisms of \( H \) are triangular and understand their diagonal coefficients. The automorphisms are given by \( N_0 \mapsto u_0^{-1}N_0u_0, N_1 \mapsto \)
$u_1^{-1}N_1u_1$ for $u_0, u_1 \in R^*$, which clearly respect the relations. (And, of course, the adjoint involution inverts both $u_0$ and $u_1$ as expected.) Since

$$u_0^{-1}N_0u_0 = s_0(u_0)u_0^{-1}N_0 + u_0^{-1}v_0(u_0), \quad (2.26)$$

we conclude that the action of this automorphism on $H$ is indeed triangular with respect to the filtration, and on the subquotient corresponding to $w = s_0s_1s_0 \cdots$ acts as left multiplication by

$$s_0(u_0)u_0^{-1} \times s_0(s_1(u_1))s_0(u_1)^{-1} \times s_0(s_1(s_0(u_0)))s_0(s_1(u_0))^{-1} \times \cdots \quad (2.27)$$

(Note that for gluing purposes, we also need to take into account the fact that $N_0$ is only determined up to multiplication by $S^*_0$; this gives rise to factors $\pi^iY_0$ in the resulting line bundles, and similarly for $N_1$.)

With this in mind, let $N_w$ denote the line bundle defined inductively by $N_1 = O_X$ and

$$N_{s_iw} = s_i^*L_i^{-1} \otimes L_i \otimes \pi_i^*Y_i \otimes s_i^*N_w \quad (2.28)$$

whenever $\ell(s_iw) > \ell(w)$; note that more generally one has

$$N_{ww'} \cong N_w \otimes (w^{-1})^*N_{w'} \quad (2.29)$$

Similarly, let $H_w$ be the sheaf subbimodule defined inductively by $H_1 = O_X$ and

$$H_{s_iw} = \mathcal{A}_{L_i, \pi_i}H_w \quad (3.30)$$

for $\ell(s_iw) > \ell(w)$. In the affine case, this is precisely the submodule corresponding to the interval under $w$ under the Bruhat filtration.

**Theorem 2.7.** For any $w \in D_\infty$, $H_w$ is locally free as a left $O_X$-module, of rank $|\{w' : w' \leq w\}|$, and in the corresponding bimodule filtration of $H$, the subquotient corresponding to $w$ is $N_{ww'}$. Moreover, if $\ell(wu') = \ell(w) + \ell(u')$, then $H_{ww'} = H_wH_{u'}$.

**Proof.** Everything except the precise identification of the line bundle in the subquotient follows immediately from the corresponding statement in the affine case, while the identification of the line bundle follows by an easy induction from Proposition 2.3. 

Although this filtration is particularly convenient for calculations, we will need some slightly coarser filtrations for the final construction. Define subbimodules $\overline{H}_{ij}$ for $i, j \in \mathbb{Z}$ with $j \geq i$ as follows:

$$\overline{H}_{i,i+2l} = H_{s_{i+(i+1)s_i)} \quad (2.31)$$

where by convention $s_i := s_{i \mod 2}$. (We add 1 to the length here to reflect the fact that $H_{s_0}$ and $H_{s_1}$ are subalgebras.) We similarly denote the affine version by $\overline{H}_{ij}$, and note that the adjoint identifies $\overline{H}_{ij}$ with $\overline{H}_{-j,-i}$.

**Proposition 2.8.** For $i \leq j \leq k$ one has $\overline{H}_{jk}\overline{H}_{ij} \subset \overline{H}_{ik}$.

In other words, the sheaf bimodules $\overline{H}_{jk}$ fit together to form a (positively graded) sheaf $\mathbb{Z}$-algebra $\overline{H}$. (I.e., an enhanced category with objects $\mathbb{Z}$ and Hom spaces given by sheaf bimodules which are 0 unless the degree is nonnegative.) This sheaf $\mathbb{Z}$-algebra is manifestly invariant under shifting the degrees by 2, and thus one could also consider the corresponding graded sheaf algebra, the Rees algebra of $H$ with respect to the filtration $\{\overline{H}_{0,2l} : l \in \mathbb{N}\}$, without changing the category of coherent sheaves.
In the \( \mathbb{Z} \)-algebra form, each object has an endomorphism ring of the form \( A_{L, \pi} \), and thus there is a Morita-equivalent sheaf \( \mathbb{Z} \)-algebra in which \( \mathcal{S}_{ij} \) is a sheaf bimodule on \( Y_i \times Y_j \). (Here and below, we extend the indices on \( Y_i, N_i \), etc. to be periodic of period 2.) Locally, this has the following description. For \( i \in \mathbb{Z} \), consider the (cyclic) \( H \)-module \( H/(N_i) \), with generator \( e_i \). Then \( \mathcal{S}_{ij} \) is the subspace of \( \text{Hom}(H(e_j, H(e_i))^{\text{op}} \) such that the image of \( e_j \) is in the image of \( \mathcal{P}_{ij} \); equivalently (since it is determined by the image of \( e_j \)), it is the subspace of \( \mathcal{P}_{ij} e_i \) which is annihilated by \( N_j \), and the composition \( \mathcal{S}_{ij} \times \mathcal{S}_{jk} \to \mathcal{S}_{ik} \) may be computed by taking \( x * y \) to be the image of \( y \) after replacing \( e_j \) by \( x \). For gluing purposes, in addition to \( N_i \mapsto u_i^{-1} N_i u_i \), we must take \( e_i \mapsto u_i^{-1} e_i \). (Note that in the description of \( \mathcal{S}_{ij} \) as a subspace of \( \mathcal{P}_{ij} e_i \), we must left multiply by \( u_j \) after applying the automorphism to \( \mathcal{P}_{ij} e_i \).

The following slightly modified local description is useful.

**Lemma 2.9.** We have \( \mathcal{S}_{ij} = N_j \mathcal{P}_{ij} e_i \).

**Proof.** Since \( \mathcal{P}_{ij} e_i \) is a projective \( \text{End}_{S_j}(R) \)-module, this reduces to the fact that \( \ker(N_j) = \text{im}(N_j) \) inside \( R \) (the unique indecomposable projective module).

The relations in \( \mathcal{P}_{ij} \) make it straightforward to give a direct sum decomposition of \( \mathcal{S}_{ij} \). Indeed, \( \mathcal{P}_{ij} e_i \) is clearly the span of

\[
R N_j N_{j-1} \cdots N_{i+1} e_i, R N_{j-1} \cdots N_{i+1} e_i, \cdots
\]

(2.32)

since every other element of the standard basis annihilates \( e_i \). Since \( N_j \mathcal{P}_{jj} = N_j R \), we can write any element of \( N_j \mathcal{P}_{ij} e_i = N_j \mathcal{P}_{i(j-1)} e_i \) as a sum

\[
N_j s_j(e_j) N_{j-1} \cdots N_{i+1} e_i + N_{j-2} s_j(e_{j-2}) N_{j-1} \cdots N_{i+1} e_i + \cdots
\]

(2.33)

with \( c_j \in R \), except that when \( j - i \) is even, the last term has the form \( c_i e_i \) with \( c_i \in S_i \). This, of course, glued to give an analogue for \( \mathcal{S}_{ij} \) of the Bruhat filtration of \( \mathcal{P}_{ij} \).

**Lemma 2.10.** One has \( \mathcal{S}_{ii} \cong \mathcal{O}_{Y_i} \), while for \( j > i \) one has a short exact sequence

\[
0 \to \mathcal{S}_{i(j-2)} \to \mathcal{S}_{ij} \to (\pi_i \times \pi_j)_*(\mathcal{L}_{j}^{-1} \otimes \mathcal{N}_{s_j, s_{i+1}} s_j \cdots s_{i+1} \otimes \mathcal{L}_i) \to 0
\]

(2.34)

of \( (\mathcal{O}_{Y_i}, \mathcal{O}_{Y_j}) \)-bimodules.

**Remark.** Note that when taking the direct image under \( \pi_i \times \pi_j \) that one must take into account the twisting by \( s_j \cdots s_{i+1} \). In addition, one can move the twist by \( s_j \) to the left and absorb it into \( \pi_j \) to get an alternate description as the bimodule induced by

\[
\mathcal{L}_j^{-1} \otimes \pi_j^* \mathcal{O}_{Y_j} \otimes \mathcal{N}_{s_j, s_{i+1}} s_j \cdots s_{i+1} \otimes \mathcal{L}_i.
\]

(2.35)

**Lemma 2.11.** The sheaf \( \mathbb{Z} \)-algebra \( \mathcal{S} \) is a quadratic algebra; that is, it is generated by the Hom bimodules of degree 1 and the relations are generated by relations in degree 2.

**Proof.** It suffices to show this locally, i.e., for the \( \mathbb{Z} \)-algebra \( \mathcal{S} \). For generation in degree 1, we need to show that

\[
N_{j+1} \mathcal{P}_{j(j+1)} N_j \mathcal{P}_{0j} e_0 = N_{j+1} \mathcal{P}_{0(j+1)} e_0,
\]

(2.36)

but this is an immediate consequence of the fact that \( \mathcal{P}_{jj} N_j \mathcal{P}_{jj} = \mathcal{P}_{jj} \).

It thus remains only to show that the only relations are in degree 2. For \( i \in \{0, 1\} \), let \( \xi_i \in R \) be such that \( \nu_i(\xi_i) = 1 \). Then as a (bimodule) \( \mathbb{Z} \)-algebra, \( \mathcal{S} \) is generated by elements
$N_1 e_0, N_1 \xi_1 e_0 \in \overline{S}_{2i(2i+1)}$ and $N_0 e_1, N_0 \xi_0 e_1 \in \overline{S}_{(2i-1)2i}$ subject to the bimodule relations (i.e., that right-multiplying a generator by an element of the relevant $S_i$ equals the appropriate left-$S_{i+1}$-linear combination of generators) and the quadratic relations

$$(N_0 e_1) (N_1 \xi_1 e_0) - (N_0 s_1(\xi_1)e_1)(N_1 e_0) = 0$$

$$(N_1 e_0)(N_0 \xi_0 e_1) - (N_1 s_0(\xi_0)e_0)(N_0 e_1) = 0.$$  

(This follows from $N_1 \xi_1 - s_1(\xi_1)N_1 = \nu_1(\xi_1) = 1$ and $N_0 e_0 = 0$.) Using these quadratic relations, any monomial in the generators that has $(N_0 e_1)$ followed by $(N_1 \xi_1 e_0)$ or $(N_1 e_0)$ followed by $(N_0 \xi_0 e_1)$ can be expressed in terms of monomials which are strictly smaller in an appropriate ordering: take $(N_1 e_0) < (N_1 \xi_1 e_0)$ and $(N_0 e_1) < (N_0 \xi_0 e_1)$ and order monomials reverse lexicographically (i.e., compare the last factor, then the second to last, etc.). We thus conclude that in the $\mathbb{Z}$-algebra presented in this way, each Hom bimodule has a left spanning set consisting of those monomials such that all appearances of $\xi_i$ are as far to the left as possible. In Hom$(i,j)$ for $j \geq i$, this spanning set contains $j - i + 1$ elements; since the Bruhat filtration shows that $\overline{S}_{ij}$ is free of rank $j - i + 1$, there can be no further relations.  

**Remark.** In particular, to compute the adjoint, it suffices to compute it in degree 1, where we find that it swaps $(N_0 re_1)$ and $(N_1 re_0)$. Globally, we need to twist slightly to make the Hom bimodules agree, and thus either take $L_i \mapsto L_i^{-1} \otimes \pi_i^* \det(\pi_i^* O_{Y_i})$ or $L_i^{-1} \otimes \pi_i^* \omega_{Y_i}$. (These are not the same but differ only by a common factor of $\omega_X$, which has no effect on the sheaf $\mathbb{Z}$-algebra.)

Locally, the quadratic relation has the following less basis-dependent description: we have a natural (surjective!) map

$$\Pi_{11} \to \mathbb{S}_{02}$$

given by $x \mapsto N_0 x e_0$, and thus an induced map

$$R \to \Pi_{11} \to \mathbb{S}_{02}. \hspace{1cm} (2.38)$$

The quadratic relation starting at 0 is then the composition of this map with the inclusion $S_0 \to R$. Much the same holds globally, except that $\Pi_{11}$ gets twisted so that we instead have a surjection

$$\text{Hom}_{Y_1}(\pi_{1*} L_1, \pi_{1*}(L_1 \otimes \pi_0^* O_{Y_0})) \to \mathbb{S}_{02} \hspace{1cm} (2.39)$$

and thus an induced map

$$\pi_{0*} \pi_0^! O_{Y_0} \to \mathbb{S}_{02}, \hspace{1cm} (2.40)$$

and the relation is the composition with the natural map

$$\det(\pi_{0*} O_X)^{-1} \to \pi_{0*} \pi_0^! O_{Y_0}. \hspace{1cm} (2.41)$$

Note that since the composition is a relation in $\mathbb{S}_{02}$, the cokernel maps to $S_{02}$, giving a natural global section of $\mathbb{S}_{02}$, locally given by the element $e_0$.

Since the $\mathbb{Z}$-algebra is generated in degree 1, we record the corresponding special case of Lemma 2.10.

**Corollary 2.12.** One has the bimodule isomorphism

$$\mathbb{S}_{01} \cong (\pi_0 \times \pi_1)_* (L_1^{-1} \otimes \pi_1^! O_{Y_1} \otimes L_0) \hspace{1cm} (2.42)$$

Let $\text{qcoh}\mathbb{S}$ denote the category of quasicoherent sheaves over $\mathbb{S}$; that is, the quotient of the category of $\mathbb{S}$-modules by the subcategory generated by right-bounded modules.
Theorem 2.13. There is a natural equivalence between \( \text{qcoh}\mathcal{S} \) and the noncommutative \( \mathbb{P}^1 \)-bundle corresponding to the sheaf bimodule \( (\pi_0 \times \pi_1)_*(L_0 \otimes L_1^{-1}) \).

Proof. Both categories are constructed from quadratic sheaf \( \mathbb{Z} \)-algebras, so it will suffice to show that the algebras are twists of each other; that is, that we can associate a line bundle \( L'_i \) on \( Y_i \) in each degree such that \( L'_i \otimes Y_i \mathcal{S}_{ij} \otimes Y_j L'_j \) agrees with the algebra constructed in \([53]\). Since

\[
(\pi_0 \times \pi_1)_*(L_1^{-1} \otimes \pi_1^* O_{Y_1} \otimes L_0) \cong (\pi_0 \times \pi_1)_*(L_1^{-1} \otimes L_0) \otimes Y_1 \det(\pi_1^* O_{Y_1})^{-1},
\]

this holds for \( \mathcal{S}_{01} \), and \( \mathcal{S}_{-10} \) is the appropriate adjoint bimodule, so is also correct. Both constructions are invariant under shifting the object group, and thus it remains only to verify that the quadratic relations agree, and this is straightforward.

This is most useful in the case that \( Y_0, Y_1 \) are smooth quasiprojective curves over a field \( k \), as in that case every noncommutative \( \mathbb{P}^1 \)-bundle arises in this way.

Proposition 2.14. Let \( k \) be a field and \( C_0/k, C_1/k \) smooth quasiprojective curves. For any sheaf bimodule \( E \) on \( C_0 \times C_1 \) such that \( \pi_0 E \) and \( \pi_1 E \) are both locally free of rank 2, there is a curve \( \hat{Q} \) with finite flat morphisms \( \phi_i : \hat{Q} \to C_i \) of degree 2 and an invertible sheaf \( L \) on \( \hat{Q} \) such that \( E \cong (\phi_0 \times \phi_1)_* L \).

Proof. Suppose first that \( E \) is not a rank 2 vector bundle supported on the graph of an isomorphism, and let \( \hat{Q} := \text{Hom}_{C_0 \times C_1}(E, E) \). Then \( \pi_0 \hat{Q} \) may be interpreted as the subalgebra of \( \text{End}_{C_0}(\pi_0 E) \) consisting locally of elements that commute with the action of \( O_{C_1} \). The generic fiber has rank 2, and the cokernel is torsion-free, so flat, and thus \( \pi_0 \hat{Q} \) is itself flat. In particular \( \hat{Q} := \text{Spec} \hat{Q} \) is a double cover of \( C_0 \) (and thus of \( C_1 \), by symmetry) as required. Since \( \pi_0 \hat{Q} \) is saturated in \( \text{End}_{C_0}(\pi_0 E) \), it follows that \( \pi_0 E \) is locally a cyclic module over \( \pi_0 \hat{Q} \), and thus \( E \) is the image of an invertible sheaf as required.

Now suppose \( E \) is a rank 2 vector bundle supported on the graph of an isomorphism, or WLOG that \( C_0 = C_1 = C \) and \( E \) is a vector bundle on the diagonal. Let \( \hat{Q} \) be any curve in the corresponding projective bundle over \( C \) that does not contain any fiber and meets the generic fiber twice. Then there is a line bundle \( L_0 \) on \( C \) such that \( \pi_* O_{\hat{Q}} \cong E \otimes L_0 \), and thus \( E \cong \pi_*(\pi^* L_0^{-1}) \).

Remark. The notation \( \hat{Q} \) here reflects the fact that this curve is only the “horizontal” part of a more natural curve \( Q \).

Note that although both constructions give the same results geometrically, they behave quite differently in families. This appears not just in the commutative case (where the \( \hat{Q} \)-based construction depends on a suitable choice of curve in the surface), but in the noncommutative case as well. The problem is that all we can say about the algebra \( \hat{Q} \) in general is that its cokernel in the relevant endomorphism ring is torsion-free. Over a curve, this is not a problem, but once we are dealing with a family, it is quite possible for the quotient to fail to be flat. Indeed, if \( \mathcal{O}_{\hat{Q}} \) is a nodal biquadratic curve in \( \mathbb{P}^1 \times \mathbb{P}^1 \), then there is a natural flat family of bimodules in \( \mathbb{P}^1 \times \mathbb{P}^1 \) parametrized by \( \mathcal{O}_{\hat{Q}} \), such that the fiber over each point is the image of the corresponding ideal sheaf in \( \mathcal{O}_{\hat{Q}} \). Over the smooth locus of \( \mathcal{O}_{\hat{Q}} \), the bimodule is the image of an invertible sheaf on \( \mathcal{O}_{\hat{Q}} \), so has associated algebra \( \mathcal{O}_{\hat{Q}} \). But over the singular point, the associated algebra is instead the structure sheaf of the normalization. But this cannot be flat: \( \mathcal{O}_{\hat{Q}} \) has Euler characteristic 0, while the structure sheaf of the normalization has Euler characteristic 1. This also gives rise to a sheaf bimodule on \( \mathbb{P}^1 \times \hat{Q} \times \mathbb{P}^1 \times \hat{Q} \) (or on the corresponding normalization!) such that the corresponding noncommutative \( \mathbb{P}^1 \)-bundle does not arise from the above construction. Luckily, our
present interest is only in the curve case, and many of the results we wish to show need only be checked on geometric fibers. (For instance, if we did not already know flatness from \[53\], we could easily prove it when \(C_0, C_1\) are projective by using the Bruhat filtration to check that the Euler characteristic is the same on every geometric fiber.)

One nice aspect of the curve case is that there is a natural representation of \(\overline{\mathcal{S}}_{ij}\) in terms of (twisted) difference or differential operators. It suffices to give such an interpretation in degree 1 (the quadratic relation will turn out to be automatically satisfied). We may write \(\overline{\mathcal{S}}_{ij}\) as the tensor product

\[
(1 \times \pi_1)_*(\mathcal{L}_1^{-1} \otimes \pi_1^! \mathcal{O}_{Y_1}) \times (\pi_0 \times 1)_* \mathcal{L}_0 \otimes \mathcal{X}.
\]

(2.44)

Here the second factor may be interpreted as the sheaf bimodule of \(\mathcal{O}_{Y_0}\)-linear maps \(\mathcal{O}_{Y_0} \to \mathcal{L}_0\), while the first factor may similarly be viewed as the sheaf bimodule of \(\mathcal{O}_{Y_1}\)-linear maps \(\mathcal{L}_1 \to \mathcal{O}_{Y_1}\). So if \(\mathcal{L}_0 = \mathcal{L}_1\), then we may interpret \(\overline{\mathcal{S}}_{01}\) as the sheaf bimodule of compositions

\[
\mathcal{O}_{Y_0} \to \mathcal{L}_0 \to \mathcal{O}_{Y_1}
\]

(2.45)

with the first factor \(\mathcal{O}_{Y_0}\)-linear and the second factor \(\mathcal{O}_{Y_1}\)-linear. In particular, if we take \(\mathcal{L}_0 = \mathcal{O}_X\), then the first factor can clearly be taken to be the natural inclusion, and thus the map \(\mathcal{O}_{Y_0} \to \mathcal{O}_{Y_1}\) is the restriction to \(\mathcal{O}_{Y_0}\) of a general \(\mathcal{O}_{Y_1}\)-linear map \(\mathcal{O}_X \to \mathcal{O}_{Y_1}\).

Thus suppose \(C_0/k, C_1/k\) are projective curves over a field \(k\), or localizations thereof, and let \(\pi_i : \hat{Q} \to C_i\) be a pair of double covers. There are three main cases to consider: both maps \(\pi_i\) are separable, both maps are inseparable, or precisely one of the two maps is inseparable (and thus \(k\) is a field of characteristic 2). (In the first two cases, we assume that the two maps cannot be identified by an isomorphism \(C_0 \cong C_1\), and thus when both maps are inseparable, \(\hat{Q}\) must be nonreduced.)

If \(\hat{Q}\) is reduced and both maps are separable, then the typical \(\mathcal{O}_{C_1}\)-linear map \(\mathcal{O}_{\hat{Q}} \to \mathcal{O}_{C_1}\) locally has the form \(f \mapsto c_0 f + s_1(c_0)s_1(f)\) with \(c_0\) in the inverse different, i.e., the sheaf of elements of \(\mathcal{O}_{\hat{Q}} \otimes k(C_1)\) such that any element of the corresponding fractional ideal has integral trace. (As a line bundle, the inverse different is isomorphic to \(\pi_1^! \mathcal{O}_{C_1}\), and gives an expression of the latter in terms of an effective Cartier divisor.) The restriction to \(\mathcal{O}_{C_0}\) can be expressed in the same form, but we can also write it as \(f \mapsto \alpha f + s_1(\alpha)s_1(s_0(f))\), and similarly for \(\overline{\mathcal{S}}_{12}\). In each case, the operator involves either \(s_1 \circ s_0\) or its inverse, so that \(\overline{\mathcal{S}}_{0i}\) maps to an operator of the form

\[
f \mapsto \sum_{-|d/2| \leq i \leq |d/2|} c_i(s_1 \circ s_0)^i(f)
\]

(2.46)

with coefficients satisfying \(c_{(d \text{ mod } 2) - i} = s_d(c_i)\) (as well as conditions along the ramification divisor which can be fairly complicated in general, especially where \(\hat{Q}\) is singular). In the case \(\hat{Q}\) is elliptic and \(C_0, C_1\) rational, this recovers the untwisted version of the symmetric elliptic difference operators of \[12\].

If \(\hat{Q}\) is reduced but not integral, then each component induces an isomorphism between \(C_0\) and \(C_1\), so we may as well use one component to identify them with a single curve \(C\), and then the other component induces a nontrivial automorphism \(\alpha \in \text{Aut}(C)\). In that case, the description of \(\overline{\mathcal{S}}_{01}\) simplifies to operators of the form

\[
f \mapsto c_0 f + c_1 \alpha(f)
\]

(2.47)

where \(c_0, c_1 \in \mathcal{O}_C\) must agree to appropriate order wherever the corresponding branches of \(\hat{Q}\) meet (necessarily at fixed points of \(\alpha\)). More generally, \(\overline{\mathcal{S}}_{0d}\) maps to operators

\[
f \mapsto \sum_{-|d/2| \leq i \leq |d/2|} c_i \alpha^i(f).
\]

(2.48)
In the nonreduced case, the reduced subscheme of \( \hat{Q} \) induces an isomorphism \( C_0 \cong C_1 \), so that again we may as well identify both curves with some fixed curve \( C \). Then the coordinate ring of \( \hat{Q} \) over \( C_0 \) is

\[
\mathcal{O}_{\hat{Q}} = \mathcal{O}_C \oplus \epsilon \mathcal{L}
\]

for some line bundle \( \mathcal{L} \) on \( C \). The embedding \( \mathcal{O}_{C_1} \to \mathcal{O}_{\hat{Q}} \) then has the form \( f \mapsto f + \epsilon \partial f \) where \( \partial \) is a derivation \( \mathcal{O}_{C_1} \to \mathcal{L} \). It follows that \( \mathcal{L} \) contains \( \omega_C \), and thus there is some divisor \( D_c \) (essentially a conductor) such that \( \mathcal{L} \cong \omega_C(D_c) \) and \( \partial f = df \). The general \( \mathcal{O}_{C_1} \)-linear map \( \mathcal{O}_{\hat{Q}} \to \mathcal{O}_{C_1} \) then takes the form

\[
f + \epsilon \xi \mapsto \alpha f + \beta(g - df)
\]

with \( \alpha \in \mathcal{O}_{\hat{Q}} \) and \( \beta \in \omega_{C_0}(D_c)^{-1} \). Restricting this to \( \mathcal{O}_{C_0} \) gives

\[
f \mapsto \alpha f - \beta df,
\]

or in other words the general first-order differential operator such that the coefficient of differentiation vanishes along \( D_c \). Similarly, the restriction to \( \mathcal{O}_{C_1} \) of the general \( \mathcal{O}_{C_0} \)-linear map \( \mathcal{O}_{\hat{Q}} \to \mathcal{O}_{C_0} \) takes the form \( f \mapsto \alpha f + \beta df \). We thus see more generally that \( \mathcal{S} \) has a representation inside the sheaf of differential operators on \( C \) such that the image of \( \mathcal{S}_{ij} \) locally consists of operators of order \( j - i \) such that the coefficient of \( (d/dz)^i \) vanishes along \( ID_c \).

Finally, if only one of the two maps is separable, then we end up with a hybrid operator representation. Supposing \( \pi_1 \) is the separable morphism, then \( \mathcal{S}_{01} \) has the same interpretation as in the purely separable case \( (f \mapsto \alpha f + s_1(\alpha f) \) for suitable \( \alpha \)). On the other hand, \( \mathcal{S}_{12} \) consists of the restriction to \( \mathcal{O}_{C_1} \) of linear maps \( \mathcal{O}_{\hat{Q}} \to \mathcal{O}_{C_0} \). Since \( \pi_0 \) is inseparable, for any local section \( f \) of \( \mathcal{O}_{\hat{Q}} \), \( df \) may be interpreted as a local section on \( C_0 \) of \( \omega_{C_0} \otimes \det(\pi_{0*}\mathcal{O}_{\hat{Q}})^{-1} \), so that if \( g \) is any local section of \( \pi_{0*}(\omega_{C_0}^{-1} \otimes \det(\pi_{0*}\mathcal{O}_{\hat{Q}})) \), then \( f \mapsto d(fg) \) is a linear map \( \mathcal{O}_{\hat{Q}} \to \mathcal{O}_{C_0} \), and any such map arises in this way. We thus see that \( \mathcal{S}_{12} \) has a natural interpretation as differential operators. It is worth noting that the resulting hybrid operator representation is far from faithful; indeed, it already has a nontrivial kernel in degree 2. (We will see below that in this case \( \mathcal{S} \) has the same category of coherent sheaves as a maximal order in a quaternion algebra on a commutative ruled surface.)

When \( \mathcal{L}_0 \otimes \mathcal{L}_1^{-1} \) is nontrivial, the above interpretation must of course be twisted accordingly. To understand the nature of such twisting, it suffices to consider the corresponding automorphisms in the affine case. Although this in principle involves a pair of units, only their ratio actually appears, and one thus obtains the automorphism \( N_1re_0 \mapsto N_1ure_0 \) and \( N_0re_1 \mapsto N_0u^{-1}r e_1 \) of \( \mathcal{S} \) for some unit \( u \in R^* \). To interpret this, note that \( N_1e_0 \) is an operator from \( S_0 \) to \( S_1 \) that annihilates 1, and similarly for \( N_0e_1 \), while \( N_1\xi e_0 \) and \( N_0\xi e_1 \) similarly map 1 to 1. Let \( F_{0,u} \) be a formal solution (in \( S_0 \)) of the equation \( N_1ue_0 \cdot F_{0,u} = 0 \), and let \( F_{1,u} \) be the formal image \( N_1ue_1 \cdot F_{0,u} \). We then find that

\[
(N_0u^{-1}e_1) \cdot F_{1,u} = (N_0u^{-1}N_1ue_0) \cdot F_{0,u} = (N_0u^{-1}s_1(\xi)N_1ue_0) \cdot F_{0,u} = 0,
\]

so that \( F_{1,u} \) is a formal solution to \( N_0u^{-1}e_1 \cdot F_{1,u} = 0 \). Similarly,

\[
(N_0u^{-1}\xi e_1) \cdot F_{1,u} = e_0 \cdot F_{0,u},
\]

so that one may reasonably identify \( F_{2,u} \) with \( F_{0,u} \). We also find that for \( a \in S_0 \),

\[
(N_1uae_0) \cdot F_{0,u} = \nu_1(a)F_{1,u},
(N_1ue_1a) \cdot F_{0,u} = \nu_1(a\xi)F_{1,u}
\]

(2.54)
corresponding to the formal identities

\[
F_{1,u}^{-1}(N_1 u e_0) F_{0,u} = N_1 e_0.
\]

\[
F_{1,u}^{-1}(N_1 u \xi_1 e_0) F_{0,u} = N_1 \xi_1 e_0.
\]

(2.55)

In other words, the automorphism corresponding to \( u \) may be interpreted as gauging by the system of formal symbols \( F_{i,u} \).

In the differential case, the formal equation satisfied by \( F_{0,u} \) has the form \((D - v)F_{0,u} = 0\) for suitable \( v \); that is, \( F_{0,u} \) is a formal symbol with logarithmic derivative \( v \), and one further finds that \( F_{1,u} = (u \mod \epsilon)F_{0,u} \). Similarly, in the nonsymmetric difference case, \( F_{0,u} \) is a formal solution to \( \alpha(F_{0,u}) = vF_{0,u} \), while in the symmetric difference case, it is a formal solution to the equations \( s_0(F_{0,u}) = F_{0,u} \) and \( s_1(uF_{0,u}) = uF_{0,u} \). Note that in suitably analytic settings, we can represent \( F_{0,u} \) and \( F_{1,u} \) by honest functions, e.g., as the exponential of the integral of the appropriate meromorphic differential, or (when \( s_0s_1 \) has infinite order) as a suitable infinite product.

Any local trivialization of \( L_0 \otimes L_1^{-1} \) leads to an representation of \( \mathcal{S} \) as sheaves of meromorphic operators of the appropriate kind, and the above calculation shows that any other such representation will be related by a suitable scalar gauge transformation (by the solution of a first-order equation). This is particularly useful in the rational case; when \( C_0 \cong C_1 \cong \mathbb{P}^1 \) and the image of \( \hat{Q} \) in \( \mathbb{P}^1 \times \mathbb{P}^1 \) is singular, we can always localize to the complement of a singular point, which will make all curves affine and all line bundles trivial. This covers every case for which \( C_0 \cong C_1 \cong \mathbb{P}^1 \) except the case when \( \hat{Q} \) is smooth genus 1, for which see [42].

One useful consequence of the operator interpretation is that it makes it straightforward to show that \( \mathcal{S}_{ij} \) is a domain. We in fact have the following.

**Proposition 2.15.** Let \( Y_0, Y_1 \) be integral schemes, and let \( E \) be a sheaf bimodule of birank \((2,2)\) on \( Y_0 \times Y_1 \). Then the corresponding sheaf \( \mathbb{Z}\)-algebra is a domain.

**Proof.** Enlarging the sheaf \( \mathbb{Z}\)-algebra can only introduce zero divisors, so we may as well restrict to the generic points of \( Y_0 \) and \( Y_1 \). This makes \( E \) invertible on its support, and thus the resulting \( \mathbb{Z}\)-algebra is of the form \( \mathcal{S}_{ij} \) with \( S_0 = \mathcal{S}_{00} \), \( S_1 = \mathcal{S}_{11} \) fields.

If \( R \) is a field, then given any pair of morphisms composing to 0, one of their leading coefficients with respect to the Bruhat filtration must vanish, since the leading coefficient of the product is the (automorphism twisted) product of leading coefficients. But in that case we can factor out the degree 2 element \( e_0 \) or \( e_1 \) on the appropriate side to obtain a smaller such pair, eventually yielding a contradiction.

If \( R \) is a sum of two fields, then the derivation of the difference operator interpretation gives a faithful homomorphism from \( \mathcal{S}_{ij} \) to the twisted group algebra \( S_0[\langle \alpha \rangle] \). But this is a domain (by the same leading coefficient argument).

Finally, if \( R \) is nonreduced, then \( \mathcal{S}_{ij} \) consists of polynomials in some fixed derivation (or, rather, an element acting as such a derivation) of \( S_0 \), and again leading coefficients produce the domain property.

As mentioned, the curve \( \hat{Q} \) is only a piece of a somewhat larger curve contained in the non-commutative surface. That \( \hat{Q} \) itself embeds in the surface follows by observing that the system of elements \( (e_i) \in \mathcal{S}_{i(i+2)} \) is “central” in a suitable sense; indeed, if \( D \in \mathcal{S}_{ij} \) then \( (e_j)D = D(e_i) \), where we use the natural identification between \( \mathcal{S}_{ij} \) and \( \mathcal{S}_{(i+2)(j+2)} \). The quotient by the corresponding ideal takes \( \mathcal{S}_{ij} \) to the quotient \( \mathcal{S}_{ij}/\mathcal{S}_{(i-2)(j+2)} \), which as computed above globalizes to the image of an invertible sheaf on \( \hat{Q} \). We thus find that the quotient \( \mathbb{Z}\)-algebra is a twisted version (à la [7]) of the
homogeneous coordinate ring of $\hat{Q}$, and thus the corresponding category of sheaves is just $\text{qcoh} \, \hat{Q}$. Moreover, this not only embeds $\hat{Q}$ in the noncommutative surface, but it does so as a divisor in the sense of [21], which in particular means that any point of $\hat{Q}$ is a suitable candidate for the blowing up construction given therein. (Note that everything stated here applies more generally to embed $X$ as a divisor in the corresponding noncommutative $\mathbb{P}^1$-bundle.) To be precise, there is an endofunctor $\mathcal{L}(\hat{Q})$ of $\text{qcoh} \, \hat{S}_i$, which simply shifts indices by 2, and a natural transformation $\mathcal{L}(\hat{Q}) \to \text{id}$ which is 0 on a subcategory isomorphic to $\text{qcoh} \, \hat{Q}$, and has cokernel mapping to that subcategory.

The larger curve is also embedded as a divisor, and arises by asking for the largest quotient $\text{Z}$-algebra that satisfies the same twisted commutativity relation as $\hat{Q}$ (or $X$). Passing to the local case, we find that we should consider the two-sided ideal generated by quasi-commutators of the form

$$(N_0 x e_1)(N_1 s_1(y) e_0) - (N_0 y e_1)(N_1 s_1(x) e_0) \quad \text{or} \quad (N_1 x e_0)(N_0 s_0(y) e_1) - (N_1 y e_0)(N_0 s_0(x) e_1). \quad (2.56)$$

We may simplify

$$(N_0 x e_1)(N_1 s_1(y) e_0) - (N_0 y e_1)(N_1 s_1(x) e_0) = N_0 (x N_1 s_1(y) - y N_1 s_1(x)) e_0, \quad (2.57)$$

and observe that since $N_1$ is nilpotent, so is negated by the intrinsic adjoint in $\text{End}_{S_1}(R)$, the terms $x N_1 s_1(y)$ and $-y N_1 s_1(x)$ are intrinsic adjoints, and thus their sum is in $S_1$. (Moreover, taking $x = 1$ gives $\nu_1(y)$, and thus any element of $S_1$ arises in this way.) We thus see that the two-sided ideal of quasi-commutators is the same as that generated by $N_1 s_1 = \nu_1(S_1) e_1 \subset \Sigma_{i+2}$. In particular, it is indeed contained in the ideal corresponding to $\hat{Q}$. Moreover, it is essentially given by a conductor.

**Lemma 2.16.** We have $\nu_0(S_1) R = \nu_1(S_0) R = \{x : x \in R \mid xR \subset S_0 S_1\}$.

**Proof.** For $f \in S_1$, $g \in R$, we have $\nu_0(f) g = \nu_0(f s_0(g)) + f \nu_0(g) \in S_0 S_1$, so that

$$\nu_0(S_1) R \subset \{x : x \in R \mid xR \subset S_0 S_1\}. \quad (2.58)$$

Conversely, if $cR \subset S_0 S_1$, and $\xi_0$ is such that $\nu_0(\xi_0) = 1$, then both $c$ and $c s_0(\xi_0)$ are in $S_0 S_1$, so that $\nu_0(c)$ and $\nu_0(c s_0(\xi_0))$ are in $\nu_0(S_0 S_1) = S_0 \nu_0(S_1)$, and thus

$$c = \nu_0(c s_0(\xi_0)) + \xi_0 \nu_0(c) \in \nu_0(S_1) R \quad (2.59)$$

as required. \qed

**Remark.** Note that if $S_0$, $S_1$ are Dedekind domains with distinct images inside $R$, then both $R$ and $S_0 S_1$ are orders inside the normalization, and $\{x : x \in R \mid xR \subset S_0 S_1\}$ is the conductor of $S_0 S_1$ as a suborder of $R$. (In the commutative case, this ideal is of course 0.) This can be described in more global terms by noting that, as an ideal in $S_0$, the conductor is $\nu_0(S_0 S_1)$, or in other words the image of the suborder under the natural map $R \to R/S_0$. We thus see that locally (for curves) the corresponding ideal sheaf is the image of the natural map $\det(\pi_{0*} \mathcal{O}_C) \otimes \det(\pi_{0*} \mathcal{O}_Q)^{-1} \to \mathcal{O}_{C_0}$, where $\mathcal{Q}$ is the image of $\hat{Q}$ in $C_0 \times C_1$ and the map is induced by the natural inclusion $\mathcal{O}_C \to \mathcal{O}_Q$, which is the identity on $\mathcal{O}_{C_0}$. This measures the failure of $\mathcal{E}$ to be invertible along $\mathcal{Q}$.

In the curve case (and assuming $\pi_0$ and $\pi_1$ are not related by an isomorphism $C_0 \cong C_1$), the ideals $S_0 \nu_0(S_1)$ and $S_1 \nu_1(S_0)$ globalize to line bundles contained in $\mathcal{O}_{C_0}$, $\mathcal{O}_{C_1}$ respectively, with the property that both bundles pull back to isomorphic bundles on $\hat{Q}$. Normally, twisting $\mathcal{L}_0$ or $\mathcal{L}_1$
by pulled back line bundles gives an equivalence between different surfaces, but in this case the
 twisting has no effect on $\mathfrak{S}_{i(i+1)}$ and thus gives rise to an autoequivalence. Composing this with
 the shift-by-2 autoequivalence gives an autoequivalence equipped with a natural transformation
 to the identity such that the cokernel is quasicommutative. In particular, we find that the result
 is a twisted version of the homogeneous coordinate ring of a commutative scheme. Of course,
 if $\pi_0$ and $\pi_1$ are related by an isomorphism, then the ideal is trivial, and $\mathfrak{S}$ is itself the twisted
 homogeneous coordinate ring of a commutative scheme (in this case a ruled surface). We denote
 the corresponding autoequivalence of $\text{qcoh} \mathfrak{S}$ by $\underline{(-Q)}$, and note that the natural transformation
 $\underline{(-Q)} \to \text{id}$ factors through $\underline{(-\hat{Q})} \to \text{id}$.

To identify this scheme, suppose $k \subset S_0 \cap S_1$ is some subring, and let $M \subset R$ be an $S_0S_1$
 submodule such that $M/R$ is locally free of rank 1 over $k$. Base changing to make this free, we
 then see that there are ideals $I_i \subset S_i$ such that $M \supset I_iR$, and then for $y \in I_1$,

\[
(N_1Re_0)(N_0Me_1) \equiv (N_1e_0)(N_0\xi e_1) - (N_1s_0(\xi)e_0)(N_0ye_1) = N_1ye_1 = \nu_1(y)e_1, \tag{2.60}
\]

so that $(N_1Re_0)(N_0Me_1) \supset \nu_1(I_1)e_1$. Any element of $S_1$ can be written as $a + y$ for $a \in k$, $y \in I_1$,
 and thus $\nu_1(I_1) = \nu_1(S_1)$, so that the left ideal generated by $N_0Me_1$ contains the left ideal generated
 by $\nu_1(S_1)$, and thus the two-sided ideal so generated. In particular, for $r \in R$, $m \in M$, we have

\[
(N_1re_0)(N_0me_1) \equiv (N_1s_0(m)e_0)(N_0s_0(r)e_1), \tag{2.61}
\]

modulo that ideal, and thus

\[
(N_1Re_0)(N_0Me_1) = (N_1s_1(M)e_0)(N_0Re_1). \tag{2.62}
\]

We thus obtain two conclusions: first that any such $M$ induces a representation of $\mathfrak{S}_{ij}$ which
 is locally free of rank 1 over $k$ in every degree, and second the degree 2 elements of the form
 $\nu_1(S_0)e_1$ and $\nu_0(S_1)e_0$ act as 0 on any such representation. In other words (and globalizing),
 the corresponding commutative scheme is precisely the moduli space of such representations, which
 in turn may be identified with $\text{Quot}(\mathfrak{S}_{01}, 1)$ (the moduli space globalizing the moduli space of
 submodules $M$).

These identifications were already known for general noncommutative $\mathbb{P}^1$-bundles [32]: the
 one new observation is that in the surface case (i.e., when $Y_0$, $Y_1$ are curves) the resulting curve
 (denoted $Q$) is embedded as a divisor in the noncommutative surface. In other words, any point of
 a noncommutative surface obtained from this construction is eligible to be blown up à la [51]. To see
 that $Q$ is a curve, note that since a $S_0S_1$-module is also an $S_0$-module, there is a natural morphism
 $Q = \text{Quot}(\mathfrak{S}_{01}, 1) \to \text{Quot}(\pi_0, \mathfrak{S}_{01}, 1)$, embedding $Q$ as a subscheme of a $\mathbb{P}^1$ bundle over $C_0$.
 Moreover, that subscheme is locally cut out by the equation $v \wedge \phi(v) = 0$, where $\phi \in \text{End}_{\mathcal{O}_{C_0}}(\pi_0, \mathfrak{S}_{01})$
 is the image of a local generator of $\mathcal{O}_Q$ over $\mathcal{O}_{C_0}$. Since

\[
v \wedge \phi(v) = \gamma(v \wedge \xi v) \tag{2.63}
\]

where $\xi$ is a local generator of $\mathcal{O}_Q$ over $\mathcal{O}_{C_0}$, and $\gamma$ is a local generator of the conductor, we see that
 $Q$ splits as a divisor isomorphic to $\hat{Q}$ and transverse to every fiber, plus a vertical divisor given by
 the pullback of the conductor. Note in particular that this implies that the arithmetic genera of
 the three curves are related by $g(Q) = g(\hat{Q}) + c = g(\mathfrak{S})$, where $c$ is the degree of the conductor.
 Indeed, the first equation follows from intersection theory, while the second follows by comparing
differents.

We should also note that in the 1-dimensional case, the pullback of any $S_0$-ideal containing
 the conductor descends to an $S_1$-ideal containing the conductor, and thus gives rise to a corresponding
commutative curve embedded as a divisor. This is mainly relevant in the commutative case (when the conductor is 0), as it means that we still have natural models of \( \bar{Q} \) and various curves \( Q \) inside the surface.

We would like to have a classification of sheaf bimodules associated to noncommutative surfaces, but this in general appears to be quite difficult to control; indeed, any smooth curve with a pair of order 2 automorphisms gives rise to at least one such bimodule for every invertible sheaf (and possibly more, if the composition of the automorphisms has fixed points). Although this is largely intractable, it turns out that nearly every such configuration is uninteresting from a noncommutative geometry perspective, as the corresponding noncommutative \( \mathbb{P}^1 \)-bundle can be described as a finite algebra over a corresponding commutative ruled surface.

With this in mind, we define a noncommutative quasi-ruled surface to be any surface obtained from the above construction in the case that \( C_0, C_1 \) are smooth projective curves, so that we may single out a subclass of noncommutative ruled surfaces, which (by Proposition 2.18 and Theorem 3.1 below) include all of the interesting cases and are much easier to classify. We say that the quasi-ruled surface corresponding to \( \bar{Q}, \pi_i, L_i \) is a (geometrically) ruled surface if (possibly after a field extension) there is an isomorphism \( \phi : C_0 \cong C_1 \) such that the divisor \( (\pi_0 \times \pi_1)(\bar{Q}) \) is algebraically equivalent to twice the graph of \( \phi \). This of course includes the commutative case \( \pi_1 = \pi_0 \circ \phi \), as well as the case that \( \bar{Q} \) is nonreduced (since then the reduced subscheme is the graph of such a \( \phi \)). Moreover, any component of the moduli stack of quasi-ruled surfaces that contains a ruled surface contains either a commutative surface or a surface on which \( \bar{Q} \) is nonreduced, and it is easy to see that the latter can be degenerated to the commutative case. So roughly speaking the noncommutative ruled surfaces are those cases which are deformations of commutative ruled surfaces (though there is one exotic type of such a deformation which is not ruled, see below).

The ruled surfaces are also nearly characterized by the following fact.

**Proposition 2.17.** The curve \( Q \) associated to a quasi-ruled surface has arithmetic genus \( \geq 1 \), with equality precisely when either the surface is ruled or \( Q \) is smooth of genus 1 and \( \pi_0 \) and \( \pi_1 \) are distinct 2-isogenies.

**Proof.** We have already shown that \( g(Q) = g(\bar{Q}) \), so it suffices to consider the latter. In particular, since the double diagonal in \( C \times C \) has arithmetic genus 1, we certainly have equality in the ruled surface case. Similarly, in the 2-isogeny case, \( Q \) is embedded in the product of quotients, and thus \( \bar{Q} \cong Q \) has arithmetic genus 1.

For the other direction, we may assume \( \bar{Q} \) reduced. Let \( \tilde{Q} \) be the normalization of \( \bar{Q} \), and observe that \( g(\tilde{Q}) \leq g(\bar{Q}) \). Since \( \tilde{Q} \) may not be connected, its arithmetic genus could be negative, but since it has at most two components, the arithmetic genus is at least \(-1\). In any event, if \( g(\tilde{Q}) \leq 0 \), then some component of \( \tilde{Q} \) has genus 0, and \( C_0 \) and \( C_1 \) are images of that component, so must themselves have genus 0. But in that case, we (geometrically) have \( C_0 \times C_1 \cong \mathbb{P}^1 \times \mathbb{P}^1 \) with \( \bar{Q} \) of bidegree \((2,2)\), so are in the ruled case.

We thus reduce to the case that \( g(\tilde{Q}) = 1 \) and no component has genus 0. Moreover, \( \tilde{Q} \) must embed in \( C_0 \times C_1 \), since otherwise \( \bar{Q} \) has strictly larger arithmetic genus than \( \tilde{Q} \). If \( \tilde{Q} \) is reducible, then both components must be smooth genus 1 curves isomorphic to both \( C_0 \) and \( C_1 \). Without loss of generality, we may use one component to identify \( C_0 \) and \( C_1 \), so that \( \bar{Q} \) is the union of the diagonal and the graph of some automorphism of \( C \). If that automorphism had fixed points, then the two graphs would intersect, and thus the automorphism must be a translation; since the group of translations is connected, \( \bar{Q} \) is algebraically equivalent to the double diagonal, so the surface is ruled. If \( \bar{Q} \) is integral, then any degree 2 morphism is either a 2-isogeny or a map to \( \mathbb{P}^1 \). If both maps are to \( \mathbb{P}^1 \), then we are again in the bidegree \((2,2)\) case, while if both maps are 2-isogenies then
they are distinct (since otherwise \( \tilde{Q} \) would be nonreduced). In the remaining case, \( \tilde{Q} \) is a bidegree \((2,2)\) curve on a surface \( E \times \mathbb{P}^1 \), so has arithmetic genus 3 by Hirzebruch-Riemann-Roch. □

**Remark 1.** Unlike \( \tilde{Q} \), the curve \( Q \) is flat for any flat family of rank \((2,2)\) sheaf bimodules, and thus in particular its arithmetic genus is constant on any component of the moduli stack. As a result, we find that any component on which the genus is \( > 1 \) cannot possibly contain any commutative fibers. Since the components corresponding to ruled surfaces certainly do contain such fibers, the only question involves the 2-isogeny case. When \( \text{Pic}^0(C)[2] \) is étale, the requirement that the 2-isogenies are distinct is preserved under arbitrary deformation, and thus any commutative fiber must have characteristic 2. On the other hand, the modular curve parametrizing pairs of 2-isogenies (equivalently the modular curve classifying “cyclic” 4-isogenies) splits into three components in characteristic 2, and on one of those components, the two 2-isogenies agree. In other words, there exists a curve over a 2-adic dvr such that the generic fiber admits a pair of distinct 2-isogenies which become the same on the special fiber. Taking that curve to be \( \tilde{Q} \) gives a 2-adic point of the given component of the moduli stack such that the special fiber is indeed commutative. In the untwisted case, the special fiber is \( \mathbb{P}(\pi_*\mathcal{O}_{\tilde{Q}}) \), and \( \pi_*\mathcal{O}_{\tilde{Q}} \) is the unique indecomposable bundle of rank 2 and trivial determinant. The deformation induces a Poisson structure on that ruled surface which vanishes precisely on the image of \( \tilde{Q} \). This explains the exotic characteristic 2 Poisson surfaces arising in the classification of [39].

**Remark 2.** In the ruled and 2-isogeny cases, since every connected component of \( \tilde{Q} \) has arithmetic genus 1, there is a noncanonical isomorphism \( \omega_{\tilde{Q}} \cong \mathcal{O}_{\tilde{Q}} \). Since \( \tilde{Q} \) is a double cover of \( C_0 \), we can also write \( \omega_{\tilde{Q}} \cong \pi_0^*\omega_{C_0} \cong \pi_0^*(\omega_{C_0} \otimes \det(\pi_{0*}\mathcal{O}_{\tilde{Q}}))^{-1} \), and similarly for \( C_1 \). In the ruled cases, one in fact has \( \omega_{C_i} \cong \det(\pi_{i*}\mathcal{O}_{\tilde{Q}}) \) for \( i \in \{0,1\} \); indeed one can check in each case that \( \text{Pic}(C_i) \to \text{Pic}(\tilde{Q}) \) is injective. In the 2-isogeny case, this fails for at least one of the \( C_i \). Indeed, in that case, \( \det(\pi_{i*}\mathcal{O}_{\tilde{Q}}) \) corresponds to the nontrivial point of the kernel of the dual 2-isogeny; since \( \tilde{Q} \) has at most one 2-isogeny with inseparable dual, we have \( \det(\pi_{i*}\mathcal{O}_{\tilde{Q}}) \not\cong \mathcal{O}_{\tilde{Q}} \cong \omega_{C_i} \) for at least one \( i \). We will see below that the isomorphism \( \omega_{C_i} \cong \det(\pi_{0*}\mathcal{O}_{\tilde{Q}}) \) is equivalent to the divisor \( Q \) of points being anticanonical (i.e., such that \( (-Q)[2] \) is a Serre functor), giving us another characterization of ruled surfaces.

The key to showing that non-ruled quasi-ruled surfaces are nearly commutative is the following result.

**Proposition 2.18.** If \( \tilde{Q} \), \( \pi_0 \), \( \pi_1 \) corresponds to a noncommutative quasi-ruled surface which is not ruled, then the automorphism \( s_0s_1 \) has finite order.

**Proof.** Suppose otherwise. Since we have excluded the ruled surface case, either \( g(\tilde{Q}) > 1 \) or \( \tilde{Q} \) is a smooth genus 1 curve and \( s_0 \), \( s_1 \) are translations by distinct 2-torsion points (one of which may be the identity in characteristic 2). In the latter case, \( s_0s_1 \) is again translation by a 2-torsion point, so has order 2. We may thus assume \( g(\tilde{Q}) > 1 \). Since \( s_0s_1 \) acts on the normalization \( \tilde{Q} \) preserving the components, and smooth projective curves of genus \( > 1 \) have finite automorphism groups, the claim is automatic unless the (isomorphic via \( s_0 \)) components have genus \( \leq 1 \); since a genus 0 component would force the configuration to correspond to a ruled surface, the components in fact have genus 1. But \( s_0s_1 \) not only acts on \( \tilde{Q} \), but preserves the finite set of preimages of singular points of \( \tilde{Q} \), so that some power of \( s_0s_1 \) fixes all preimages and a further power fixes \( \tilde{Q} \). □

In general, if \( \pi_0 \) and \( \pi_1 \) are separable, and \( s_0s_1 \) has finite order, then the étale algebra \( k(\tilde{Q})^{(s_0s_1)} \) is a quadratic extension of the field \( k(\tilde{Q})^{(s_0s_1)} \). We let \( C' \) be the smooth curve with the latter function field, and define \( \tilde{Q}' \) to be the unique curve with the former generic étale algebra such that
the conductor of $\tilde{Q}'$ in its normalization is the norm of the corresponding conductor for $\tilde{Q}$. We will see in Section 3 that the center of the untwisted quasi-ruled surface corresponding to $\pi_1 : \tilde{Q} \to C_1$ is the (commutative) untwisted quasi-ruled surface corresponding to $\pi : \tilde{Q}' \to C'$, in the sense that the category of coherent sheaves on the noncommutative surface is the category of coherent modules of a sheaf of algebras on the commutative surface. The twisted situation is slightly trickier to describe, but we note that any line bundle on $C$ may be thought of as falling in the category of coherent sheaves on the noncommutative surface, compatible with the sheaf of algebras structure.

The hybrid case is similar; if $\pi_0$ is inseparable, then we take $C'$ to be the Frobenius image of $C_1$, so that $C_0$ is a separable double cover of $C'$, and we take $\tilde{Q}'$ to be the corresponding singular model of $C_0$, such that the conductor is the norm of the conductor of $\tilde{Q}$.

Finally, if $\tilde{Q}$ is nonreduced of characteristic $p$ (so that WLOG $C_0 = C_1 = C$ and $\Omega$ is the double diagonal), we take $C'$ to be the image of $C$ under Frobenius. If $\tilde{Q} = \Omega$, then we take $\tilde{Q}'$ to be the double diagonal in $C'$, and in general construct $\tilde{Q}'$ so that its conductor relative to the double diagonal is the norm of that of $\tilde{Q}$. Nontrivial twists (i.e., not in Pic($C$)) only exist when the conductor is trivial, in which case they are given (modulo Pic($C$)) by a class in $H^1(\omega_C)$. To describe the resulting map $H^1(\omega_C) \to H^1(\omega_{C'})$, it suffices to give a local (\mathbb{F}_p-linear) map $\Omega_C \to \Omega_{C'}$ inducing it.

The key idea is the following observation.

**Proposition 2.19.** Let $u \in k(C)$ be a function which is a uniformizer at some point. Then in the algebra of differential operators on $k(C)$, one has the relation

$$
\left(\frac{d}{du} + f\right)^p = \left(\frac{d}{du}\right)^p + f^p + \frac{d^{p-1}f}{du^{p-1}}
$$

for any function $f$.

**Proof.** Since $\frac{d}{du} \mapsto \frac{d}{du} + f$ induces an automorphism of the algebra of differential operators and $(d/du)^p$ is central, the operator $(\frac{d}{du} + f)^p$ must also be central, and thus a (monic) $k(C')$-linear combination of $(d/du)^p$ and 1. Applying this to a composition of such automorphisms, we find that the map

$$
f \mapsto \left(\frac{d}{du} + f\right)^p - \left(\frac{d}{du}\right)^p
$$

from $k(C)$ to $k(C')$ is $\mathbb{F}_p$-linear.

This map is given by a polynomial in $f$ and its iterated derivatives which is homogeneous of degree $p$ with respect to the grading in which $\deg(d^l f/du^l) = l + 1$, corresponding to rescaling both $u$ and $f$. Moreover, $\mathbb{F}_p$-linearity implies that every monomial that appears must have degree a power of $p$ with respect to the grading by rescaling $f$ alone. It follows that

$$
\left(\frac{d}{du} + f\right)^p = \left(\frac{d}{du}\right)^p + af^p + \frac{d^{p-1}f}{du^{p-1}}
$$

for suitable constants $a, b \in \mathbb{F}_p$. Each of those monomials arises from exactly one of the $2^p$ terms on the left, and thus one easily verifies that $a = b = 1$ as required. \hfill \Box

**Lemma 2.20.** For any meromorphic differential $\omega$ on $C$, the differential

$$
\tau(\omega) := \left[\left(\frac{d}{du}\right)^p \left(\frac{du}{d}\right)\right] d(u^p) = \left[\left(\frac{\omega}{du}\right)^p + \frac{d^{p-1}\omega}{du^{p-1}}\right] d(u^p)
$$

on $C'$ is independent of $u$, so induces a canonical $\mathbb{F}_p$-linear sheaf map $\tau : \Omega_C \to \Omega_{C'}$. 

23
Proof. We first claim that for $f \in k(C)$, we have the invariant description $\tau(df) = d(f^p)$. Indeed, plugging into the definition of $\tau$ and using the fact that $p$-th derivatives vanish gives us the expression $\tau(df) = \left(\frac{df}{du}\right)^p d(u^p)$, which agrees with $d(f^p)$ when $f$ is a power of $u$ and thus by $F_p$-linearity for all $f \in k((u))$, and in particular on the subspace $k(C)$.

Similarly, if $g \in k(C')$, so that $dg = 0$, we claim that $\tau(gf^{-1}df) = (g^p - g)f^{-p}d(f^p)$ for any $f \in k(C)^*$. It suffices to verify this in the completion, and thus by continuity when $f$ is a polynomial, and thus, since both sides are multiplicative homomorphisms in $f$, for $f = u - u_0$. But in that case we explicitly compute

$$\frac{\tau(g(u - u_0)^{-1}d(u - u_0))}{d((u - u_0)^p)} = g^p(u - u_0)^{-p} + g\frac{d^{p-1}(u - u_0)^{-1}}{du^{p-1}} = (g^p - g)(u - u_0)^{-p}. \quad (2.68)$$

The topological span of the two $F_p$-subspaces on which these invariant descriptions are defined is $k((u))du$ (indeed, each differential $\alpha u^k du$ can be expressed in one of the two forms), and thus the two formulas uniquely determine $\tau$, making it invariant. Moreover, if $\omega$ is holomorphic at $x$, then we may use a uniformizer at $x$ to see that that $\tau(\omega)$ is also holomorphic, so that it gives a sheaf map as required. \qed

Corollary 2.21. There is a multiplicative monoid map $Nm' : k(C) \oplus \epsilon \Omega_{k(C)} \to k(C') \oplus \epsilon \Omega_{k(C')}$ given by

$$Nm'(f + \epsilon \omega) \mapsto f^p + f^p \tau(\omega/f)\epsilon \quad (2.69)$$

when $f \neq 0$ and with $Nm'(egdh) = g^p d(h^p)\epsilon$. Moreover, $Nm'(f) = Nm'(f + \epsilon df) = f^p$. \medskip

Proof. The definition of $\tau$ via a uniformizer $u$ gives an expression for $Nm'(f + \epsilon gdu)$ which is polynomial in the derivatives of $f$ and $g$, and agrees with the given description when $f = 0$. Furthermore, the values of $Nm'(f)$ and $Nm'(f + \epsilon df)$ follow from the definition of $\tau$. To show that $Nm'$ is multiplicative, it will suffice to show it for $f$ nonzero, i.e., that it gives a homomorphism on $(O_C \oplus k(C))^*$. Since

$$Nm'(h(f + \epsilon \omega)) = h^p Nm'(f + \epsilon \omega) = Nm'(h) Nm'(f + \epsilon \omega), \quad (2.70)$$

we may further reduce to the case $f = 1$, where it follows from the fact that $\tau$ is an additive homomorphism. \qed

By considering how $\tau$ acts when applied to a differential with poles, we find that the restriction of $Nm'$ to $O_C$ takes values in $O_C^*$, and thus in particular gives a well-defined homomorphism $H^1(O_C^*) \rightarrow H^1(O_{C'}^*)$ between the respective Picard groups.

In each case, we have associated a double cover of a smooth curve and a line bundle on that double cover, and thus a commutative ruled surface corresponding to the direct image of that line bundle. We will see below that the original quasi-ruled (possibly ruled) surface is a maximal order in a certain division ring over the function field of this commutative ruled surface.

As we mentioned above, although quasi-ruled surfaces are difficult to fully classify, the ruled case is fairly straightforward. We should first note that the isomorphism $C_0 \cong C_1$ making the sheaf bimodule algebraically equivalent to the double diagonal is not in general unique: we can compose it with anything in the identity component of $\text{Aut}(C_1)$ without actually changing the noncommutative surface (which depends only on the category of representations and the choice of structure sheaf, i.e., the pullback of $O_{C_0}$). We can similarly twist by the pullback of any line bundle on $C_1$ without
any effect. (Twisting by a line bundle on \( C_0 \) gives a Morita-equivalent noncommutative surface.) Thus when classifying ruled surfaces, we should feel free to identify \( C_0 \cong C_1 \) with \( C \), but must take these symmetries into account.

We assume we are over an algebraically closed field; although the classification could be done over a general field with only slightly more work, the result would be misleading, since not every noncommutative surface over \( k \) which is ruled over \( \overline{k} \) is ruled over \( k \). (This is true even in the commutative case: not only must one contend with conic bundles in general, but the fact that \( \mathbb{P}^1 \times \mathbb{P}^1 \) has two geometric rulings, neither of which need be defined over the ground field. These issues can be dealt with, but the simplest approach is via yet another construction to be discussed below.)

In the nonreduced case (e.g., if \( g(C_0) \geq 2 \)), we have already seen that \( \hat{Q} \) has the form \( \text{Spec}(\mathcal{O}_{C_0} \oplus \omega_{C_0}(D)e) \) for some effective divisor \( D \), with \( e^2 = 0 \), and it remains only to understand the possible twists, i.e., \( \text{Pic}(\hat{Q})/\text{Pic}(C_1) \). The automorphism freedom is fixed by taking \( \mathcal{Q} \) to be the double diagonal.) We claim that in fact \( \text{Pic}(\hat{Q})/\text{Pic}(C_1) = 1 \) unless \( D = 0 \), when it is isomorphic to \( \mathbb{G}_a(k) \).

Restricting to the underlying reduced curve gives a splitting of \( \text{Pic}(C_1) \to \text{Pic}(\hat{Q}) \), so it suffices to understand the case that \( \mathcal{L} \) is trivial on the reduced curve. In that case, the corresponding cocycle takes values in the group \( 1 + \epsilon \omega_{C_0}(-D) \), or equivalently in the sheaf \( \omega_{C_0}(-D) \), and thus \( \text{Pic}(\hat{Q})/\text{Pic}(C_1) \) is canonically isomorphic to \( H^1(\omega_{C_0}(D)) \cong H^0(\mathcal{O}_C(-D)) \). In other words, if \( D > 0 \), there is no scope for twisting, while for \( D = 0 \) there is a one-parameter family of twists (corresponding to the usual notion of twisting for differential operators).

In the reduced but nonintegral case, we split into three cases. The first is that \( g(C_0) = g(C_1) = 1 \). In that case, we note that any divisor which is algebraically equivalent to the double diagonal is a union of two translates of the diagonal, and thus we may use the \( \text{Aut}(C_1)^0 \) freedom to make one of the two components be the diagonal. Then the other component is disjoint from the diagonal, so that \( \hat{Q} = \mathcal{Q} \) is smooth. We can further use the \( \text{Pic}(C_1) \) freedom to make the line bundle trivial on the diagonal. We thus find that such cases are classified by \( \text{Pic}^0(C) \times \text{Pic}(C) \), with the first coordinate determining the translation and the second determining the line bundle on the corresponding component, and the corresponding algebra is a compactification of the relevant algebra of twisted elliptic difference operators. (To be precise, these surfaces are classified by the quotient of \( \text{Pic}^0(C) \times \text{Pic}(C) \) by the involution corresponding to swapping the two components.)

In the reduced but nonintegral cases with \( g(C_0) = g(C_1) = 0 \), we similarly find that the curve is determined by a choice of nontrivial automorphism. Geometrically, an element of \( \text{PGL}_2(k) \) is either diagonalizable, corresponding to a linear fractional transformation \( z \mapsto qz \) (the multiplicative case), or unipotent, corresponding to \( z \mapsto z + h \) (the additive case). There are a few possible choices for \( \hat{Q} \): in the multiplicative case, there are four, depending on whether \( \hat{Q} \) is singular over 0 or \( \infty \), while in the additive case there are three: \( \hat{Q} = \mathcal{Q}, \hat{Q} = \mathcal{Q}, \) and an intermediate case for which the conductor has degree 1. There is a nontrivial map \( \text{Pic}(\hat{Q})/\text{Pic}(C_0) \to \mathbb{Z} \) given by taking the degree on the nonidentity component, which is an isomorphism unless \( Q = \mathcal{Q} \), when the kernel is \( \mathbb{G}_m \) or \( \mathbb{G}_a \) as appropriate.

Finally, in the reduced integral case, where necessarily \( g(C_0) = g(C_1) = 0 \), \( \mathcal{Q} \) is an integral biquadratic curve, which is either smooth, nodal, or cuspidal. The smooth case is classified by a smooth genus 1 curve \( Q \) along with two classes \( \eta_0, \eta_1 \in \text{Pic}^2(Q) \) (i.e., the two maps to \( \mathbb{P}^1 \)) and one in \( \text{Pic}(Q)/\langle \eta_1 \rangle \) (the line bundle for twisting), and corresponds to the construction in [12].

In the nodal and cuspidal cases, \( \hat{Q} \cong \mathbb{P}^1 \) (assuming both maps are separable) equipped with a pair of involutions, and \( \hat{Q} \in \{ \overline{Q}, \overline{Q} \} \). If the product of involutions has two fixed points, then the involutions swap the fixed points and can be made to look like \( z \mapsto 1/z, z \mapsto q/z \), giving symmetric \( q \)-difference operators (with \( \overline{Q} \) a nodal curve). If the product of involutions has a single fixed point, then the involutions have the form \( z \mapsto a - z, z \mapsto a + h - z \), where we may take \( a = 0 \) except
in characteristic 2. In characteristic 2, we also have the (hybrid) inseparable case in which one of the maps is \( z \mapsto z^2 \) and the other can be taken to be \( z \mapsto z^2 + z \). In each of these cases, there are two possible twists when \( \tilde{Q} \neq \overline{Q} \) (since \( \text{Pic}(\mathbb{P}^1) \) injects as an index 2 subgroup of \( \text{Pic}(\tilde{Q}) \)), and otherwise the group of twists is an extension of \( \mathbb{Z}/2\mathbb{Z} \) by \( \mathbb{G}_m \) or \( \mathbb{G}_a \) as appropriate.

For Hirzebruch surfaces (i.e., ruled surfaces over \( \mathbb{P}^1 \)), there is another approach to the classification which is particularly convenient for some purposes. Recall that \( Q \) naturally embeds in a ruled surface over \( C_1 = \mathbb{P}^1 \); furthermore, it intersects the generic fiber transversely with multiplicity 2, and has arithmetic genus 1, thus must be anticanonical. There is thus a natural map from the moduli stack of noncommutative Hirzebruch surfaces to the moduli stack of (commutative) anticanonical Hirzebruch surfaces. Given a noncommutative Hirzebruch surface, there is also an associated line bundle \( q \) of degree 0 on \( Q \) given by \( \pi_0^* \mathcal{O}_{\mathbb{P}^1}(-1) \otimes \pi_1^* \mathcal{O}_{\mathbb{P}^1}(1) \), giving a map from the moduli stack of noncommutative Hirzebruch surfaces to the relative \( \text{Pic}^0 \) (that is, the stack classifying invertible sheaves which are degree 0 on every component of every fiber) of the universal anticanonical curve of the moduli stack of anticanonical Hirzebruch surfaces.

We claim that this map to the relative \( \text{Pic}^0 \) is an isomorphism. Indeed, we can recover line bundles \( \eta_0 = \pi_0^* \mathcal{O}_{\mathbb{P}^1}(1) \) and \( \eta_1 = \eta_0 \otimes q \) from the given data. Both bundles are acyclic of degree 2: their inverses have degree \(-2\) and have (the same) nonpositive degree on every component, so are ineffective. Thus both bundles induce (isomorphism classes of) maps from \( Q \) to \( \mathbb{P}^1 \), and since they have degree 0 on every vertical component, this restricts to an embedding \( Q \to \mathbb{P}^1 \times \mathbb{P}^1 \). The sheaf bimodule can then be recovered as the direct image of the relative \( \mathcal{O}(1) \) of the commutative Hirzebruch surface. (Since \( \tilde{Q} \) meets every fiber twice, there is a natural map \( \mathcal{O}_Q(1) \to \mathcal{O}_{\tilde{Q}}(1) \) with kernel an extension of sheaves \( \mathcal{O}_f(-1) \) supported on fibers of the ruling, and thus both sheaves have the same direct image.)

Note here that \( \text{Pic}^0(Q) = \text{Pic}^0(\overline{Q}) \) is an elliptic curve, \( \mathbb{G}_m \), or \( \mathbb{G}_a \), depending on whether \( Q \) is smooth, nodal, or cuspidal/nonreduced. Moreover, when \( \overline{Q} \) is reduced, \( q \) corresponds directly to the shift in the difference operator interpretation, while for \( \overline{Q} \) nonreduced, it corresponds to the traditional \( h \) used to view differential operators as deformations of commutative polynomials.

There is a minor technical issue ignored above: to recover the data from the surface, we must in general include the embedding of \( Q \) (i.e., consider the moduli stack of anticanonical noncommutative Hirzebruch surfaces), as when \( q \) is the identity, the corresponding surface is commutative. We also caution the reader that although every (anticanonical) commutative Hirzebruch surface over the generic point of a dvr extends (nonuniquely), this fails in the noncommutative case, since \( \text{Pic}^0(Q) \) need not be proper. (This is related to the fact that although \( \overline{Q} \) has a limit inside \( C_0 \times C_1 \), that limit may contain preimages of points of \( C_0 \) or \( C_1 \), making it impossible for a limiting sheaf on \( \overline{Q} \) to be a sheaf bimodule.)

Something similar holds for other ruled surfaces; in general, the moduli stack of (anticanonical) noncommutative ruled surfaces over \( C \) is the relative \( \text{Pic}^0(Q)/\text{Pic}^0(C) \) over the moduli stack of anticanonical ruled surfaces over \( C \). (If \( C \) is a genus 1 curve of characteristic 2, we must also exclude those anticanonical ruled surfaces for which the anticanonical curve is connected and smooth, as these correspond to the 2-isogeny case.) The map from noncommutative surfaces is the same as for genus 0 (where we note that \( \text{Pic}^0(C_0) \) and \( \text{Pic}^0(C_1) \) have the same embedding in \( \text{Pic}^0(Q) \)), but the inverse is trickier to construct. However, we can verify in both the differential and elliptic difference cases that the map is surjective and that we can reconstruct the sheaf bimodule from this data.
3 The semicommutative case

As mentioned above, many examples of noncommutative quasi-ruled surfaces are not “truly” noncommutative, in that the corresponding sheaf \( \mathbb{Z} \)-algebra has a large center. Our objective in the present section is to make this more precise, by constructing a (coherent) sheaf of algebras on a corresponding commutative ruled surface \( Z \) having the same category of coherent modules. In fact, we will see that this \( \mathcal{O}_Z \)-algebra is a maximal order (see [43] for an expository treatment). (Recall that an order on an integral scheme \( Z \) is a coherent, torsion-free, \( \mathcal{O}_Z \)-algebra such that the generic fiber is a central simple algebra, and an order is maximal if it is not a proper subalgebra of an order with the same generic fiber.) This not only completes our justification for frequently restricting our attention to ruled surfaces (as maximal orders have been extensively studied via commutative means), but gives useful additional information about semicommutative ruled surfaces (the differential case in characteristic \( p \), as well as difference cases in which the translation is torsion).

Our first goal is to establish the following result.

**Theorem 3.1.** Suppose that \( X \) is the quasi-ruled surface associated to maps \( \pi_i : \hat{Q} \to C_i \) (with \( C_i \) smooth projective curves) and a line bundle \( \mathcal{L} \) on \( \hat{Q} \). Suppose that \( k(C_0) \) is algebraic of degree \( r \) over the intersection \( k(C_0) \cap k(C_1) \) inside \( k(\hat{Q}) \), and let \( C' \) be the curve with function field \( k(C_0) \cap k(C_1) \). Then there is a commutative ruled surface \( Z \) over \( C' \) and a maximal order \( A \) on \( Z \) with generic fiber a division ring of index \( r \) such that there is a natural equivalence \( \text{coh} A \cong \text{coh} X \) taking the regular representation to the structure sheaf.

**Remark.** By Proposition 2.18, the hypothesis is automatically satisfied (for some \( r \)) for any quasi-ruled surface which is not ruled. We will further be able to identify the rank 2 vector bundle on \( Z \), although this identification is surprisingly subtle when \( \mathcal{L} \) is nontrivial.

A key observation is that being a maximal order is a local condition (up to some mild subtleties in how one identifies the center), so to a large extent we may restrict our attention to the analogous affine question.

Let us first consider the differential case in characteristic \( p \), where as usual we may assume that \( R = S_0[\epsilon]/\epsilon^2 \), with \( S_0 \cong S_0 \) embedded as \( f \mapsto f + (df/\omega)\epsilon \) for some nonvanishing meromorphic differential \( \omega \). Let \( u \) be a uniformizer at some point of the curve \( \text{Spec}(S_0) \), and observe that the differential \( du \) is holomorphic and nonvanishing in a neighborhood of that point. We may thus reduce to the case that \( du \) is nowhere vanishing, and thus the conductor is principal, generated by \( c := du/\omega \in S_0 \). We then find that \( \mathfrak{S}_0 = \mathfrak{S}_{12} = S_0 + S_0cD \), where \( D \) satisfies the commutation relation \( Df - fD = df/du \). In other words, \( \mathfrak{S} \) is the \( \mathcal{Z} \)-algebra associated to the subalgebra \( A_c := S_0(t,cDt) \) of the graded algebra \( A = S_0(t,Dt) \), where \( t \) is central.

**Lemma 3.2.** If \( S_0 \) has characteristic \( p \), then the \( p \)-th Veronese of the center of \( A_c \) is \( S_0^p[t^p, c^pD^p t^p] \), and the corresponding sheaf of algebras over \( \text{Proj}(S_0^p[t^p, c^pD^p t^p]) \) is locally free.

**Proof.** We first need to show that the central element \( c^pD^p t^p \in A \) is in \( A_c \). But this follows easily from the identity

\[
e^a(cDt) = ((cDt) - ac't)e^a
\]

valid over \( S_0(t,Dt) \), where \( c' = dc/du \); in particular, we find

\[
e^kD^k t^k = e^{k-1}(cDt)D^{k-1}t^{k-1} = (cDt - (k - 1)c't)e^{k-1}D^{k-1}t^{k-1},
\]

so that by induction, \( e^kD^k t^k \in A_c \) for all \( k \).

As an operator, \( e^pD^p t^p \) annihilates \( S_0 \), and any homogeneous element of degree \( d \) in \( A_c \) can be expressed as \( t^d \) times a polynomial of degree \( < p \) in \( cD \) plus a multiple of \( e^pD^p \). Since differential
operators of degree $< p$ act faithfully, we conclude that $c^p D^p t^p$ generates the kernel of the natural map $A_c \to \text{End}_{S_0}(S_0)[t]$. A central element $x \in A_c$ of degree a multiple of $p$ maps to a central element of $\text{End}_{S_0}(S_0)[t]$, and thus has the form $f_0 t^{pd} + (c^p D^p t^p)y$ where $f_0 \in S_0^0$ and $x \in A_c$. Since $A_c$ is a domain, $y$ must also be central, and since it has lower degree than $x$, the first claim follows by induction.

For local freeness, it suffices to show that the submodule of $A_c$ consisting of elements of degree congruent to $-1$ modulo $p$ is free over the center of $A_c$. A degree $dp + (p - 1)$ element of $A_c$ has a unique expression of the form

$$\sum_{0 \leq i \leq d} x_i t^{p(d-i)} (c^p D^p t^p)^i$$

with each $x_i$ homogeneous of degree $p - 1$. Since the space of degree $p - 1$ elements is free as a $S_0^0$-module, the claim follows.

In particular, we have established that coh $\mathcal{S}$ is the category of coherent sheaves on an order $\mathcal{A}$ over the surface $\mathcal{Z} := \text{Proj}(S_0^0[t^p, c^p D^p t^p])$, which is a ruled surface over $	ext{Spec}(S_0^0)$. Note that since $\mathcal{S}$ is a domain, the generic fiber of $\mathcal{A}$ is a division ring. Over most of $\mathcal{Z}$, maximality is straightforward, and in fact we have the following stronger statement.

**Lemma 3.3.** On the complement of the divisor $c^p t^p = 0$, $\mathcal{A}$ is an Azumaya algebra.

**Proof.** Without loss of generality, we may assume that $c$ is a unit, and thus this reduces to showing that $S_0(D)$ is an Azumaya algebra over $	ext{Spec}(S_0^0[D^p])$. The fiber over any point (with field $\ell$) of $\text{Spec}(S_0^0[D^p])$ has a presentation of the form $\ell\langle u, D \rangle$ with relations $u^p = U$, $D^p = \delta$, $Du - uD = 1$, with $U, \delta \in \ell$ and both $u$ and $D$ commuting with $k$. Passing to the algebraic closure of $\ell$ lets us subtract $p$th roots of $U$ and $\delta$ from $D$ and $u$ respectively, and thus reduce to the case $U = \delta = 0$, in which case the algebra is readily identified with $\text{Mat}_p(\mathcal{O})$ as required.

Since $\mathcal{A}$ is locally free, and thus reflexive, it is maximal iff its codimension 1 localizations are maximal, so that it remains only to check maximality along components of $c^p t^p = 0$. Here we may use the criterion that an order over a dvr is maximal if its radical is principal (as a left ideal) and its semisimple quotient is central simple. (If the radical is principal, it is invertible, and thus the order is hereditary, and the result follows by [9, Thm. 2.3]). There are two cases to consider: the fibers where $c$ vanishes, and the curve $t^p = 0$.

In the first case, we may assume $S_0$ is a dvr and the conductor has the form $c = z^c$ for some uniformizer $z$ and some positive integer $c$, and consider the completion $\hat{S}$ of $S$ along the divisor $z = 0$, or equivalently the base change of $S|_{\mathcal{Z}}$ to the extension $k(z^c D^p)[[z^p]]$ of its center. Consider the two-sided ideal $\hat{S} z \hat{S}$. Since $c$ is positive, $z$ is normalizing:

$$z(z^c D) = (z^c D - z^{c-1})z,$$

and thus $\hat{S} z \hat{S} = z \hat{S}$ is principal as a left ideal. Moreover, the $p$-th power ideal $(z \hat{S})^p = z^p \hat{S}$ is contained in the radical, since $z^p$ generates the maximal ideal of the center. We conclude that $\hat{S} z \hat{S}$ is contained in the radical of $\hat{S}$. The quotient by this two-sided ideal is the field $k(z^c D)$, and thus $\hat{S} z \hat{S}$ actually is the radical, and the quotient is a field, so is central simple as required.

In the second case, we have a completion of the form $K\langle\langle D^{-1}\rangle\rangle$ where $K$ is the field of fractions of $S_0$ and $D^{-1}$ satisfies the commutation relation

$$D^{-1} f = \sum_{0 \leq j} (-1)^j \frac{d^j f}{du^j} D^{-1-j} = \sum_{0 \leq j < p} (-1)^j \frac{d^j f}{du^j} D^{-1-j}.$$

28
Here we find that the radical is the principal one-sided ideal generated by $D^{-1}$, and the quotient is again a field.

The above calculation carries over to the untwisted case, showing that $\text{coh } S$ is a maximal order on a ruled surface over the image $C^{(p)}$ of $C_0 = C_1 = C$ under Frobenius. In fact, our computation allows us to identify the corresponding rank 2 vector bundle as $\mathcal{O}_{C^{(p)}} \oplus \omega_{C^{(p)}}(\epsilon')$ where $\epsilon'$ is the norm of the conductor, corresponding to a curve $\tilde{C}$ on a ruled surface over the image.

In the disconnected case, twisting is relatively easy to deal with, since the center is preserved by the automorphisms used under gluing, and we can compute the effect of nontrivial twists using Proposition 2.19. (This will be trickier to deal with in general, when we need a more subtle notion of center.)

Note that when the conductor is nontrivial, we should really consider the curve $Q$ rather than $\tilde{Q}$, which leads us to consider the curve $Q'$ obtained by adding fibers with the appropriate multiplicities to $Q'$. We can then verify that $Q'$ is an anticanonical curve on the center.

Another useful observation for the non-differential cases is that since $\overline{T}$ and $\overline{S}$ are Morita equivalent, they have the same centers (appropriately defined), and one is maximal iff the other is maximal. This means that we can feel free to work with whichever of the two is most convenient at any given point in the argument. In particular, in the difference case, it will be more convenient to work with $\overline{T}$ for the bulk of the argument. As in the differential case, a key step is identifying the kernel of the action on $R$.

We first suppose that $S_0$ and $S_1$ are complete dvr’s (and we are in the difference case, so $R$ is separable over both $S_0$ and $S_1$). Then $R$ is an order in either a dvr or a sum of two copies of $S_0$. In the first case, $R$ inherits a valuation from $S_0$, and we take $\xi$ to be an element of smallest absolute value that generates $R$ over $S_0 = k[[x_0]]$. Valuation considerations then imply that $\xi$ also generates $R$ over $S_1 = k[[x_1]]$. In the disconnected case, we similarly suppose that $\xi$ vanishes in some summand, and among such elements has maximal absolute value in the other summand; this again forces $\xi$ to generate over both $S_0$ and $S_1$. In either case, we use this element to define the requisite twisted derivations: for $f, g \in S_0$, $\nu_0(f + g\xi) = g$, and similarly for $\nu_1$.

In the differential case, the fact that the conductor is normalizing was crucial. In the differential case, it turns out that we get a nontrivial normalizer not only when the conductor is nontrivial but also when there is suitable ramification. Associate a positive integer $m$ to the configuration $(R, S_0, S_1)$ as follows. If $R \neq S_0S_1$ (which in particular happens if $S_0 = S_1$), let $m = 1$; otherwise, if $r > 1$ is the order of $s_0s_1$, we take $m$ to be the $p'$-part of $r$, unless $r$ is a power of $p$, in which case $m = p$.

**Lemma 3.4.** The element $(x_1/x_0)^m \in R^*$.  

**Proof.** It will suffice to show that $\nu_0(x_1^m) \in x_0^mS_0$, since then valuation considerations force $x_1^m - \nu_0(x_1^m)\epsilon \in x_0^mS_0$ as well, so that $(x_1/x_0)^m \in R$, with the unit property following by symmetry. If $R \neq S_0S_1$, so $m = 1$, then $x_1$ cannot generate $R$ over $S_0$, and thus neither can $\nu_0(x_1)\epsilon = x_1 - (x_1 - \nu_0(x_1)\epsilon) \in x_1 + S_0$. But this implies that $\nu_0(x_1) \in S_0$ is not a unit, and thus $\nu_0(x_1) \in x_0S_0$ as required.

In the remaining cases, since $\nu_0$ is a twisted derivation, we may write

$$\nu_0(x_1^m) = \nu_0(x_1) \sum_{0 \leq i < m} x_1^i s_0(x_1)^{m-1-i}. \quad (3.6)$$

Since $s_0$ preserves the valuation(s) of $x_1$ (it either preserves the unique valuation of the normalization of $R$ or swaps the two valuations; since $x_1$ is $s_1$-invariant and $s_1$ has the same effect on the valuations, its valuation is $s_0$-invariant), we find that $s_0(x_1)/x_1 \in \overline{R}$, and thus we may compute

$$\nu_0(x_1^m) = \nu_0(x_1)x_1^{m-1} \sum_{0 \leq i < m} (s_0(x_1)/x_1)^{m-1-i}. \quad (3.7)$$

29
In particular, if
\[ \sum_{0 \leq i < m} (s_0(x_1)/x_1)^{m-1-i} \]
(3.8)
is in the radical of \( \tilde{R} \), then \( x_1^{1-m} \nu_0(x_1^m) \) has positive valuation, so that \( x_0^{1-m} \nu_0(x_1^m) \) has positive valuation as required.

If Spec\((R)\) is disconnected, then \( x_1 \) is a uniformizer in each direct summand, and thus modulo the radical, \( s_0(x_1)/x_1 = s_0(s_1(x_1))/x_1 \) is given by the action of \( s_0s_1 \) on the two tangent vectors. Since \( S_0 \neq S_1 \), we have \( s_0s_1 \neq 1 \); if it has order a power of \( p \), then it fixes the tangent vectors, and otherwise it acts as inverse \( m \)-th roots of unity, and in either case the sum vanishes.

If Spec\((R)\) is connected and \( \pi \) is a uniformizer of \( \tilde{R} \), then \( s_0s_1(\pi)/\pi \) is congruent to 1 since both \( s_0 \) and \( s_1 \) act as \(-1\) on the tangent vector. It follows that the order of \( s_0s_1 \) is a power of \( p \), and again the claim follows.

**Corollary 3.5.** The elements \( x_0^m \) and \( x_1^m \) normalize \( H \).

**Proof.** Since \( x_1^m \) commutes with \( N_1 \), it suffices to show that \( x_1^m N_0 \in N_0H \). But this follows by writing
\[ x_1^m N_0 = (x_1/x_0)^m x_0^m N_0 = (x_1/x_0)^m N_0 x_0^m = (x_1/x_0)^m N_0 (x_0/x_1)^m x_1^m. \]
(3.9)

Define a sequence of elements \( x_0^{(l)} \), \( 1 \leq l \), by \( x_0^{(1)} := x_0 \), \( x_0^{(l)} := s_{(l-1) \mod 2}(x_0^{(l-1)}) \), and similarly for \( \xi^{(l)} \). Note that all of these elements have the same valuation(s) as \( x_0 \).

**Corollary 3.6.** For any integer \( 1 \leq l \), we have
\[ \nu_l \mod 2(x_0^{(l)})H = H \nu_l \mod 2(x_0^{(l)}). \]
(3.10)

**Proof.** It will suffice to show that \( \nu_l \mod 2(x_0^{(l)}) \), when nonzero, has valuation(s) a multiple of that of \( x_0^{m \mod 2} \). This is immediate if \( m = 1 \), so we may assume we have trivial conductor; i.e., \( R = S_0S_1 \). Since we are in the difference case, we can write
\[ \nu_l \mod 2(x_0^{(l)}) = \frac{x_0^{(l)} - s_l \mod 2(x_0^{(l)})}{\xi - s_l \mod 2(\xi)} \]
(3.11)
Now, \( x_0^{(l)} \) is invariant under the involution \( s_1s_0s_1 \cdots \) of length \( 2l - 1 \), and thus we can rewrite the second term as \( (s_0s_1)^{\pm l}(x_0^{(l)}) \) where the sign depends on the parity of \( l \). That the ratio has valuation as required then follows from the Hasse-Arf theorem.

To understand the kernel of the action, it will be helpful to consider a larger algebra of \( (k\text{-linear}) \) operators. For each integer \( l \geq 0 \), the subspace of \( H \) with length bounded by \( l \) has rank \( 2l + 1 \), and thus we would naively expect that there should be a unique (up to scale) such operator that annihilates the \( 2l \) elements \( 1, \ldots, x_0^{l-1} \) and \( \xi, \ldots, x_0^{l-1}\xi \). The nonuniqueness could then be eliminated (at the cost of making the section of \( H \) meromorphic) by insisting that the image of \( x_0^l \) be 1. This of course fails once \( l \) is large enough, as the image of \( H \) in \( \text{End}_k(R) \) has finite rank, but either via experimentation for small \( l \) or by computing appropriate determinants, one finds that
the resulting action can be computed explicitly, and extends to arbitrary $l$. Thus for each integer $l \geq 0$, let $L_l$ denote the unique continuous $k$-linear operator on $R$ such that

$$L_l \frac{1}{1-tx_0} = \prod_{1 \leq i \leq l+1} \frac{t}{1-tx_0^{(i)}}$$

(3.12)

$$L_l \frac{\xi}{1-tx_0} = \xi^{(l)} \prod_{1 \leq i \leq l+1} \frac{t}{1-tx_0^{(i)}}.$$  

(3.13)

This should be interpreted as saying that if we expand both sides as formal power series in $t$, then each coefficient transforms as stated. This is clearly well-defined, since it specifies $L_l$ on a (topological) basis of $R$. Moreover, it follows by triangularity that the operators $L_0, N_0 L_0, L_1, N_0 L_1, \ldots$ form a topological basis of the algebra of continuous $k$-linear endomorphisms of $R$.

By our original motivation, we expect the operators $L_l$ to be representable as meromorphic sections of $H$, at least for $l$ sufficiently small. Such an expression is an immediate consequence of the following recurrence.

**Lemma 3.7.** These operators satisfy the recurrence

$$\nu_l(x_0^{(l)}) L_l = (N_l - \frac{\nu_l(\xi^{(l)})}{\nu_{l-1}(\xi^{(l-1)})} N_{l-1}) L_{l-1}. $$

(3.14)

**Proof.** We need to show that applying the right-hand side to $(1-tx_0)^{-1}$ and $\xi(1-tx_0)^{-1}$ gives the correct result. The key observation is that

$$\prod_{1 \leq i \leq l} \frac{t}{1-tx_0^{(i)}}$$

(3.15)

is $s_{l-1}$-invariant and thus annihilated by $\nu_{l-1}$, and similarly

$$\prod_{1 \leq i \leq l-1} \frac{t}{1-tx_0^{(i)}}$$

(3.16)

is $s_l$-invariant. Since $\nu_l$ is an $s_l$-twisted derivation, we compute

$$\nu_l \left( \prod_{1 \leq i \leq l} \frac{t}{1-tx_0^{(i)}} \right) = \nu_l \left( \frac{t}{1-tx_0^{(l)}} \right) \prod_{1 \leq i \leq l-1} \frac{t}{1-tx_0^{(i)}}$$

$$= \frac{1}{\xi - s_l(\xi)} \left( \frac{t}{1-tx_0^{(l)}} - \frac{t}{1-tx_0^{(l+1)}} \right) \prod_{1 \leq i \leq l-1} \frac{t}{1-tx_0^{(i)}}$$

(3.17)

$$= \nu_l(x_0^{(l)}) \prod_{1 \leq i \leq l+1} \frac{t}{1-tx_0^{(i)}},$$

so that both sides indeed have the same action on $(1-tx_0)^{-1}$. Since

$$(N_l - \frac{\nu_l(\xi^{(l)})}{\nu_{l-1}(\xi^{(l-1)})} N_{l-1}) \xi^{(l-1)} = \xi^{(l)} N_l - s_{l-1}(\xi^{(l-1)}) \frac{\nu_l(\xi^{(l)})}{\nu_{l-1}(\xi^{(l-1)})} N_{l-1},$$

(3.18)

the actions on $\xi(1-tx_0)^{-1}$ also agree.

**Remark.** Since $\xi^{(l)}$ satisfies the same valuation conditions as $\xi$ (apart from possibly swapping the two components when $R$ is not a domain), we find that $\nu_l(\xi^{(l)})$ is a unit.
Although this only gives a meromorphic expression for $L_l$, we can control the poles.

**Corollary 3.8.** For any integer $l \geq 0$, there is an element of
\[ H_{\leq s_{l-1} \cdots s_0} + H_{s_l \cdots s_1} \]  
with unit leading coefficients that acts as the operator
\[ \left( \prod_{1 \leq i \leq l} \nu_i(x_0^{(i)}) \right) L_l. \]  

**Proof.** We have the operator identity
\[ \left( \prod_{1 \leq i \leq l} \nu_i(x_0^{(i)}) \right) L_l = \left( \prod_{1 \leq i \leq l-1} \nu_i(x_0^{(i)}) \right) (N_l - \frac{\nu_l(\xi(l))}{\nu_{l-1}(\xi(l-1))} N_{l-1}) L_{l-1}. \]  
The coefficient normalizes $H$ by Corollary 3.6 and thus we can move it to the right to obtain an expression of the form
\[ \left( \prod_{1 \leq i \leq l} \nu_i(x_0^{(i)}) \right) L_l = (\alpha_l N_l + \beta_l N_{l-1} + \gamma_l) \left( \prod_{1 \leq i \leq l-1} \nu_i(x_0^{(i)}) \right) L_{l-1}, \]  
with $\alpha_l, \beta_l \in R^*$, $\gamma_l \in R$. The claim follows by induction. \qed

**Remark.** This expression is uniquely determined unless $\nu_i(x_0^{(i)}) = 0$ for some $1 \leq i < l$.

**Corollary 3.9.** Suppose that $S_0$ has degree $r < \infty$ over $S_0 \cap S_1$. Then the image of $H$ in $\text{End}_{S_0 \cap S_1}(R)$ is the same as the images of the Bruhat intervals corresponding to the two elements of length $r$, both of which inject in $\text{End}_{S_0 \cap S_1}(R)$.

**Proof.** Since $r$ is the order of $s_0 s_1$, we find that $\nu_i(x_0^{(i)}) = 0$ iff $i$ is a multiple of $r$, and thus there is an element in the union of the Bruhat intervals with unit leading coefficients that acts as
\[ \left( \prod_{1 \leq i \leq r} \nu_i(x_0^{(i)}) \right) L_r = 0. \]  
We can use the resulting element of the kernel to reduce any word of length $> r$ to a linear combination of shorter words with the same image, and thus the Bruhat intervals of length $r$ both span the image of $H$.

For injectivity, we observe that the elements
\[ (\prod_{1 \leq i \leq l} \nu_i(x_0^{(i)}))L_l, (\prod_{1 \leq i \leq l} \nu_i(x_0^{(i)}))(N_{l+1} - \nu_{l+1}(\xi(l+1)))L_l \]  
for $0 \leq l < r$ form a basis of the relevant Bruhat interval, so it suffices to show that their images are linearly independent. But this follows by considering how they act on $1, \xi, x_0, x_0 \xi, \ldots$. \qed

**Remark.** Although we did the calculations assuming $S_0$ and $S_1$ are complete local rings, the corresponding result before completion follows immediately.
Now, let us consider the nonintegral case; that is, $S_0$ and $S_1$ are regular with $S_0 \cap S_1$ a dvr. Assuming again that $S_0 \cap S_1$ is complete, the normalization of $R$ contains a number of idempotents, all of which must in fact be contained in $R$; indeed, we can represent any idempotent of the normalization as a product of $s_0$- and $s_1$-invariant idempotents. Since $S_0 \cap S_1$ is local, the dihedral group acts transitively on the idempotents of $R$, and if we multiply an idempotent which is not $s_2$-invariant by general element of $S_i$, we obtain a general element of that summand of the normalization. In other words, if $R$ is not integral, then it is normal. Furthermore, the automorphism $s_0 s_1$ permutes the idempotents; if it acts as an $r'$-cycle, then the action of $D_{2r}$ on $R$ can be obtained by induction from an action of $D_{2r}/r'$ on either a complete dvr or a sum of two complete dvrs swapped by the reflections. In particular, the nonintegral case is always obtained by such an induction from a normal instance $R_0$ of the integral case.

We can use this structure to construct a generator of the kernel in general. If $R$ has $2r'$ idempotents (so $R_0$ has two summands), then $H$ is equal to the twisted group algebra (the coefficient of $N_i$ in $s_i$ is a unit), and thus the kernel is generated by the difference of the reduced words of length $r$. Thus suppose that $R$ has $r'$ idempotents. Then precisely two of those idempotents are invariant under some reflection (which will be the same reflection if $r'$ is even, and different otherwise), giving rise to a pair of operators $\iota_i N_{j(i)} \iota_i$ where $\iota_1$, $\iota_2$ are the two idempotents and $j(i)$ is the index of the reflection fixing $\iota_i$. Note that each operator acts on the corresponding summand as an operator of the form $\nu$. Using this, we obtain a collection of $2r'$ operators from the two reduced words of length $r'$ by replacing single reflections by the corresponding operators $\iota_i N_{j(i)} \iota_i$. (We can either replace any reflection in this way, or can only replace half the reflections, but can do so in two different ways.) Each resulting operator annihilates all but one summand of $R$ and maps into the image of that summand under either word of length $r'$. We have two operators for each such pair of summands, which essentially act as the $N_0$ and $N_1$ on the corresponding copy of $R_0$. We can thus construct a sum of words of length $\leq r/r'$ in such elements with unit (in $R_0$) leading coefficients acting trivially, giving rise to a corresponding sum of words of sum of words of length $\leq r$ in $H$ inside the kernel. The resulting expressions no longer have unit leading coefficients, but their leading coefficients are units inside the appropriate summands, and thus adding up $r'$ such expressions gives the desired generator of the kernel. (Uniqueness in either case follows by base changing to the field of fractions of $S_0 \cap S_1$.)

Thus in any difference case, we have constructed a generator of the kernel of the action of $H$, which we denote by $k$. As an element of the twisted group algebra, we have an expression

$$k = f((\cdots s_1 s_0) - (\cdots s_0 s_1))$$

for some element $f$ of the base change to the field of fractions. Unlike in the differential case, this element does not even commute with multiplication by $R$. This at least partly arises from the fact that “center” is a somewhat ill-defined concept in the case of a $\mathbb{Z}$-algebra like $\mathbf{P}$. The point is that in order to interpret a $\mathbb{Z}$-algebra as coming from a graded algebra, we need to choose an isomorphism between the algebra and a suitable shift, and such an isomorphism need not be unique! In our case, although $k$ does not commute with $R$, it does act as an automorphism of $R$; indeed, if $\omega$ denotes the longest element of $D_{2r}$, then we find that $k x = \omega(x) k$ for all $x \in R$. We also find

$$\omega(\nu_{i}(\omega(f))) = \nu_{i+r}(\omega(\xi))^{-1} \nu_{i+r}(f)$$

and thus this automorphism of $R$ induces an (order 2) automorphism of $H$ by

$$\omega(N_i) = \nu_{i+r}(\omega(\xi))^{-1} N_{i+r}.$$  

We may thus define the “quasi-center” of $\mathbf{P}$ to consist of those morphisms $\phi$ of degree $dr$ such that $\phi \psi = (\omega^d \psi) \phi$. This agrees with the naive notion of center in degrees a multiple of $2r$, but is
better-behaved for odd multiples of $r$, and globalizes just as easily, at least in the untwisted case. It is then straightforward to determine which elements of the rank 2 module $R(\cdots s_1 s_0) + Rk$ are quasi-central.

**Lemma 3.10.** An element $f(\cdots s_1 s_0) + g(\cdots s_0 s_1)$ of degree $r$ is quasi-central iff $f = s_0(g) = s_0 s_1(f)$.

Any quasi-central element of degree $r$ must have this form, and thus to determine the degree $r$ elements of the quasi-center, it suffices to understand the corresponding conditions on $f$ and $g$. It follows from our above calculations that there is a fractional ideal $I$ over $R$ such that $f(\cdots s_1 s_0) + g(\cdots s_0 s_1)$ is in $H$ iff $f, g \in I$ and $f + g \in R$, and thus we need to understand the elements $f \in R_{s_0 s_1}$ such that $f \in I$ and $f + s_0(f) \in R$.

The fractional ideal $I$ can be expressed as a norm (of the inverse of the conductor of $R$ inside its normalization) times a product of inverse differentials (of the normalization of $R$ relative to the $r$ subrings fixed by involutions). The product of inverse differentials is itself an inverse different, due to the following fact.

**Proposition 3.11.** Let $K$ be the field of fractions of a Dedekind ring, and let $L/K$ be a Galois étale $K$-algebra with Galois group $D_{2r}$, let $F_1, \ldots, F_r$ be the subalgebras fixed by the $r$ reflections, and let $E$ be the subalgebra fixed by $G_r$. Then the different of $E/K$ can be computed in terms of the different of $L/F_i$:

$$d_{E/K} = \prod_{1 \leq i \leq r} d_{L/F_i}. \quad (3.28)$$

**Proof.** This is equivalent to the corresponding claim for discriminants, which in turn follows from the conductor-discriminant formula and basic properties of the Artin conductor. \qed

**Corollary 3.12.** The quasi-central elements of degree $r$ in $H$ are naturally identified with the elements of the inverse different of a quadratic extension of $S_0 \cap S_1$.

**Proof.** Letting $K, L, \ldots$ be the étale algebras corresponding to the action of $D_{2r}$ on $R$, we find that the coefficient ideal $I$ is the product of the inverse different $d_{E/K}^{-1}$ by the inverse of the norm $C'$ of the conductor of $R$ inside $O_K$. We thus find that the quasi-central elements may be identified with the space

$$\{x : x \in C'^{-1} d_{E/K}^{-1} | x + s_0(x) \in O_E \}. \quad (3.29)$$

But this is the inverse different of the suborder of conductor $C'$ in $O_E$, which can be expressed as

$$\{x : x \in O_E | x - s_0(x) \in C' d_{E/K} \}. \quad (3.30)$$

\qed

**Corollary 3.13.** The rank 2 free module $R(\cdots s_0 s_1) + Rk$ has an $R$-basis consisting of quasi-central elements.

**Proof.** Let $R'$ be the above quadratic order over $O_K$, so that the quasi-center may be described as the space of elements

$$s_0(f)(\cdots s_0 s_1) + f(\cdots s_1 s_0) \quad (3.31)$$

with $f$ in the inverse different of $R'$. If $\xi'$ generates $R'$ over $O_K$, then this has an $O_K$-basis of the form

$$s_0(f_0)(\cdots s_0 s_1) + f_0(\cdots s_1 s_0), s_0(\xi' f_0)(\cdots s_0 s_1) + \xi' f_0(\cdots s_1 s_0), \quad (3.32)$$

34
where $f_0$ generates the inverse different. It suffices to show that the corresponding $R'$-module contains $(\cdots s_0s_1)$, since then it also contains
\[ f_0((\cdots s_0s_1) - (\cdots s_1s_0)) \in R'k. \] (3.33)
The $R'$-module clearly contains
\[ (s_0(\xi'f_0) - \xi's_0(f_0))(\cdots s_0s_1); \] (3.34)
since
\[ s_0(\xi'f_0) - \xi's_0(f_0) = s_0((\xi' - s_0(\xi'))f_0) \] (3.35)
and $(\xi' - s_0(\xi'))f_0$ is a unit, the result follows. \qed

**Corollary 3.14.** The quasi-center of $\overline{T}$ is generated in degree $r$, and $\overline{T}$ is locally free over its quasi-center.

*Proof.* The space of degree $r$ quasi-central elements has an $S_0 \cap S_1$-basis $Z_0$, $Z_1$ such that $Z_1$ is a unit multiple of $k$ and $Z_0$ acts (as an operator) on $R$ as $\omega$. (Indeed, we may take $Z_1 = f((\cdots s_0s_1) - (\cdots s_1s_0))$ where $f$ is an anti-invariant element of $I$, and then the other basis element in any extension to a basis will act as a unit multiple of $\omega$). If $\phi$ is quasi-central of degree $dr$, then $\phi$ acts on $R$ as an $S_0 \cap S_1$-multiple of $\omega^d$, and thus has the same operator action as some $S_0 \cap S_1$-multiple of $Z_0^d$. Subtracting this multiple to make the operator action trivial makes $\phi$ a left multiple of $Z_1$, and right dividing by $Z_1$ gives a quasi-central element of degree $(d - 1)r$, so that the quasi-center of $\overline{T}$ is generated by $Z_0$, $Z_1$.

Similarly, if $\phi$ is a morphism of degree $dr + (r - 1)$, then there is a unique element $\mu_0$ of degree $r - 1$ acting on $R$ as $\omega^d\phi$, and subtracting $Z_0^{d-1}$ times this element gives $Z_1$ times a morphism of degree $(d - 1)r + (r - 1)$, inducing a unique expression of the form
\[ \phi = \sum_{0 \leq i \leq d} Z_1^i Z_0^{d-i} \mu_i. \] (3.36)
(Here we have used $\omega$ to identify the different Hom spaces of degree $r$ so that it makes sense to take a product of elements $Z_i$, and such products commute as expected.) Local freeness follows immediately. \qed

In particular, $\overline{T}$ indeed corresponds to a (locally free) order over the appropriate ruled surface $Z$, and to show maximality it remains only to check maximality in codimension 1. This is again an Azumaya algebra over a large open subset of $Z$; indeed, if $R$ is regular and unramified over $S_0 \cap S_1$, then the fiber over any point not “at infinity” (i.e., not on the image of $Q$) is a “dihedral” algebra, i.e., the analogue of a cyclic algebra in which the cyclic group is replaced by a dihedral group. The same argument as in the cyclic case tells us that the fiber is central simple of rank $4r^2$. (This is 4 times what we had in the differential case since we are working with $\overline{T}$ rather than $\overline{S}$.)

It remains to consider fibers over ramified points and components of $Q$. The first case reduces to the case that $S_0 \cap S_1$ is a complete dvr. If both $S_0$ and $S_1$ are integral with generators $x_0$, $x_1$, then Lemma 3.31 above gives us a minimal positive integer $m$ such that $(x_1/x_0)^m \in R^*$, and we find as in the differential case that $Hx_0^mH = x_0^mH$ is contained in the radical of the localization of $H$. The quotient by this ideal is central simple (a dihedral algebra of rank $4m^2$), and thus we have maximality as required. (Note that if $m = r$, then we still obtain an Azumaya algebra away from the intersection of $Q$ with the given fiber.) If at least one of $S_0$ or $S_1$ fails to be integral, then $R$ must be integrally closed, and one finds that the radical of the localization of $H$ is generated by
the (principal) radical of \( S_0 \), with quotient central simple of degree \( 4c^2 \) where \( c \) is the number of irreducible components of \( \text{Spec}(R) \). (So again, if \( c = r \), we obtain an Azumaya algebra away from \( \hat{Q} \).

For the completion along a component of \( \hat{Q} \), we may first base change to the function field \( K \) of the base curve. Then \( S_0 \) and \( S_1 \) are fields, and \( R \) is either a field or a sum of two fields, and in each case the completion along \( \hat{Q} \) is the completion along the two-sided homogeneous ideal \( P \rightarrow 2P = t^2P \) (which may not be prime). (The factor of 2 comes from the fact that \( t^r \) is not quasi-central in general!) We find as before that \( P \rightarrow 2P = t^2P \) is contained in the radical of this completion. The \( 2r \)-th Veronese of the quotient is precisely \( Rt^{2r} \), so that the quotient is a field whenever \( R \) is a field, giving maximality in that case. When \( R \) is a sum of two fields, we note that it suffices to prove the corresponding maximality for the spherical algebra, which is a complete Ore ring of the form \( S_0(\langle \rho \rangle) \) where \( \rho \) is an order \( r \) automorphism depending on the choice of component of \( \hat{Q} \). The radical is then the principal ideal generated by \( \rho \), and the quotient is the field \( S_0 \) as required.

We thus conclude that for a quasi-ruled surface of difference type such that \( s_0s_1 \) has order \( r \), \( P \rightarrow \) is (in large degree) isomorphic to the algebra of sections of a maximal order of rank \( 4r^2 \) over the appropriate commutative ruled surface, and this continues to hold globally for an untwisted surface. Twisting is somewhat tricky in this instance, as the quasi-center is not actually invariant under twisting. The existence of some global surface is easy enough, as we can simply take the second Veronese of the quasi-center (i.e., the elements of degree a multiple of \( 2r \)), as then the notion of quasi-center agrees with the naive notion of center and is thus invariant under twisting. This immediately tells us that there is at least a global conic bundle over which the noncommutative surface is a maximal order. We could in principle pin this down by carefully looking at how the twisting occurs, but the precise identification will in any event follow once we have a sufficient understanding of noncommutative elementary transformations. Indeed, we will see below that any twisted quasi-ruled surface of difference type can be related to an untwisted such surface by a sequence of (noncommutative) elementary transformations in smooth points of \( \hat{Q} \), and thus (by Theorem [3.15]) its center is related to the untwisted center by a corresponding sequence of commutative elementary transformations.

In the remaining (hybrid) case, in which one of the two maps (say \( \text{Spec}(R) \rightarrow \text{Spec}(S_0) \)) is inseparable, we have a similar result, in which \( S \) corresponds to a quaternion algebra over an appropriate ruled surface. Note that the argument from the difference case still gives an element \( k \) generating the kernel, so the only missing step is showing that the span of \( s_1 \) and \( k \) is generated by quasi-central elements. This can in principle be done by a direct computation, but we also note that there is an argument via semicontinuity. This is slightly tricky, as we do not actually have suitable semicontinuity locally, but we can rescue this by embedding the desired local situation in a suitable global configuration. It is easy to see that any complete local hybrid case appears inside a global case in which \( C_0 \) (and thus \( C' \)) is isomorphic to \( \mathbb{P}^1 \), so that \( \hat{Q} \) (and thus \( C_\mathbb{Q} \)) is hyperelliptic. We can embed such cases in a larger family by allowing the degree 2 map \( C_0 \rightarrow \mathbb{P}^1 \) to vary (constructing \( \hat{Q} \) via the compositum of field extensions). In the untwisted case with \( \hat{Q} = Q \), the global version of the span of \( s_0s_1 \) and \( k \) is flat over this family, while the \( \mathcal{O}_Q \)-submodule generated by quasi-central elements is upper semicontinuous (as a \( \mathcal{O}_{C'} \)-module) and generically agrees with the larger module, so always agrees with the larger module. It thus follows that any local configuration with trivial conductor has the desired basis of quasi-central elements. To deal with conductors, we observe that the general configuration \( (C_0 \cong \mathbb{P}^1, C_1 \text{ hyperelliptic}, s_0s_1 = s_1s_0) \) makes sense in characteristic 0, and there are characteristic 0 examples with nontrivial conductor. A similar semicontinuity argument gives some characteristic 2 examples with nontrivial conductor, and we can then get
more general characteristic 2 examples with nontrivial conductor by suitable limits (e.g., taking a limit in which several simple cusps coalesce).

One reason we did not spend too much effort determining the explicit center in the twisted case is that there is an alternate approach to computing the center once we know that we actually have a maximal order. The key idea is that, most easily on the Azumaya locus, we can identify the center as a moduli space of 0-dimensional sheaves of degree \( r \) on the noncommutative surface. Indeed, any point on the center pulls back to a degree \( r^2 \) representation of the maximal order corresponding to \( \overline{\mathcal{H}} \), which if the point is in the Azumaya locus is the \( r \)-th power of an irreducible representation of degree \( r \). Thus in particular the fiber of the Azumaya locus over a point of \( C' \) will correspond to such a sheaf which is supported over that point. Using the semiorthogonal decomposition (Theorem 3.4 below), such a sheaf determines and is determined by a morphism of the form

\[
\pi_1^* Z_1 \to \pi_0^* Z_0 \otimes \mathcal{L}
\]

where \( Z_0, Z_1 \) are the respective pullbacks of the point sheaf on \( C' \). Thus the space of such morphisms may be naturally identified with the fiber of \( \pi_* \mathcal{L} \) over the given point of \( C' \). Two such morphisms determine the same object of the derived category iff they are in the same orbit under the actions of \( \text{Aut}(Z_0) \) and \( \text{Aut}(Z_1) \), which act as the corresponding fibers of \( \mathcal{O}_{C_0}^* \) and \( \mathcal{O}_{C_1}^* \), respectively.

There are some technical issues here in general, since not every morphism will correspond to an injective morphism of sheaves on the noncommutative surface, and one must also consider the sheaves only up to \( S \)-equivalence to obtain a well-behaved moduli space. The first issue can be resolved by considering only those morphisms which are isomorphisms of sheaves on \( \hat{\mathcal{O}} \); this gives an open subset which is still large enough to determine the surface. The second issue is more subtle, in general, though only an issue away from the Azumaya locus.

This is, however, enough to let us understand twisting in the difference setting. Consider the locus of \( C' \) over which \( \hat{\mathcal{O}} \) is unramified and equal to \( \overline{\mathcal{O}} \). Over this locus, the fibers of \( \mathcal{O}_{\hat{\mathcal{O}}}^* \) (over which \( \pi_* \mathcal{L}^* \) is a torsor) are algebraic tori, and it is straightforward to see that two points are in the same coset of \( \mathcal{O}_{C_0}^* \mathcal{O}_{C_1}^* \) iff their norms down to \( \mathcal{O}_{\hat{\mathcal{O}}}^* \) are in the same coset over \( \mathcal{O}_{C_0}^* \). We thus find more generally that this component of the moduli space of 0-dimensional sheaves compactifies (fiberwise) to a \( \mathbb{P}^1 \)-bundle (which will, in fact, be the GIT quotient): two nonzero elements of an unramified fiber of \( \pi_* \mathcal{L} \) correspond to the same point of this \( \mathbb{P}^1 \)-bundle iff their norms in the corresponding fiber of \( N_{Q\text{ram}}/Q\text{ram}(\mathcal{L}) \) are in the same \( \mathcal{O}_{C_0}^* \)-orbit.

This description makes sense even on the ramified fibers, with one important caveat: we do not know in general that the norm on \( k(\hat{\mathcal{O}}) \) takes \( \mathcal{O}_{\hat{\mathcal{O}}} \) to \( \mathcal{O}_{\hat{\mathcal{O}}'} \). This holds trivially whenever \( \hat{\mathcal{O}} \) is smooth, and is easy to verify at simple nodes of \( \hat{\mathcal{O}} \), and thus in particular holds as long as \( k(\hat{\mathcal{O}})/k(\hat{\mathcal{O}}') \) is tamely ramified wherever it is totally ramified. As long as it holds, we can define norms of line bundles on \( \hat{\mathcal{O}} \) by taking norms of their 1-cocycles, and find that the norm indeed gives a polynomial function of degree \( r \) from \( \mathcal{L} \) to its norm, compatible with the norms from \( \mathcal{O}_{C_0}^* \) and \( \mathcal{O}_{C_1}^* \) to \( \mathcal{O}_{\hat{\mathcal{O}}}^* \). In other words, the norm induces a morphism from the family of quotient stacks \( \mathcal{O}_{\hat{\mathcal{O}}}^* \mathcal{O}_{C_0}^* \mathcal{O}_{\hat{\mathcal{O}}}^* \) to the \( \mathbb{P}^1 \)-bundle on \( C' \) associated to \( N_{Q\text{ram}}/Q\text{ram}(\mathcal{L}) \). Over the locus where \( k(\hat{\mathcal{O}}) \) is unramified over \( k(\hat{\mathcal{O}}') \), it is easy to see the restriction to \( \mathcal{O}_{\hat{\mathcal{O}}}^*/\mathcal{O}_{C_0}^* \mathcal{O}_{\hat{\mathcal{O}}}^* \) makes the image a coarse moduli space (i.e., that the ratio of the coefficients of the norm generates the field of invariants); outside the Azumaya locus, this fails since the resulting sheaves are no longer irreducible and the \( S \)-equivalence classes contain multiple isomorphism classes.

In fact, since any local trivialization of \( \mathcal{L} \) can be refined to one in which the overlaps are contained in the smooth (or unramified) locus, we can define \( N_{Q\text{ram}}/Q\text{ram}(\mathcal{L}) \) by taking the norm of the associated cocycle; since this is consistent with the gluing of the center over the unramified
locus, this gives us the desired description of the global center. (This strongly suggests that the norm indeed always takes \( \mathcal{O}_Q \) to \( \mathcal{O}_{\hat{Q}'} \).) We can rephrase this in terms of divisors: if \( D \) is a divisor supported on the smooth locus of \( \hat{Q} \), then
\[
N_{\hat{Q}/\hat{Q}'}(\mathcal{O}_Q(D)) \cong \mathcal{O}_{\hat{Q}'}(D')
\]
where \( D' \) is the image of \( D \) in \( \hat{Q}' \). (Note that any line bundle has such a description, which corresponds to a sequence of (noncommutative) elementary transformations that untwist \( \mathcal{L} \).)

In the differential case, the situation is more subtle, as now the quotient is no longer even generically the quotient by a torus. It is still relatively straightforward to identify two semi-invariants of degree \( p \) on the fibers of \( \mathcal{O}_{\hat{Q}} \), namely the coefficients of the restriction of \( \text{Nm}' \) (as defined in Corollary 2.21) to the fiber. Furthermore, at least over the locus with trivial conductor, these are the only semi-invariants of degree \( p \). To see this, it suffices to consider the restriction to fibers of \( \mathcal{O}_{\hat{Q}}^* \), or equivalently to \( k[z, e]/(z^p, e^2)^* \). That \( \mathcal{O}_{C_0}^* \) acts as the norm lets us further restrict to the subgroup \( 1 + (k[z]/z^p)e \), and then using \( \mathcal{O}_{C_1}^* \)-invariance to the quotient of \( (k[z]/z^p)dz \) by the \( \mathbb{F}_p \)-span of the logarithmic differentials. These include the elements \( \frac{a y}{1 + b q} dz \) for \( a, b \in \mathbb{F}_p \), \( y \in k \), and thus (by taking suitable \( \mathbb{F}_p \)-linear linear combinations, essentially a discrete Fourier transform relative to the group \( \mathbb{F}_p^* \)) the elements \( (y + y^p z^{p-1})dz \) and \( y^l z^{p-1}dz \) for \( 1 \leq l < p \). It follows immediately that the field of invariants is generated by a unique function of degree \( p \), giving the desired result. (This fails when the conductor is nontrivial just as in the difference case.) Again, it follows immediately that \( \text{Nm}' \) gives the desired map on twisting data, and here there is no difficulty in dealing with the case of nontrivial conductor, since then \( \hat{Q} \) has trivial Picard group.

In the hybrid case, we suppose that \( \hat{Q} \to C_0 \) is inseparable and consider the locus of \( C' \) over which \( C_0 \) is étale. The corresponding fibers of \( \mathcal{O}_{\hat{Q}} \) have the form \( k[z]/z^2 \oplus k[z]/z^2 \), with \( \mathcal{O}_{C_1}^* \) acting diagonally and \( \mathcal{O}_{C_0}^* \) acting as multiplication by \( k^* \times k^* \). We again find that there are (only) two invariants of degree 2, which on \( (a_0 + a_1 z, b_0 + b_1 z) \) take the values \( a_0 b_0 \) and \( a_0 b_1 + a_1 b_0 \). In particular, just as in the difference case, this is the norm down to \( k(\hat{Q}') \), so that we can deal with twisting in the same way. (Again, we expect this norm to take \( \mathcal{O}_\hat{Q} \) to \( \mathcal{O}_{\hat{Q}'} \) even at singular points of \( \hat{Q} \).)

One reason why twisting was tricky to deal with is that not every line bundle on the noncommutative surface will be the pullback of a line bundle on the center, and we cannot expect there to be a natural choice of such a pullback of degree \( r \) relative to the fibration. In the untwisted case, there was no difficulty: the above construction associates sheaves to any point of a fiber of \( \mathcal{O}_{\hat{Q}} \), and thus in particular associates a canonical family of sheaves to the identity section. This gives rise to a corresponding section of the \( \mathbb{P}^1 \)-bundle over \( C' \), which is why in this case we not only can identify the relevant rank 2 vector bundle on \( C' \), but have a natural choice of map from that vector bundle to \( \mathcal{O}_{C'} \), such that the corresponding section is disjoint from the image of \( \hat{Q} \).

Since we are not only interested in quasi-ruled surfaces themselves, but also those surfaces which are merely birationally quasi-ruled, we also want to understand how to translate a blowup à la van den Bergh into an operation on maximal orders. There is a folklore result (subject to some implicit conditions that exclude some cases of interest in finite characteristic) saying that such a blowup corresponds to blowing up the corresponding point of the underlying commutative surface and choosing a maximal order containing the pulled back algebra. We give a fully general proof of this below. In principle, we would also need to understand blowing down, but this will be dealt with (at least for blowdowns of blowups of quasi-ruled surfaces) via Theorem 8.9 below.

Our objective is to prove the following.
Theorem 3.15. Let $Z$ be a (commutative) smooth surface, let $A$ be an order on $Z$, and let $I \subset A$ be an invertible two-sided ideal such that there is an equivalence $\phi: \text{coh} Y \cong \text{coh}(A/I)$ for a commutative curve $Y$. Let $x \in Y$ be a point such that $\phi(O_X)$ has finite injective dimension as an $A$-module and $A$ is locally free at the point $z \in Z$ on which $\phi(O_x)$ is supported. Then the van den Bergh blowup $\tilde{X}$ of $A$ at $x$ is equivalent to the category $\text{coh} \tilde{A}$ where $\tilde{A}$ is a maximal element of the poset of orders on the blowup $\tilde{Z}$ of $Z$ at $z$ that agree with $A$ on the complement of the exceptional divisor.

Remark. In particular, if $A$ is a maximal order, then so is $\tilde{A}$.

Proof. Since $A$ is an honest sheaf of algebras, the construction of the van den Bergh blowup simplifies considerably, and we find that the blowup may be expressed as the relative Proj of a Rees algebra:

$$\tilde{X} = \text{Proj}(A[m_x \otimes I^{-1}t]),$$

(3.39)

where $m_x$ is the maximal ideal corresponding to $x$ and $t$ is an auxiliary central variable. On the complement of $z$, we get

$$\tilde{X} \cong \text{Proj}(A[I^{-1}t]) \cong \text{coh} A,$$

(3.40)

so it will suffice to understand what happens over the local ring at $z$.

For each integer $l$, define a maximal ideal $m_l \subset A$ by

$$(m_x I^{-1})^l = m_0 m_{-1} \cdots m_{1-l} I^{-l},$$

(3.41)

The quotient $A/m_l$ is supported on $z$ for all $l$, so we may view these as maximal ideals of $A_z$. The significance of these maximal ideals is that

$$(m_x I^{-1})^l = m_0 m_{-1} \cdots m_{1-l} I^{-l}.$$ 

(3.42)

Since $I$ permutes the maximal ideals, the sequence $m_i$ is periodic of some period $n$, and this lets us twist the $rn$-th Veronese of the graded algebra:

$$\tilde{X} \cong \text{Proj}(A[m_0 \cdots m_{1-n} I^{-n}t]) \cong \text{Proj}(A[m_0 \cdots m_{1-n} I^{-l}t]).$$

(3.43)

The latter turns out to have the better behaved center; in particular, we claim that for a suitable choice of $r$, its center is precisely

$$O_Z[m_z t],$$

(3.44)

or in other words that

$$(m_0 \cdots m_{1-n})^{lr} \cap O_Z = m_z^l$$

(3.45)

for all $l \geq 0$. For this claim, it suffices to consider the completion $\hat{A}_z \cong A \otimes O_Z \hat{O}_{Z,z}$.

A somewhat different completion of $A$ was studied in [54], namely the completion with respect to the intersection $\cap_0 \leq i < n m_{-i}$. (To be precise, they studied a ring constructed from the Serre subcategory generated by the $n$ simple modules of $A$, but this is Morita equivalent to the given completion.) Luckily, this completion is equal to $\hat{A}_z$, due to the following fact.

Lemma 3.16. Every maximal ideal of $A_z$ is of the form $m_i$ for some $i$.

Proof. Suppose otherwise, and let $m'$ be some other maximal ideal lying over $z$. Idempotents in $A_z/\text{rad} A_z$ lift over $A_z$, and thus we may find an idempotent $e \in \hat{A}_z$ such that $e \in m_i$ for all $i$. 39
but \( e \notin \mathfrak{m}' \). Since central simple algebras do not have nontrivial two-sided ideals, the ideal \( \hat{A}_z e \hat{A}_z \) contains an ideal of the form \( \mathcal{J} \hat{A}_z \) where \( \mathcal{J} \) is a nonzero ideal of \( \hat{O}_{Z,z} \). In particular, we find that

\[
\mathcal{J} \hat{A}_z \subset \hat{A}_z e \hat{A}_z \subset m_0 \cdots m_{1-l}
\]

for all \( l \geq 0 \), so that

\[
m_0 \cdots m_{1-l} \supset (m_z^l + \mathcal{J}) \hat{A}_z.
\]

It follows in particular that

\[
\dim(\hat{A}_z/m_0 \cdots m_{1-l}) \leq \text{rank}(A) \dim(\hat{O}_{Z,z}/m_z^l + \mathcal{J}) = O(l).
\]

On the other hand, it was shown in [51 Cor. 5.2.4] that this quotient has length \( l(l+1)/2 \), giving a contradiction.

It thus follows from [74] that the completion \( \hat{A}_z \) is Morita equivalent to an algebra \( A \) of the following form. If \( A = R \) is local (so \( \hat{A}_z \) is local), then \( R \) has the form \( k\langle x, y \rangle / \langle \phi \rangle \) where the relation \( \phi \in m_R^2 \) and its image in \( m_R^2 / m_R^3 \) is a rank 2 element of \( (m_R / m_R^2) \otimes k \), and \( Y \) has the form \( \text{Spec}(R/UR) \) where \( U \in m_R \) is a normalizing element such that \( [R, R] \subset UR \). (Note that per [54 Prop. 7.1], the commutator \( [x, y] \) is itself a normalizing element.) More generally, if \( A \) (thus \( A_z \)) has \( n \) maximal ideals, then there is a pair \( (R, U) \) as above with \( U \notin m_R^2 \) such that \( A \) is isomorphic to the subalgebra of \( \text{Mat}_n(R) \) in which the coefficients above the diagonal are multiples of \( U \). In this case, the curve \( Y \) is cut out by the normalizing element \( N \) which has just below the diagonal, \( U \) in the upper right corner, and 0 everywhere else. We note that the center of \( A \) consists precisely of the matrices \( zI \) with \( z \in Z(R) \), so that that \( A \) is free over its center if \( R \) is free over its center. The maximal ideals of \( A \) are \( m_1, \ldots, m_n \) where \( m_i \) is cut out by the condition that \( a_{ii} \in m_R \), and these satisfy \( Nm_i = m_{i+1}N \), with subscripts interpreted cyclically.

Note that in our case, the algebra \( A \) satisfies the additional condition that it is free as a module over its center. Moreover, the claim about how the center of \( \hat{A}_z \) meets the products of maximal ideals reduces to the corresponding claim about the center of \( A \), which we refine to

\[
(m_n \cdots m_1)^r \cap Z(A) = m_{Z(A)}^r
\]

where \( r \) is the square root of the rank of \( R \) over its center. (Equivalently, \( \text{rank}(A) = r^2 \).) An easy induction shows that

\[
m_n m_{n-1} \cdots m_1 \subset m_R \text{Mat}_n(R),
\]

or in other words that given any sequence of elements of the appropriate ideals, their images in \( \text{Mat}_n(k) \) multiply to 0. The codimension of this product is known (again by [51 Cor. 5.2.4]), so that one immediately concludes

\[
m_n m_{n-1} \cdots m_1 = A \cap m_R \text{Mat}_n(R),
\]

and similarly

\[
(m_n m_{n-1} \cdots m_1)^l = A \cap m_R^l \text{Mat}_n(R).
\]

(These identities are implicit in [51 Prop. 5.2.2].) Since the center of \( A \) is the center of the diagonal copy of \( R \), we conclude that

\[
(m_n m_{n-1} \cdots m_1)^r \cap Z(A) = m_{Z(R)}^r \cap Z(R),
\]
so that it remains only to show that

$$m^l_{R} \cap Z(R) = m^l_{Z(R)}. \tag{3.54}$$

To finish the argument, we will need a couple of lemmas about orders over dvrs with sufficiently nice residue field.

**Lemma 3.17.** Let $R$ be a dvr with residue field $k$ and field of fractions $K$, and suppose that $cd(k) \leq 1$. Let $A$ be an $R$-order in a central simple $K$-algebra of degree $r$. Then any simple $A$-module has dimension at most $r$ as a $k$-space.

**Proof.** We may as well pass to the completion, as this has no effect on the simple modules. Suppose first that $A$ is a maximal order. Then $A/\text{rad}(A) \cong \text{Mat}_d(l)$ where $l/k$ is a field extension of degree $r/d$. If $A \otimes_R K$ is a division ring, then this follows from [43 Thm. 14.3] with $d = \sqrt{r}$; this result was only stated for the case of finite residue field, but the proof only used triviality of $\text{Br}(k)$. More generally, $A$ is a matrix ring over a maximal order in a division ring with center $K$, and thus the result follows in general from [43 Thm. 17.3]. Thus in the maximal order case, $A$ has a unique simple module isomorphic to $l^d$, and thus of dimension $r$ over $k$.

In general, there exists a maximal order $B$ containing $A$. Then $\text{rad}(B) \cap A \subset \text{rad}(A)$, and $A/(\text{rad}(B) \cap A) \subset B/\text{rad}(B) \cong \text{Mat}_d(l)$. It follows that $A/\text{rad}(A)$ is a sum of matrix algebras of the form $\text{Mat}_{d'}(l')$ where $l'/l$ is a field extension such that $d'[l':l] \leq d$. Each summand corresponds to a simple module with $k$-dimension $d'[l':k] \leq d[l:k] = r$ as required. \hfill \Box

**Remark.** To see that $\text{rad}(B) \cap A$ is contained in the radical of $A$, observe that this is a two-sided ideal, and thus it suffices to show that $1 - z$ is a unit for all $z \in \text{rad}(B) \cap A$. But this follows from the fact that $\lim_{n \to \infty} z^n = 0$ relative to the natural topology in $B$.

**Corollary 3.18.** With $R$ and $A$ as above, the left $A$-module $A \otimes_R k$ has length at least $r$ (with equality if $A$ is maximal).

**Proof.** Indeed, $A \otimes_R k$ has dimension $r^2$, while each simple constituent contributes at most $r$ to the dimension. \hfill \Box

**Proposition 3.19.** Let $k$ be an algebraically closed field, and let $R = k[[x,y]]/\Phi$ with $\Phi \in m^2_{R}$, $\Phi_2$ nondegenerate. If $Z(R)$ is a regular 2-dimensional ring and $R$ is a free $Z(R)$-module of rank $r^2$, then for any $l \geq 0$,

$$m^l_{R} \cap Z(R) = m^l_{Z(R)}. \tag{3.55}$$

**Proof.** Since $Z(R)$ is regular, we may write it as $k[[u,v]]$ for suitable central elements $u$ and $v$, where WLOG $\deg(u) \leq \deg(v)$; moreover, if $\deg(u) = \deg(v)$, we may assume the leading terms are linearly independent, as otherwise we can subtract a multiple of $u$ from $v$ to increase the latter’s degree. The claim will follow immediately if we can show that $\deg(u) = \deg(v) = r$, since then their images in $\text{gr} \ R$ are algebraically independent. (The center of $\text{gr} \ R$ is easily seen to be of the form $k[u',v']$ with $\deg(u') = \deg(v')$ a divisor of $r$, and linearly independent homogeneous polynomials of the same degree are algebraically independent.)

The freeness condition implies that $\dim_k(R/m_{Z(R)}R) = r^2$, while the Hilbert series of $m_{Z(R)}R = uR + vR$ (i.e., the Hilbert series of the associated graded) is upper bounded (in each coefficient) by

$$z^\deg(u)/(1 - z)^2 + z^\deg(v)/(1 - z)^2. \tag{3.56}$$
Thus the Hilbert series of the quotient is lower bounded by

\[
\frac{1 - z^{\deg(u)} - z^{\deg(v)}}{(1 - z)^2} = \frac{(1 - z^{\deg(u)})(1 - z^{\deg(v)})}{(1 - z)^2} + O(z^{\deg(u)+\deg(v)}). \tag{3.57}
\]

The first term has degree \(\deg(u) + \deg(v) - 2\), and thus the dimension is at least the value of the first term at \(z = 1\), i.e., \(\deg(u)\deg(v)\), so that \(\deg(u)\deg(v) \leq r^2\).

Now, \(u\) generates a prime ideal in \(Z(R)\), and the residue field of the localization is isomorphic to \(k((u))\), so has cohomological dimension \(\leq 1\) by \([54]\). We may thus apply the Corollary to conclude that \(R_{(u)/uR_{(u)}}\) has length \(\geq r\), so that we may choose a chain

\[
R_{(u)} = I_0 \supseteq I_1 \supseteq \cdots \supseteq I_r = uR_{(u)} \tag{3.58}
\]

of left ideals. Since \(R\) has global dimension \(2\) (\([51]\)), each module \(R \cap I_i\) is free, and thus we may choose a sequence of elements \(z_i\) such that \(R \cap I_i = z_iR\), with \(z_0 = 1\), \(z_r = u\), so that we have represented our chain as a descending chain of principal left ideals. Since \(z_iR \supseteq z_{i+1}R\), it follows that \(z_i \in z_i m_i\) for \(1 \leq i \leq n\), and thus \(u = z_r \in m_r^r\), so that \(r \leq \deg(u) \leq \deg(v)\), which together with \(\deg(u)\deg(v) \leq r^2\) implies \(\deg(u) = \deg(v) = r\).

**Remark.** It follows from the proof that \(uR + vR\) has Hilbert series \((2z^r - z^{2r})/(1 - z)^2\), and thus that \(\text{gr } u\) and \(\text{gr } v\) have no nontrivial syzygies. In particular, they have trivial gcd as elements of the polynomial ring \(\mathbb{Z}(\text{gr } R)\).

We thus find that the van den Bergh blowup indeed corresponds to a sheaf \(\mathcal{A}\) of algebras on \(\tilde{Z}\). Moreover, that sheaf is coherent, since if we quotient by the degree 1 elements of the center, the resulting graded algebra has bounded degree; this reduces immediately to the completion and thus to \(A\) since it is really a question about modules.

It remains only to show that \(\mathcal{A}\) is maximal among orders agreeing with \(A\) outside the exceptional locus \(e\). This reduces to showing that it is locally free at any point of \(e\) and that its completion at the corresponding valuation is maximal. Here we may use what we know about sheaves on the blowup.

The local freeness condition reduces to showing that \(\mathcal{A} \otimes_{\mathcal{O}_{\tilde{Z}}} \mathcal{O}_e\) is a torsion-free sheaf on \(e\). The result is an extension of \(\mathcal{A}\)-modules of the form \(\mathcal{O}_e(d)\), so it suffices to prove the result for those modules. Twisting by \(\mathcal{O}_{\tilde{Z}}(-ne)\) for \(n \gg 0\) lets us reduce to the case \(d < 0\), where it follows from the fact that \(\mathcal{O}_e(d)\) has no global sections. (Here we meant \(\mathcal{O}_e(d)\) as a sheaf on the blowup, though it follows from torsion-freeness and the Euler characteristic that it is also \(\mathcal{O}_e(d)\) as a sheaf on \(\tilde{Z}\) …)

It remains only to show maximality over the local ring at \(e\). Since \(A_z\) has global dimension 2 (its simple modules have injective dimension 2, since this holds for \(A\), the same holds for the blowup, and thus the localization of the blowup has global dimension 1, so is hereditary. Moreover, it has a unique simple module (the now isomorphic sheaves \(\mathcal{O}_e(d)\)), and thus is maximal as required, finishing the proof of Theorem 3.15. \(\square\)

**Corollary 3.20.** With hypotheses as above, if the orbit of \(x \in Y\) has size \(r\), then \(\mathcal{A}\) is an Azumaya algebra on every point of \(e\) not meeting the blowup of \(Y\).

**Proof.** In this case, \(R = Z(R)\) and \(A\) is the order in \(\text{Mat}_r(R)\) consisting of matrices in which the entries above the diagonal are multiples of the equation \(U\) of \(Y\) inside \(\text{Spec}(R)\). The relevant affine patch of the blowup is then given by \(A[m_r \cdots m_1 U^{-1}] \cong \text{Mat}_r(R[m_R/U])\), so that \(\mathcal{A}\) is a matrix algebra on the complement of \(Y\) in the pullback of the local ring at \(z\). \(\square\)
Remark. This result is particularly nice in the case of ruled surfaces, when every orbit has size 1 or \( r \), so that when an iterated blowup of a noncommutative ruled surface is a maximal order, it is an Azumaya algebra on the complement of the curve of points.

In the cases of present interest, the invertible ideal corresponding to the divisor \( Y \) is \([A, A]A\) (i.e., the ideal sheaf of the scheme classifying \( A \)-module quotients of \( A \) with Hilbert polynomial 1 over \( Z \)), and we would like to understand the corresponding ideal in \( \widetilde{A} \). That is, we want to know how the curve of points on \( \widetilde{X} \) is related to the curve of points on \( X \).

**Proposition 3.21.** Let \( Z \) be a (commutative) smooth surface, let \( A \) be an order on \( Z \) such that the commutator ideal is invertible, and let \( \mathfrak{m} \) be a maximal ideal of \( A \) containing the commutator ideal. If \( \widetilde{A} \) is the order obtained by blowing up \( \mathfrak{m} \), then the commutator ideal of \( \widetilde{A} \) is invertible, and in the notation of [51] is isomorphic to \( \mathcal{O}(-1) \).

**Proof.** This is a local question, and thus reduces to showing that for \( l \gg 0 \), the degree \( l \) component of the commutator ideal of the graded algebra \( A[(n \cdots m_1)^r \cdot t] \) is equal to

\[
Nm_{n-1} \cdots m_1(m_n \cdots m_1)^{r-1} t^l,
\]

(3.59)
corresponding to the ideal generated by \( t \) in the original graded algebra before taking the Veronese and twisting.

For \( n > 1 \), we first observe that

\[
A[\mathfrak{m} \cdots \mathfrak{m}_1, \mathfrak{m} \cdots \mathfrak{m}_1^2]A \subset N\mathfrak{m}_{n-1} \cdots \mathfrak{m}_1(m_n \cdots m_1)
\]

(3.60)
or in other words the subspace of \( A \) in which the coefficients on or above the diagonal are in \( \mathfrak{m}_R \) and the coefficients below the diagonal are in \( \mathfrak{m}_R^2 \). This is a two-sided ideal, so it suffices to consider commutators, and since the ideal differs from \( (\mathfrak{m}_n \cdots \mathfrak{m}_1)^2 \) only in the diagonal, it suffices to consider the diagonal coefficients of commutators. The only commutators that can possibly contribute are those of diagonal matrices, where the claim follows from \([R, R] \subset U R\).

We can now compute by induction that for \( a, b \geq 1 \),

\[
A[(n \cdots m_1)^a, (n \cdots m_1)^b]A \subset Nm_{n-1} \cdots m_1 (m_n \cdots m_1)^{a+b-1},
\]

(3.61)
while a similar calculation gives

\[
A[A, (n \cdots m_1)^a]A = Nm_{n-1} \cdots m_1 (m_n \cdots m_1)^{a-1}.
\]

(3.62)
It follows that the given ideal agrees with the commutator ideal in positive degree, so the saturations agree.

It remains only to consider the case \( n = 1 \). Let \( r' = p \) if \( \text{gr} \ R \) is abelian, and otherwise let \( r' \) be the rank of \( \text{gr} \ R \) over its center. Then \( r \) is a multiple of \( r' \), and we may reduce to showing

\[
R[m^{r'}, m^{r''}]R \subset m^{2r'-1} U
\]

(3.63)
and

\[
R[R, m^{r''}]R = m^{r'-1} U.
\]

(3.64)
If \( \text{gr} \ R \) is abelian, then \( (g, h) \mapsto [g, h]U^{-1} \) induces a Poisson structure on \( \text{gr} \ R = k[x, y] \), namely the degree \(-2\) bracket \( \{x, y\} = 1 \), and the claims become that the bracket vanishes when both arguments have degree \( p \) and that any homogeneous polynomial of degree \( p - 1 \) is in the span of the brackets with one argument of degree \( p \). For the first claim, we have

\[
x^a y^{p-a}, x^b y^{p-b} = (a(p-b) - (p-a)b)x^{a+b-1}y^{2(p-a)-1} = 0,
\]

(3.65)
and the second claim follows by noting that the brackets with \( x \) span the polynomials not of degree \( p - 1 \) in \( y \), while the brackets with \( y \) span the polynomials not of degree \( p - 1 \) in \( x \).

When \( \text{gr} \, R \) is not abelian, then the calculation reduces to one in \( \text{gr} \, R \), so that we reduce to considering \( k(x, y)/(yx - qxy) \) and \( k(x, y)/(yx - xy - x^2) \). The first (q-Weyl) case is straightforward:

\[
[x^{a} y^{b}, x^{c} y^{d}] = (q^{bc} - q^{ad}) x^{a+c} y^{b+d},
\]

which again is 0 if \( q^{a+b} = q^{c+d} = 1 \), and the span \( \langle [x, x^{a} y^{b}], [y, x^{a} y^{b}] \rangle \) for \( a + b = \text{ord}(q) \) has the correct dimension.

For \( k(x, y)/(yx - xy - x^2) \), we observe that this has a representation in differential operators: \( x = \pi, y = t^2 D_t \). We in particular easily find \( [y, x^{a} y^{p-a}] = a x^{a+1} y^{p-a} \) which together with \( [x, x^{p-1} y] = -x^{p+1} \) span a space of the correct dimension. It thus remains only to show that \( [x^{a} y^{p-a}, x^{b} y^{p-b}] = 0 \).

Doing the change of variable \( t \mapsto 1/t \) in the corresponding commutator of differential operators and observing that \( t^p \) is central reduces this to showing that \( [t^a D_t^b, t^b D_t^b] = 0 \), which is true in arbitrary characteristic since \( t^a D_t^b \) is a polynomial in \( t D_t \) for all \( a \geq 0 \).

\[ \square \]

In the proof that the blowup of a maximal order is a maximal order, we skirted around the question of determining the precise structure of the localization along the exceptional divisor. Although this is somewhat tricky to determine in general, it is fairly straightforward in the cases corresponding to ruled surfaces.

For instance, in the difference cases of elliptic or multiplicative type, the division ring is a localization of the ring of (symmetric) difference operators. Over the local ring of a codimension 1 point, the residue field of the maximal order is a separable extension of the residue field of the center. Choose an element \( u \) whose image generates that extension (of degree \( n \) if the division ring has dimension \( n^2 \)), and observe that if take the corresponding unramified base change, then this splits the division ring, and lets us see that for each element \( \sigma \) of the Galois group, there is an \( n \)-dimensional subspace of the division ring consisting of elements \( v \) satisfying \( v u = \sigma(u) v \), which is then a 1-dimensional space over \( k(u) \). In particular, there exists an element of this form having valuation 1, so that \( v^n \) is a uniformizer of the center.

For the remaining cases, a key observation is that given a discrete valuation on the center of a division ring, there is a unique extension to a maximal order over the valuation ring. In particular, blowing up does not change the division ring, merely the set of available valuations. We claim that the division ring is generated over its center by elements \( u, v \) such that \( [u, v] = 1 \). This is clear in the differential cases, while the remaining cases (additive difference and the hybrid case) are birational to the differential case, so have the same division ring. We then find the following.

**Proposition 3.22.** Let \( X \) be a rationally ruled surface over a field of characteristic \( p \) such that \( Q \) has a non-nodal singular point. Then \( X = \text{Spec}(\mathcal{A}) \) for a maximal order \( \mathcal{A} \) with generic fiber a division ring, and for any associated point \( x \in Q \), the localization \( \mathcal{A}_x \) is generated by elements \( u, v \) with \( u \) a unit, \( v \) of valuation 1, and \( [u, v] = v^m \), where \( m \) is the multiplicity of \( Q \) along \( x \).

**Proof.** We need to understand the extension of the generic fiber of \( A \) to the corresponding valuation ring, and have already observed that the generic fiber is generated by elements \( u, v \) with \( [u, v] = 1 \), \( u^p = U, v^p = V \) for appropriate elements \( U, V \) of the center. If these elements are both integral, then \( 1 \in [A_x, A_x] \), so that \( x \) was not a component of \( Q \). If \( U \) has valuation a multiple of \( p \) and its leading coefficient is a \( p \)-th power, then we can subtract a central element from \( u \) to make \( U \) smaller, and similarly for \( V \). If \( U \) and \( V \) still both have valuation a multiple of \( p \), then we can rescale \((u, v) \mapsto (\pi^i u, \pi^{-i} v)\), where \( \pi \) is a uniformizer of the center, to make \( U \) a unit which is not
a $p$-th power in the residue field. In particular, $U + m$ generates the residue field over its $p$-th power subfield, so that we may add a suitable polynomial in $u$ to $v$ to reduce its valuation.

In this way, we reduce to the case that at least one of $u$ or $v$ (say $v$) has valuation prime to $p$. For any integers $a, l$ with $a$ prime to $p$, there is an automorphism

$$(u, v) \mapsto (a^{-1}v^{-1}u^{1-a}, \pi^l u^n)$$

(3.67)

of the division ring, and thus by suitable choice of $l$ and $a$, we may arrange to have $v$ (and thus $V$) of valuation $1$. If $U$ has valuation $-l$, then $v^l u$ is a unit, and we have

$$[v^l u, v] = v^l.$$  

(3.68)

These elements still generate the division ring, and the order they generate is easily verified to be maximal, so that they generate $A_x$ as required. Moreover, it follows that the 2-sided ideal generated by commutators is the principal ideal generated by $v^l$, so that the quotient has length $l = m$.

$\square$

Remark. Note that when the multiplicity is 1, this looks like $uv = v(u + 1)$, which is an instance of the separable case, and in particular shows directly that the additive difference cases are birational to the differential cases.

Remark. The situation for quasi-ruled surfaces is more complicated, as the residue field extension may be an inseparable extension of degree larger than $p$.

It would be nice to have a similar description for the localizations of $A$ at closed points of $Q$, even if only for the corresponding completion. For the completion, there is no difficulty at smooth points, as in the ruled case the relevant automorphism acts faithfully, and thus we obtain the situation above with $A \subset \text{Mat}_n(R)$ and $R$ abelian. At nodes, the situation is only slightly more complicated. In that case, the leading term of the relation of $R$ must be $vu - quv$ with $q$ a primitive $n$-th root of unity, and in any such ring, one can perform changes of variables to make the relation have the form $vu = quv + u\Phi v$ where $\Phi$ is in the span of $v^i u^j$ with $i + j > 0$. (We certainly have a relation of the form $vu = quv + \Phi'$ with $\Phi'$ in the span of $u^i v^j$ with $i + j > 0$, and if $\Phi'$ is only of the form $u\Phi v$ to degree $d$, then we can improve the agreement by adding suitable terms of degree $d$ to $u$ and $v$.) Then $(u, v) \mapsto (qu, v)$ and $(u, v) \mapsto (u, qv)$ are automorphisms, so act on the center. The center is generated by two elements of degree $n$, the leading terms of which must be central in the associated graded of $R$, so are in the span of $u^n$ and $v^n$. It then follows that the center is generated by invariant elements, and must therefore (by Hilbert series considerations) be isomorphic to $k[[u^n, v^n]]$. In particular, $\Phi$ is central, and thus

$$v^n u^n = (q + \Phi)^n u^n v^n,$$

(3.69)

so that $\Phi = 0$. In other words, the completion at a node has the form $k(\langle u, v \rangle)/(vu - quv)$ where $q$ is a primitive $n$-th root of unity.

Thus only the differential (or additive) case remains open. It is unclear whether simply having degree $p^2$ over the center is enough to pin down the completion (possibly together with the known possibilities for the structure of $R/R[R, R|R]$) as it was in the above case of degree prime to $p$.

4 Noncommutative surfaces as $t$-structures

Although the above construction of noncommutative ruled surfaces was well suited to an interpretation via difference/differential operators as well as to understanding the center, it is not ideal
for a number of other applications, especially since it does not behave well in families. Van den Bergh's original construction does not have this issue, but in some respects turns out to be too explicit; constructing the various isomorphisms we require (e.g., between the two interpretations of a noncommutative $\mathbb{P}^1 \times \mathbb{P}^1$ as a ruled surface) via that construction either requires working with sheaves on highly singular curves or requires that one split into a large number of separate cases that can be dealt with explicitly. Luckily, it turns out that there is another way to construct noncommutative $\mathbb{P}^1$-bundles: there is a relatively simple description of the corresponding derived category, as well as the associated $t$-structure. Although this construction cannot quite replace van den Bergh's construction (our proof that the category is the derived category of the heart of the $t$-structure uses van den Bergh's construction), it gives an alternate approach to constructing isomorphisms, namely as derived equivalences respecting the $t$-structures. In each of the cases of interest, it is easy to construct the derived equivalence corresponding to the desired isomorphism, and not too difficult to show sufficient exactness.

The overall approach works for each of the main constructions in the literature (noncommutative (projective) planes \cite{Bergh1, Bergh2}, noncommutative $\mathbb{P}^1$-bundles \cite{VdB}, and blowups \cite{Huyb}), but we begin by considering the $\mathbb{P}^1$-bundle case. The basic idea is that there is a natural semiorthogonal decomposition of the derived category of a commutative $\mathbb{P}^1$-bundle over a smooth projective scheme. Not only does this extend to the noncommutative setting, but we shall see that one can recover the $t$-structure from the decomposition. Although the discussion below works for general noncommutative $\mathbb{P}^1$-bundles over smooth projective schemes, we consider only the surface case, and at least initially work over an algebraically closed field. (Otherwise, we would need to consider things like conic bundles!)

Recall that the category qcoh $\tilde{S}$ is defined as the quotient of the category of $\tilde{S}$-modules by the subcategory of bounded such modules (i.e., which become 0 in sufficiently large degree), with coh $\tilde{S}$ the subcategory of Noetherian modules. For each $d$, there is a natural functor $\rho_d^{-1}$ from coh($C_d := C_{d \mod 2}$) to the category of $\tilde{S}$-modules taking a coherent sheaf $M$ on $C_d$ to the representation which in degree $d'$ is $\tilde{S}_{d'} \otimes_{C_d} M$. Composition with the quotient morphism gives a functor $\rho_d^* : \text{coh } C_d \to \text{coh } \tilde{S}$. Since the quotient morphism has a right adjoint, as does $\rho_d^{-1}$, it follows that $\rho_d^*$ has a right adjoint $\rho_d$.

**Lemma 4.1.** For any vector bundle $V$ on $C_0$, the quadratic relation gives rise to an exact sequence

$$0 \to \rho_2^*(V \otimes \text{det}(\pi_0, \mathcal{O}_Q)^{-1}) \to \rho_1^*(\pi_1(\pi_0^*V \otimes \tilde{S}_0)) \to \rho_0^*V \to 0. \tag{4.1}$$

**Proof.** It suffices to check exactness locally, where it reduces to showing exactness of

$$0 \to \tilde{S}_{2n} \to \tilde{S}_{1n} \otimes \tilde{S}_0 \to \tilde{S}_{0n} \to 0. \tag{4.2}$$

The second (multiplication) map is surjective since $\tilde{S}$ is generated in degree 1, while the first map is

$$x \mapsto (xN_0e_1 \otimes N_1\xi_1e_0) - (xN_0s_1(\xi_1)e_1 \otimes N_1e_0), \tag{4.3}$$

which maps into the kernel of the second map. Since

$$x = (xN_0e_1)(N_1\xi_1\xi_0e_0) - (xN_0s_1(\xi_1)e_1)(N_1\xi_0e_0), \tag{4.4}$$

the map from $\tilde{S}_{2n}$ to the kernel of the second map splits, and is thus an isomorphism by rank considerations.

**Lemma 4.2.** For $M \in D_{\text{qcoh}}\tilde{S}$, if $R\rho_0_*M = R\rho_1_*M = 0$, then $M = 0$.
Proof. Suppose $M$ is an object such that $R\rho_0 M = R\rho_1 M = 0$. From the previous Lemma, we deduce that for any vector bundle $V$ on $C_0$, $R\text{Hom}(L\rho_0^* V, M) = 0$, and thus $R\rho_2 M = 0$. It follows by induction that $R\rho_d M = 0$ for all $d \geq 0$, and thus that the cohomology modules of the corresponding complex in $\mathcal{S}\text{-mod}$ are torsion, so that $M$ is in $D_{\text{qcoh}}\mathcal{S}$. \qed

The following was essentially shown in [29], subject to the (luckily unused) assumption that the two base schemes (i.e., $C_0$ and $C_1$) are equal. (To be precise, the reference showed the result when $M$ and $N$ are line bundles, but this implies it in general.)

Lemma 4.3. [29, Lem. 4.4] For $M, N \in D_{\text{coh}}^b C_d$, one has $R\text{Hom}(L\rho_d^* M, L\rho_d^* N) = R\text{Hom}(M, N)$, while for $N' \in D_{\text{coh}}^b C_{d+1}$ one has $R\text{Hom}(L\rho_d^* M, L\rho_{d+1}^* N') = 0$.

Combining the above, we obtain the following.

Theorem 4.4. The subcategories $L\rho_0^* D_{\text{coh}}^b C_0$ and $L\rho_1^* D_{\text{coh}}^b C_1$ form a semiorthogonal decomposition of $D_{\text{coh}}^b \mathcal{S}$: for any object $M \in D_{\text{coh}}^b \mathcal{S}$, there is a unique distinguished triangle of the form

$$L\rho_0^* N_0 \to M \to L\rho_1^* N_1 \to .$$

(4.5)

Proof. Adjunction gives a natural morphism $L\rho_0^* R\rho_0 M \to M$, which extends to a distinguished triangle

$$L\rho_0^* R\rho_0 M \to M \to M' \to .$$

(4.6)

Applying $R\rho_0$ and using $R\rho_0 L\rho_0^* \cong \text{id}$ implies that $R\rho_0 M' = 0$. The natural distinguished triangle

$$L\rho_1^* R\rho_1 M' \to M' \to M'' \to$$

(4.7)

then gives an object $M''$ such that $R\rho_1 M'' = 0$ and $R\rho_0 M'' \cong R\rho_0 M' = 0$, and thus $M'' = 0$, so that $M'$ is in the image of $L\rho_1^*$.

For uniqueness, observe that for any such triangle, applying $R\rho_0$ gives $N_0 \cong R\rho_0 M$. \qed

Remark. As we mentioned, the same proof shows that this holds more generally for the noncommutative $\mathbb{P}^1$-bundle associated to any sheaf bimodule on Noetherian schemes $Y_0$ and $Y_1$, except that if the base schemes are singular, one should instead work with the categories of compact objects (which on $Y_i$ are just the perfect complexes).

The semiorthogonal decomposition yields two immediate corollaries. The first is that we can easily compute the Grothendieck group of $\text{coh} \mathcal{S}$, since the Grothendieck of a derived category with a semiorthogonal decomposition is just the sum of the Grothendieck groups of the two subcategories.

Corollary 4.5. We have $K_0 \text{coh} \mathcal{S} \cong K_0 \text{coh} C_0 \oplus K_0 \text{coh} C_1$.

Furthermore, the Mukai pairing on $K_0 \text{coh} \mathcal{S}$ is easily reconstructed from the pairings on $C_0$ and $C_1$ and the induced pairing

$$(M, N) \mapsto \chi R\text{Hom}(\rho_1^* M, \rho_0^* N)$$

(4.8)

between the two curves. The relevant Hom space was again computed in [29].

Lemma 4.6. We have $R\text{Hom}(\rho_1^* M, \rho_0^* N) \cong R\text{Hom}(M, N \otimes_{C_0} \mathcal{S}_{01})$.

The other corollary is slightly more subtle. Since we have not just one semiorthogonal decomposition, but one for each $d$, and $L\rho_d^* D_{\text{coh}}^b C_d$ appears in two such decompositions, once on each side, we find that each such subcategory is admissible. Since both subcategories have Serre functors (being derived categories of projective schemes), the same is true for $D_{\text{coh}}^b \mathcal{S}$ (per [10, Prop. 3.8]). Moreover, we can compute the Serre functor explicitly.

47
Proposition 4.7. The triangulated category $\mathcal{D}_{\text{coh}}^b \hat{S}$ has a Serre functor $S$ which is the composition of $M \to M(-\hat{Q})[2]$ with twisting by the pair of line bundles $\omega_C \otimes \det(\pi_\ast \mathcal{O}_{\hat{Q}})^{-1}$ having the same pullback to $\hat{Q}$.

Proof. It suffices to compute how the Serre functor acts on the two pieces of the semiorthogonal decomposition, and thus (since shifting degrees gives another quasi-ruled surface) how it acts on an object $L_{\rho_0}^* M$. We thus need an object $SL_{\rho_0}^* M$ such that

$$\text{Hom}(L_{\rho_0}^* N, SL_{\rho_0}^* M) \cong \text{Hom}(L_{\rho_0}^* M, L_{\rho_0}^* N)^* \cong \text{Hom}(M, N)^* \cong \text{Hom}(N, SM),$$

(4.9)

where we also denote the Serre functor on $\mathcal{D}_{\text{coh}}^b C_0$ by $S$, and

$$\text{Hom}(L_{\rho_1}^* N, SL_{\rho_0}^* M) \cong \text{Hom}(L_{\rho_0}^* M, L_{\rho_1}^* N)^* = 0.$$  

(4.10)

In other words, we want $R_{\rho_0}^* SL_{\rho_0}^* M \cong SM$ and $R_{\rho_1}^* SL_{\rho_0}^* M = 0$.

Now, the short exact sequence of Lemma [4.1] extends to a distinguished triangle for perfect complexes in general, of the form

$$L_{\rho_2}^*(N \otimes \det(\pi_0^* \mathcal{O}_{\hat{Q}})^{-1}) \to L_{\rho_1}^*(N \otimes C_0 \hat{S}_{01}) \to L_{\rho_0}^*(N) \to.$$  

(4.11)

Applying $R_{\rho_0}^*$ gives

$$R_{\rho_0}^* L_{\rho_2}^*(N \otimes \det(\pi_0^* \mathcal{O}_{\hat{Q}})^{-1}) \cong N[-1]$$

(4.12)

while applying $R_{\rho_1}^*$ makes the second map an isomorphism, so that

$$R_{\rho_1}^* L_{\rho_2}^*(N \otimes \det(\pi_0^* \mathcal{O}_{\hat{Q}})^{-1}) = 0.$$  

(4.13)

We thus conclude that

$$S_{\rho_0}^* M \cong p_2^*(SM \otimes \det(\pi_0^* \mathcal{O}_{\hat{Q}})^{-1})[1].$$  

(4.14)

The claimed form for $SM$ then follows by writing $SM$ as $M \otimes \omega_{C_0}[1]$. 

Remark. The analogous result was shown (again with the assumption that the base schemes are isomorphic) for general smooth projective base in [33]. The semiorthogonal decomposition yields a significant streamlining of the argument, however.

Since $M(-Q)$ itself differs from $M(-\hat{Q})$ by a pair of twists by line bundles, we can also write the Serre functor as the composition of $\underline{(-Q)}[2]$ with twisting by $\omega_C \otimes \det(\pi_\ast \mathcal{O}_{\hat{Q}})^{-1}$. As we remarked after Proposition 2.17, these bundles are trivial iff the surface is ruled, and thus we obtain the following.

Corollary 4.8. The surface $\hat{S}$ is ruled iff the Serre functor is equivalent to $\underline{(-Q)}[2]$.

In other words, a quasi-ruled surface is ruled iff the curve of points is anticanonical.

There is one important notational issue to consider here, namely that since $\hat{Q}$ does not behave well in flat families, neither do the functors $L_{\rho_0}^*$ in general (though for $d \notin \{0, 1\}$, we can rephrase everything in terms of the sheaf bimodule). We could fix this by using the labelling of [53], but it turns out that there is an even nicer choice. If we leave $\rho_0^*$ and $\rho_1^*$ fixed, then we may twist the remaining functors by line bundles and automorphisms so that

$$L_{\rho_{d+2}^*} = SL_{\rho_d^*} S^{-1}[-1]$$

(4.15)
With this relabelling, the distinguished triangle coming from the semiorthogonal decomposition becomes

$$L\rho_{d+1}^*R\rho_{(d-1)*}M \rightarrow L\rho_{d+1}^*\rho_{d*}M \rightarrow M \rightarrow .$$

Indeed, applying $R\rho_{(d-1)*}$ to the semiorthogonal decomposition reduces this to showing

$$R\rho_{(d-1)*}L\rho_{d+1}^*[1] \cong \text{id},$$

which follows (for coherent sheaves, and thus in general) from the computation

$$R\text{Hom}(M, R\rho_{(d-1)*}L\rho_{d+1}^*[N]) \cong R\text{Hom}(L\rho_{d+1}^*M, SL\rho_{d-1}^*S^{-1}N)$$

\[ \cong R\text{Hom}(L\rho_{d-1}^*S^{-1}N, L\rho_{d-1}^*S^{-1}M)^* \]

\[ \cong R\text{Hom}(S^{-1}N, M)^* \]

\[ \cong R\text{Hom}(N, SM)^* \]

\[ \cong R\text{Hom}(M, N). \]

We will use this alternate labelling below.

The results of [35] tell us that we can reverse the above construction: given a pair of (dg-enhanced, automatic for commutative projective schemes) triangulated categories and a suitable functor from one to the other, there is a corresponding “glued” category with a semiorthogonal decomposition such that the Homs between the two subcategories are induced by the functor. This gives an immediate construction of a triangulated category from a sheaf bimodule: simply glue the two categories using the associated Fourier-Mukai functor. In the case of sheaf bimodules such that both direct images are locally free of rank 2, the above discussion shows that the resulting category is precisely the derived category of the corresponding noncommutative $\mathbb{P}^1$-bundle.

As mentioned above, we can actually extend this to give an alternate construction of noncommutative $\mathbb{P}^1$-bundles. To determine the noncommutative $\mathbb{P}^1$-bundle from its derived category, we need to specify the $t$-structure, i.e., those objects with only nonnegative or only nonpositive cohomology. We again consider the surface case, leaving the modifications for more complicated base schemes to the reader. In that case, the Serre functor has the form $\theta[2]$ where $\theta$ is an autoequivalence of the desired abelian category. Moreover, since $\theta$ is just a twist of a degree shift of the sheaf algebra, we find that $\theta^{-1}$ is relatively ample, in that any nonzero sheaf $M \in \text{coh } \mathcal{S}$ has the property that $R\rho_{0*}\theta^{-d}M$ is a nonzero sheaf for all sufficiently large $d$. It then follows more generally that $M \in D^b_{\text{coh }}\mathcal{S} \geq 0$ iff $R\rho_{0*}\theta^dM \in D^b_{\text{coh }}C^0_{\geq 0}$ for all $d$. Indeed, $\rho_{0*}$ is right exact and $\theta$ is exact, so the condition certainly holds for all $M \in D^b_{\text{coh }}\mathcal{S} \geq 0$, while if $M$ has cohomology in some negative degree, then some power of $\theta^{-1}$ makes that cohomology have nonzero direct image. We can then reconstruct the other half $D^b_{\text{coh }}\mathcal{S} \leq 0$ of the $t$-structure as the objects with no maps to objects in $D^b_{\text{coh }}\mathcal{S} \geq 1$.

The significance of this is that the Serre functor is intrinsic to the triangulated category, and thus so is $\theta$. In other words, the “geometric” $t$-structure can be reconstructed given only the triangulated category and the functor $\rho_{0*}$. This construction works fairly generally: given any functor $f : \mathcal{A} \rightarrow \mathcal{B}$ of triangulated categories such that $\mathcal{A}$ has a Serre functor and $\mathcal{B}$ is equipped with a $t$-structure, and any integer $d$, there is a putative $t$-structure defined by taking $A \geq 0$ to be those objects such that $f(S^kM[-dk]) \in \mathcal{B} \geq 0$ for all $k \in \mathbb{Z}$. If we already have a $t$-structure in mind for $\mathcal{A}$, then we say that $f$ is “pseudo-canonical (of dimension $d$)” if the putative $t$-structure agrees with the specified $t$-structure. (Note that this forces $|S|\geq d$ to be exact, so is probably not quite the right notion in general, but is good enough for us since we only care about analogues of smooth surfaces. In general, one should probably conjugate $f$ by the respective shifted Serre functors.) In
the case of a smooth commutative projective \(d\)-fold \(X\), this condition holds if either \(-K_X\) or \(K_X\) is relatively ample.

**Lemma 4.9.** Suppose that \(X\) and \(Y\) are Gorenstein quasi-schemes (\(X\) of dimension \(d\)) with \(f : \text{qcoh } X \to \text{qcoh } Y\) a left exact functor such that for all \(M \in \text{coh } X\), there exists \(l \in \mathbb{Z}\) such that \(f(S^lM[-dl]) \neq 0\). Then \(Rf\) is pseudo-canonical of dimension \(d\).

**Proof.** Since \(f\) is left exact, \(Rf\) certainly takes \(D^b_{\text{qcoh}} Y \geq 0\) to \(D^b_{\text{qcoh}} X \leq 0\), and the same applies if we compose it with any power of \(S[-d]\). So it will suffice to show that if \(\tau_{<0}RfS^lM[-dl] = 0\) for all \(l\) then \(\tau_{<0}M = 0\). If not, then let \(p\) be the smallest integer such that \(h^pM \neq 0\). This has a coherent subsheaf, and thus there is an integer \(l\) such that \(f(S^l(h^pM)[-ld]) \neq 0\). But the standard spectral sequence then tells us that \(h^p(RfS^lM[-ld]) \neq 0\), giving a contradiction. \(\blacksquare\)

**Remark.** The converse is also true: if for some nonzero sheaf \(M\), \(h^0(RfS^lM[-ld]) = 0\) for all \(l \in \mathbb{Z}\), then \(M[1]\) is not a nonnegative complex, but its image under \(RfS^l[-ld]\) is for all \(l\).

It turns out that the other two constructions we need also come with semiorthogonal decompositions such that one of the associated functors is pseudo-canonical. The first of these is blowing up. If \(C\) is a (commutative) divisor on the noncommutative surface \(X\), a “weak line bundle relative to \(C\)” is a sheaf on \(X\) such that \(X|_C\) is a line bundle\(^2\) and we say that \(X\) is “generated by weak line bundles relative to \(C\)” if every element of \(\text{qcoh } X\) is a quotient of a direct sum of weak line bundles. (Presumably one could weaken this to allow sheaves with locally free restriction.) Note that this is easily seen to be hold for a quasi-ruled surface with \(C\) the curve of points, as any sheaf of the form \(p^*_d\mathcal{L}\) is a weak line bundle. A similar statement also holds for noncommutative planes, since the sheaves \(\mathcal{O}_X(d)\) are weak line bundles relative to any curve in \(X\).

**Theorem 4.10.** \([51\text{, Thm. 8.4.1}]\) Let \(X\) be a noncommutative surface with \(C\) a commutative divisor and \(p \in C\) a point, and suppose that \(X\) is generated by weak line bundles relative to \(C\). Let \(\tilde{X}\) be the blowup at \(p\), with associated functors \(\alpha^*\), \(\alpha_*\), and let \(\mathcal{O}_e(-1)\) denote the corresponding exceptional sheaf. Then the subcategories \(D^b_{\text{qcoh}} k \otimes \mathcal{O}_e(-1)\) and \(L\alpha^*D^b_{\text{qcoh}} X\) form a semiorthogonal decomposition of \(D^b_{\text{qcoh}} \tilde{X}\).

**Remark.** To be precise, the associated distinguished triangle is

\[
L\alpha^*R\alpha_*M \to M \to R\text{Hom}_k(R\text{Hom}(M, \mathcal{O}_e(-1)), \mathcal{O}_e(-1)) \to
\]

as long as \(M\) is coherent. It follows from the explicit form of Serre duality that one can instead take

\[
L\alpha^*R\alpha_*M \to M \to R\text{Hom}(\mathcal{O}_e, M[2]) \otimes_k \mathcal{O}_e(-1) \to,
\]

and this works even when \(M\) is only quasicoherent, see the proof of Proposition 4.22 below.

**Corollary 4.11.** We have \(K_0(\tilde{X}) \cong K_0(X) \oplus \mathbb{Z}\).

To control the Serre functor, we will need to know that the two subcategories are admissible. Define a new functor \(\alpha^1\) by \(\alpha^1M = \alpha^*(M(C))(-1)\).

**Lemma 4.12.** The derived functor \(L\alpha^1\) is right adjoint to \(R\alpha_*\).

\(^2\)These were called “line bundles” in [51], but we reserve this terminology for a particular class of weak line bundles to be considered in Definition 5.1 below.
Proof. It suffices to show that for any object $M \in D^b_{qcoh} X$,
\[ R\alpha_* L\alpha^! M \cong M \quad \text{and} \quad R\text{Hom}(\mathcal{O}_e(-1), L\alpha^! M) = 0. \]

Indeed, the second claim lets us reduce to checking the adjunction on the image of $L\alpha^*$, which in turn reduces by the adjunction between $\alpha^*$ and $\alpha_*$ to checking the first claim.

By [51, Prop. 8.3.1], we have $R\alpha_*((\alpha^* E)(-1)) \cong E(-C)$ for any sheaf $E$ which is a direct sum of weak line bundles, and since these generate, the same holds for any object in $D^b_{qcoh} X$. Applying this to $M(C)$ gives the first result. It also follows that $R\alpha_*((\alpha^* M)(-1))(C) \cong M \cong R\alpha_* \alpha^* M$ (4.21) and thus $R\text{Hom}(\mathcal{O}_e, \alpha^* M) = 0$ by [51, Lem. 8.3.3(2)]. We then find
\[ R\text{Hom}(\mathcal{O}_e(-1), \alpha^! M) \cong R\text{Hom}(\mathcal{O}_e, \alpha^* M(C)) = 0 \] (4.22)
as required. \qed

Remark. It follows that there is another semiorthogonal decomposition, with distinguished triangle
\[ \mathcal{O}_e(-1) \otimes_k R\text{Hom}(\mathcal{O}_e(-1), M) \to M \to L\alpha^! R\alpha_* M \to \] (4.23)
This lets us compute the gluing functor, which again can be expressed in terms of an adjoint pair of functors.

Proposition 4.13. We have
\[ R\text{Hom}_{\tilde{X}}(V \otimes \mathcal{O}_e(-1), \alpha^* M) \cong R\text{Hom}_X(V \otimes \mathcal{O}_{\tau p}[-1], M) \cong R\text{Hom}_k(V, R\text{Hom}_X(\mathcal{O}_{\tau p}[-1], M)). \] (4.24)

Proof. We first observe that
\[ R\text{Hom}_{\tilde{X}}(\mathcal{O}_e(-1), \alpha^* M) \cong R\text{Hom}_{\tilde{X}}(\mathcal{O}_e(-2), \alpha^!(M(-C))) \cong R\text{Hom}_X(R\alpha_* \mathcal{O}_e(-2), M(-C)), \] (4.25)
so that we need to compute $R\alpha_* \mathcal{O}_e(-2)$. By [51, Prop. 8.3.2], we have a distinguished triangle
\[ L\alpha^* \mathcal{O}_{\tau p} \to \mathcal{O}_e \to \mathcal{O}_e(-1)[2] \to \] (4.26)
which twists to give
\[ L\alpha^!(\mathcal{O}_{\tau p}(-C)) \to \mathcal{O}_e(-1) \to \mathcal{O}_e(-2)[2] \to \] (4.27)
Applying $R\alpha_*$ then gives
\[ R\alpha_* \mathcal{O}_e(-2) \cong \mathcal{O}_{\tau p}(-C)[-1], \] (4.28)
so that
\[ R\text{Hom}_{\tilde{X}}(\mathcal{O}_e(-1), \alpha^* M) \cong R\text{Hom}_X(\mathcal{O}_{\tau p}[-1], M), \] (4.29)
from which the claim follows. \qed

In particular, $D_{qcoh}(\tilde{X})$ is compactly generated (so has a Serre functor) iff $D_{qcoh}(X)$ is compactly generated. Indeed, if $G$ is a compact generator of $D_{qcoh}(X)$, then $L\alpha^* G \oplus \mathcal{O}_e(-1)$ certainly generates $D_{qcoh}(X)$, and the Proposition tells us that it is compact. Moreover ([10]), given such a semiorthogonal decomposition, one can compute the Serre functor on the ambient category from that on the subcategories (and vice versa, if desired). Since the Serre functor on perf($k$) is just the identity, this is not too hard in our case.
Corollary 4.14. If $X$ is compactly generated (i.e., $D_{\text{qcoh}}(X)$ is compactly generated), then the Serre functor on $\tilde{X}$ satisfies $SL\alpha^* M \cong L\alpha^1 SM$ and $SO_e \cong O_e(-1)[2]$.

Proof. The first claim follows immediately from Lemma 4.12, while the second claim follows from (4.26), since that distinguished triangle implies that $\_ \otimes O_e(-1)[2]$ is similarly right adjoint to the projection to $\_ \otimes O_e$ in the semiorthogonal decomposition coming from $R\text{Hom}(O_e, L\alpha^* M) = 0$. □

Note that since the Serre functor is intrinsic, it commutes with any autoequivalence of perf $\tilde{X}$.

For the pseudo-canonical condition, we need a lemma about how the various functors related to a divisor interact.

Lemma 4.15. Let $A$ be an abelian category, let $G : A \to A$ be an autoequivalence, and let $\tau : G \to \text{id}$ be a natural transformation. If $A$ is generated by objects on which $\tau$ is surjective or cogenerated by objects on which $\tau$ is injective, then $\tau G = G \tau$.

Proof. The “cogenerated” case is essentially just [54, Lem. 8.3] (using the cogenerators in place of injective objects), and the “generated” case is dual. □

Remark. In particular, if $X$ is generated by weak line bundles along $C$, then this applies to the autoequivalence $\_(-C)$ and the natural transformation $\_(-C) \to \text{id}$. We may thus safely refer to “the” natural map $M(\alpha C) \to M(\beta C)$ for any $a < b$, since all ways of constructing such a map out of the natural transformation will agree.

Lemma 4.16. Let $C$ be a divisor on the noncommutative surface $X$ and suppose that $X$ is generated by weak line bundles along $C$ and has a Serre functor. Let $i_* : \text{qcoh} C \to \text{qcoh} X$ be the inclusion, with adjoints $i^*$, $i^!$. Then there is a natural isomorphism $\text{Ri}^! \cong L\alpha^*(\_(-C))[-1]$. Furthermore, for $M \in D_{\text{qcoh}} C$, $S(i_* M)(C) \cong i_* S M[1]$.

Proof. By [54, Lem. 8.1], there is a 4-term exact sequence

$$0 \to i_* i^! M \to M \to M(C) \to i_* i^*(M(C)) \to 0. \quad (4.30)$$

Since there are enough acyclic objects for both functors (injectives for $i^!$ and weak line bundles for $i^*$), we find that the functors fit into functorial distinguished triangles

$$\_(-C) \to \text{id} \to \text{Li}^* \to \quad (4.31)$$

$$\text{Ri}^! \to \text{id} \to \_(-C) \to. \quad (4.32)$$

from which the first claim follows.

Serre duality immediately gives

$$\text{Ri}^! \cong SLi^* S^{-1}, \quad (4.33)$$

and thus comparing the two expressions of $\text{Ri}^!$ gives a natural isomorphism

$$Li^*(S^{-1} M(-C)) \cong S^{-1} Li^* M[-1]. \quad (4.34)$$

Taking right adjoints gives $S(i_* M)(C) \cong i_* S M[1]$ as required. □

Remark. The fact that the twist by $C$ is an autoequivalence identifying the two adjoints of $i_*$ establishes that $i_*$ is a spherical functor in the sense of [2].

Proposition 4.17. If $X$ and $C$ are Gorenstein, then so is $\tilde{X}$, and the functor $R\alpha_* : D_{\text{qcoh}} \tilde{X} \to D_{\text{qcoh}} X$ is pseudo-canonical.
Thus the objective is to show that the scheme of points is the Proj of a quotient of \( \mathcal{O}_{\tau p} = i_* \mathcal{O}_{\tau p} \) to \( i_* (\mathcal{O}_{\tau p} \otimes \omega_C) \cong \mathcal{O}_{\tau p} \), so respects the gluing, and thus induces an autoequivalence of \( D^b_{\text{qcoh}} \( \tilde{X} \) acting trivially on \( \mathcal{O}_e(-1) \). Composing this autoequivalence with \( M \mapsto M(-1) \) gives an autoequivalence acting by

\[
La^* M \rightarrow (La^* \theta M(C))(-1) = S(La^1 M(C))(-1)[-2] \cong SLa^* M[-2] \tag{4.35}
\]

and

\[
\mathcal{O}_e(-1) \rightarrow \mathcal{O}_e(-2) = S \mathcal{O}_e(-1)[-2], \tag{4.36}
\]

which must therefore actually agree with the shifted Serre functor on \( \tilde{X} \) (which we also denote \( \theta \)). We then find

\[
R\alpha_* \theta^{-d} M \cong \theta^{-d}(R\alpha_* M(d))(-dC). \tag{4.37}
\]

Since \( \theta \) and \( M \mapsto M(C) \) are exact on \( X \), we conclude that \( \theta^{-1} \) is relatively ample for \( R\alpha_* \) iff \( M \mapsto M(1) \) is relatively ample for \( R\alpha_* \), and the latter holds by construction. \( \square \)

The construction of van den Bergh depends on a choice of divisor containing \( p \), but it follows immediately from the semiorthogonal decomposition and the pseudo-canonical property that the result does not actually depend on the divisor. For quasi-ruled surfaces, there is a natural choice of divisor, since the moduli scheme of points is embedded as a divisor. It is thus worth noting that this is preserved under blowup.

**Proposition 4.18.** Suppose \( X \) is a noncommutative surface and \( C \) is a curve embedded as a divisor, and let \( \tilde{X} \) be the blowup of \( X \) in a point \( p \in C \). Then there is a curve \( C^+ \) embedded in \( \tilde{X} \) as a divisor via a natural transformation \( \underline{\_}(-1) \rightarrow \text{id} \), which is Gorenstein whenever \( C \) is Gorenstein. If \( C \) is anticanonical on \( X \), so is \( C^+ \) on \( \tilde{X} \).

**Proof.** The graded bimodule algebra associated to the blowup is such that the homogeneous component of degree \( i \) is a sub-bimodule of the homogeneous component of degree \( i + 1 \), which gives the desired natural transformation. We need to show that the quotient is a commutative curve. If \( \tau(p) \neq p \), then the quotient is just the curve \( \tilde{C} \), and thus the claim holds, and \( C^+ \cong C \), so the Gorenstein claim is immediate.

If \( \tau(p) = p \), then we can still factor the natural transformation as

\[
\underline{\_}(-1) \rightarrow \underline{\_}(-\tilde{C}) \rightarrow \text{id}, \tag{4.38}
\]

so that the (possibly noncommutative) scheme \( C^+ \) is isomorphic to \( C \) away from \( p \). We thus reduce to showing that if we quotient by any power of the bimodule ideal associated to \( p \), then the result is commutative, and since every homogeneous component of the result is an extension of \( \mathcal{O}_p \), we may pass (via (4.34)) to a local calculation in a ring of the form \( R = k(\langle x, y \rangle)/(uy - vx) \) where \( u, v \) generate the maximal ideal \( m \), in such a way that the point sheaves of \( C \) correspond to maximal ideals of a commutative quotient \( R/U \) where \( U \) is normalizing. The blowup is then locally given by the Proj of the Rees algebra \( \bigoplus_i m^i U^{-i} t^i \) where \( t \) is a central variable of degree 1. (Note that since conjugation by \( U \) is an invertible automorphism of \( R \), it makes sense to adjoin an inverse of \( U \) to \( R \).) We need to show that the quotient by \( t \) is a commutative curve.

Since multiplying the degree 0 element \( U \) by any element of degree 1 gives a multiple of \( t \) (in fact, an element of \( mt \)), we find that \( U \) is contained in the saturation of the ideal generated by \( t \). Thus the objective is to show that the scheme of points is the Proj of

\[
R/\langle U \rangle \oplus \bigoplus_{i \geq 1} (m^i/m^{i-1}U)U^{-i} t^i. \tag{4.39}
\]
The corresponding \( \mathbb{Z} \)-algebra are unchanged if we remove the factors \( U^{-1} \) from these algebras, so that we may as well consider instead the algebra

\[
\frac{R}{\langle U \rangle} \oplus \bigoplus_{i \geq 1} (\mathfrak{m}^i/\mathfrak{m}^{i-1}U)t^i.
\]

(4.40)

This is the \( R/\langle U \rangle \)-algebra generated by \( \mathfrak{m}/\langle U \rangle t \) subject to the single relation \( (ut)(yt) = (vt)(xt) \), and thus to show that its Proj is the category of coherent sheaves of a commutative scheme, it will suffice to find an \( R/\langle U \rangle \)-linear automorphism of the degree 1 submodule that twists this into a commutator.

In other words, we need an \( R/\langle U \rangle \)-module automorphism of \( \mathfrak{m}/\langle U \rangle \) that takes \( x \) to \( u \) and \( y \) to \( v \). By [54, Prop. 7.1], there is a short exact sequence

\[
0 \longrightarrow R \stackrel{(v,-u)}{\longrightarrow} R^2 \stackrel{(x,y)}{\longrightarrow} \mathfrak{m} \rightarrow 0
\]

(4.41)

of \( R \)-modules, and thus there is an \( R \)-linear morphism \( \phi^+ : \mathfrak{m} \rightarrow \mathfrak{m}/\langle U \rangle \) taking \( x \) to \( u \) and \( y \) to \( v \) iff the corresponding map on \( R^2 \) annihilates \((v,-u)\). Since this has image \( vu - wv \in \langle U \rangle \), such a map indeed exists and is unique. Moreover, the map on \( R^2 \) takes \((y,x)\) to \( yu - xv \in uy - vx + \langle U \rangle = \langle U \rangle \), so that \( \phi^+ \) annihilates \( \langle U \rangle \), so induces a unique \( R \)-linear morphism \( \phi : \mathfrak{m}/\langle U \rangle \rightarrow \mathfrak{m}/\langle U \rangle \). The same reasoning shows that there is a unique map of right \( R \)-modules taking \((u,v)\) to \((x,y)\), which since \( R/\langle U \rangle \) is commutative must be the inverse of \( \phi \).

We may thus twist by \( \phi \) to obtain a description of this scheme as the Proj of the free commutative graded \( R/\langle U \rangle \)-algebra generated by the maximal ideal of \( R/\langle U \rangle \). Since \( R/\langle U \rangle \cong \mathcal{O}_C \), we may consider this in entirely commutative terms, and find that the local scheme of points is obtained by blowing up the origin of \( \text{Spec} k[[x,y]] \), taking the total transform of \( \mathcal{O}_C \), and removing a single copy of the exceptional divisor. In particular, the new scheme is indeed a Gorenstein curve when \( C \) is Gorenstein.

For the final claim, we note that the endofunctor \( M \mapsto \theta M(C^+) \) of \( D_{qcoh}(X) \) is the endofunctor induced via the semiorthogonal decomposition by the pair \((M \mapsto \theta M(C), \text{id})\), and is thus trivial iff \( C \) is anticanonical.

\[\square\]

\textbf{Remark.} If one can embed \( C \) as a Cartier divisor in a smooth projective surface \( X' \), then it follows from the above local description that \( C^+ \) is naturally isomorphic to the effective Cartier divisor \( \pi^*C - e \), where \( \pi : X' \rightarrow X \) is the blowup at \( \tau p \). Note that \( C \) being Gorenstein implies only that such an embedding exists locally, but we have already seen that it exists globally for quasi-ruled surfaces, while for noncommutative planes, the curve of points embeds in a commutative plane.

\textbf{Remark.} We would like to have a statement along the lines that if \( C \) is the moduli space of point sheaves on \( X \), then \( C^+ \) is the moduli space of point sheaves on \( \overline{X} \). Unfortunately, there is no intrinsic notion of a “point sheaf” on a noncommutative surface, so this is difficult to state in general. For the surfaces of present interest (iterated blowups of quasi-ruled surfaces and projective planes), we do have such a notion, and it follows easily from the above calculation that \( C^+ \) is the moduli space of such sheaves on \( \overline{X} \) iff \( C \) is the moduli space of point sheaves on \( X \). (This involves only local calculations near the exceptional curve.)

We also need to know that generation by weak line bundles is inherited, so that further blowups still have the semiorthogonal decomposition.

\textbf{Lemma 4.19.} If \( X \) is generated by weak line bundles relative to \( C \), then \( \overline{X} \) is generated by weak line bundles relative to \( C^+ \).
Proof. If $M$ is a weak line bundle on $X$ relative to $C$, then $\alpha^*M$ is a weak line bundle relative to the new curve $C^+$, and $\theta$ takes weak line bundles to weak line bundles. Since $\theta^{-1}$ is relatively ample for $\alpha_+$, $\text{qcoh} \tilde{X}$ is generated by sheaves of the form $\theta^{-d} \alpha^*M$ where $M$ ranges over any set of generators of $\text{qcoh} X$. \qed

For the next result, we assume not just that $C$ is Gorenstein, but that it is a surface curve, i.e., that it embeds as a Cartier divisor in a commutative smooth projective surface.

Lemma 4.20. Let $X$ be a compactly generated noncommutative surface and $i : C \to X$ an embedding of a surface curve as a divisor. Let $\tilde{X}$ be a blowup of $X$ in some point of $C$. If the image of $\text{perf}(X)$ generates $\text{perf}(C)$, then the image of $\text{perf}(\tilde{X})$ generates $\text{perf}(C^+)$.

Proof. Let $X'$ be a smooth projective surface containing $C$. The line bundle $\mathcal{O}_C(d)$ is certainly in the image of $\text{perf}(X')$ for any $d$, and since $\mathcal{O}_C(1)$ is ample, these bundles generate $\text{perf}(C)$. By the same argument, $\text{perf}(C^+)$ is generated by the image of $\text{perf}(\tilde{X}')$. By the semiorthogonal decomposition, $\text{perf}(\tilde{X}')$ is generated by $\text{La}^* \text{perf}(X')$ and $\mathcal{O}_e(-1)$, and thus $\text{perf}(C^+)$ is generated by the image of $\text{La}^* \text{perf}(X')$ and the image of $\mathcal{O}_e(-1)$. The result follows by noting that the Karoubian subcategory generated by the image of $\text{La}^* \text{perf}(X')$ in $\text{perf}(C^+)$ is the same as the image of $\text{perf}(C)$ in $\text{perf}(C^+)$, and the image of $\mathcal{O}_e(-1)$ in $\text{perf}(C^+)$ is the same for either $\tilde{X}$ and $\tilde{X}'$. \qed

The other construction is for noncommutative planes.

Proposition 4.21. (1) Any noncommutative plane has a strong exceptional collection consisting of three objects $\mathcal{O}_X(-2)$, $\mathcal{O}_X(-1)$, $\mathcal{O}_X$ such that $\text{Hom}(\mathcal{O}_X(-2), \mathcal{O}_X(-1))$ and $\text{Hom}(\mathcal{O}_X(-1), \mathcal{O}_X)$ are three-dimensional and

$$\text{Hom}(\mathcal{O}_X(-2), \mathcal{O}_X(-1)) \otimes \text{Hom}(\mathcal{O}_X(-1), \mathcal{O}_X) \to \text{Hom}(\mathcal{O}_X(-2), \mathcal{O}_X)$$

is surjective with three-dimensional kernel. Moreover, $D_{\text{qcoh}} X$ is compactly generated, has Serre functor $M \mapsto M(-3)[2]$, and the functor $R\text{Hom}(\mathcal{O}_X, \underline{\_})$ is pseudo-canonical of dimension 2.

Remark. The condition that the resulting category has a well-behaved $t$-structure is open in the set of surjections $k^3 \otimes k^3 \to k^6$, and reduces to the condition that there be a cubic curve $C \subset \mathbb{P}^2$ and a degree 0 line bundle $q$ on $C$ such that $\text{Hom}(\mathcal{O}_X(-1), \mathcal{O}_X) \cong \Gamma(C; q(1))$, $\text{Hom}(\mathcal{O}_X(-2), \mathcal{O}_X(-1)) \cong \Gamma(C; \mathcal{O}_C(1))$, and the composition is given by multiplication. The scheme of points is isomorphic to $C$, which embeds as a divisor via a natural transformation $\underline{(-3)} \to \text{id}$.

In particular, both noncommutative planes and noncommutative quasi-ruled surfaces have the property that any point can be blown up, and this property is inherited by such blowups. This motivates the following two definitions: a “noncommutative rationally quasi-ruled surface” is an iterated blowup of a noncommutative quasi-ruled surface, while a “noncommutative rational surface” is an iterated blowup of either a noncommutative plane or a noncommutative ruled surface over a curve of genus 0. (For technical reasons, we should include the anticanonical curve as part of the data when the surface is commutative.)

Thus in each case, we could have constructed the desired abelian category by first gluing the appropriate commutative derived categories and using the pseudo-canonical property to construct the $t$-structure. Of course, it is nontrivial to show that this is a $t$-structure and even less trivial to show that the resulting triangulated category is the derived category of its heart. So although these constructions are relatively simple to state, they are difficult enough to control to make this
In particular, there are a number of isomorphisms we would like to establish, analogous to standard constructions in commutative birational geometry: blowups in (sufficiently) distinct points should commute, a blowup of a quasi-ruled surface should be a blowup of a different quasi-ruled surface (i.e., elementary transformations), a blowup of a noncommutative plane should be a noncommutative Hirzebruch surface, and a noncommutative $\mathbb{P}^1 \times \mathbb{P}^1$ should be a noncommutative Hirzebruch surface in two different ways. In each case, we will show this by first constructing a corresponding derived equivalence, and then showing that the derived equivalence respects the $t$-structure. The latter will in turn reduce to showing that the derived equivalence respects some pseudo-canonical functor.

For commuting blowups, we note that if $X$ is a noncommutative Gorenstein surface with successive blowups $\alpha_{1s} : X_1 \to X$ and $\alpha_{2s} : X_2 \to X_1$, then there are three natural subcategories $\mathcal{O}_{2}(\alpha_{1s} \mathcal{O}_{e_{1}}(-1) \otimes D^{b}_{\text{coh}} k, \alpha_{2s} \mathcal{O}_{e_{1}}(-1) \otimes D^{b}_{\text{coh}} k$ and $\alpha_{2s} \mathcal{O}_{e_{1}} \otimes D^{b}_{\text{coh}} X$ of $D^{b}_{\text{coh}} X_2$, and these moreover form a three-step semiorthogonal decomposition. Note that

$$R \text{Hom}(\mathcal{O}_{2}(\alpha_{1s} \mathcal{O}_{e_{1}}(-1)), \mathcal{O}_{p_{2}}) \cong R \text{Hom}(\mathcal{O}_{e_{1}}(-1), \mathcal{O}_{p_{2}}),$$

and thus if $R \text{Hom}(\mathcal{O}_{e_{1}}(-1), \mathcal{O}_{p_{2}}) = 0$, we can swap the first two subcategories and still have a semiorthogonal decomposition. We find that the new semiorthogonal decomposition is again the decomposition associated to a two-step blowup, but now with $p_{1}$ and $p_{2}$ swapped. (Note that if $p_{1}$ is a singular point of $Q$, then the condition implies that $p_{2}$ is not on the component $e_{1}$ of $Q_{1} = Q^{+}$, and thus it makes sense to swap $p_{1}$ and $p_{2}$.) The resulting derived equivalence fixes the functor $\alpha_{1s} \alpha_{2s}$, and thus when this functor is pseudo-canonical, the derived equivalence respects the $t$-structure.

To see that this is pseudo-canonical (in fact relatively Fano in a suitable sense) under reasonable conditions, it will be helpful to have a way of checking in the case of a single blowup whether a sheaf is acyclic and globally generated for $\alpha$. We assume the original surface is Gorenstein (which holds in all cases of interest in the present work), but with care one should be able to replace $\theta$ by suitable functors coming from the relevant divisors of points.

**Proposition 4.22.** Let $X$ be a noncommutative surface and $\alpha : \tilde{X} \to X$ the van den Bergh blowup of $X$ in the point $x$. Then the object $M \in \text{qcoh} \tilde{X}$ is acyclic and globally generated for $\alpha$ iff $\text{Ext}^{2}(\mathcal{O}_{e}, M) = 0$.

**Proof.** We first recall that the distinguished triangle associated to the semiorthogonal decomposition takes the form

$$\text{La}^{*}R\alpha_{*} M \to M \to FM \otimes_{k} \mathcal{O}_{e}(-1) \to$$

for some functor $F : D_{\text{qcoh}} \tilde{X} \to D_{\text{qcoh}} k$, and we claimed above that $FM = R \text{Hom}(\mathcal{O}_{e}, M[2])$. To see this, note that since $R \text{Hom}(\mathcal{O}_{e}, \text{La}^{*} N) = 0$, we have

$$R \text{Hom}(\mathcal{O}_{e}, M[2]) \cong FM \otimes_{k} R \text{Hom}(\mathcal{O}_{e}, \mathcal{O}_{e}(-1))[2] \cong FM.$$

Substituting into the distinguished triangle and taking the corresponding long exact sequence gives an exact sequence ending

$$h^{0}(\text{La}^{*}R\alpha_{*} M) \to M \to \text{Ext}^{2}(\mathcal{O}_{e}, M) \otimes_{k} \mathcal{O}_{e}(-1) \to \alpha^{*}R^{1} \alpha_{*} M \to 0.$$

In particular, if $\text{Ext}^{2}(\mathcal{O}_{e}, M) = 0$, then $\alpha^{*}R^{1} \alpha_{*} M = 0$ and thus $R^{1} \alpha_{*} M = 0$ so $M$ is acyclic for $\alpha_{*}$. 

56
In general, if \( M \) is acyclic for \( \alpha_* \), then the tail of the exact sequence becomes
\[
\alpha^*\alpha_* M \to M \to \text{Ext}^2(\mathcal{O}_e, M) \otimes_k \mathcal{O}_e(-1) \to 0
\] (4.47)
and thus \( \alpha^*\alpha_* M \to M \) is surjective iff \( \text{Ext}^2(\mathcal{O}_e, M) = 0 \).

**Remark.** Of course, if \( M \) is coherent and \( X \) has a Serre functor, then we may use Serre duality to rephrase the condition as \( \text{Hom}(M, \mathcal{O}_e(-1)) = 0 \).

**Remark.** The distinguished triangle from the \( \mathcal{O}_e(-1) \), \( \alpha^! \) decomposition similarly tells us that
\[
\alpha^! R^1\alpha_* M \cong \text{Ext}^2(\mathcal{O}_e(-1), M) \otimes \mathcal{O}_e(-1),
\] (4.48)
so that \( M \) is acyclic for \( \alpha_* \) iff \( \text{Ext}^2(\mathcal{O}_e(-1), M) = 0 \). This can be viewed as a relative Castelnuovo-Mumford regularity statement, which in this case is an equivalence: relative to \( \alpha, M \) is acyclic and globally generated iff \( \theta M \) is acyclic.

**Proposition 4.23.** If \( M \in D_{\text{coh}}^b X \) is such that \( R\text{Hom}(\mathcal{O}_p, M) = 0 \), then \( L\alpha^! M \cong \alpha^! M \).

**Proof.** We have a distinguished triangle
\[
L\alpha^* M \to \alpha^! M \to R\text{Hom}(\mathcal{O}_e, \alpha^! M[2]) \otimes \mathcal{O}_e(-1) \to,
\] (4.49)
and thus it suffices to have \( R\text{Hom}(\mathcal{O}_e, \alpha^! M) = 0 \). But then
\[
R\text{Hom}(\mathcal{O}_e, \alpha^! M) \cong R\text{Hom}(L\alpha^*\mathcal{O}_p, \alpha^! M) \cong R\text{Hom}(\mathcal{O}_p, M),
\] (4.50)
so that the desired result follows.

**Remark.** Of course, if \( X \) is Gorenstein and \( M \) is coherent, then the hypothesis is equivalent to \( R\text{Hom}(M, \mathcal{O}_p) = 0 \).

**Proposition 4.24.** Let \( X_0 \) be a noncommutative Gorenstein surface, and let \( \alpha : X_1 \to X_0, \beta : X_2 \to X_1 \) be a sequence of van den Bergh blowups. If the images of the corresponding points \( x_1, x_2 \) in \( X_0 \) are not in the same orbit under \( \tau^Z \), then \( \alpha_*\beta_* \) is pseudo-canonical.

**Proof.** Let \( M \in \text{coh } X_2 \) be a nonzero sheaf. We need to show that for some \( l, \alpha_*\beta_*\theta^{-l} M \neq 0 \).

It will of course suffice to find \( l \) such that \( \theta^{-l} M \) is globally generated relative to the composed morphism. With this in mind, let \( b(M) \) be the function that assigns to each \( M \) the smallest integer such that \( \text{Ext}^2(\mathcal{O}_{e_2}, \theta^{-b} M) = 0 \), and if \( b(M) \leq 0 \), let \( a(M) \) be the smallest integer such that \( \text{Ext}^2(\mathcal{O}_{e_1}, \theta^{-a} \beta_* M) = 0 \). If \( b(M) \leq 0 \) and \( a(M) \leq 0 \), then we find that \( M \) is acyclic and globally generated for \( \beta_* \), while \( \beta_* M \) is acyclic and globally generated for \( \alpha \), which implies that \( M \) is acyclic and globally generated for \( \alpha \circ \beta \) as required. It will thus suffice to show that \( b(\theta^{-1} M) = b(M) - 1 \) and if \( b(M) \leq 0 \), then \( a(\theta^{-1} M) = a(M) - 1 \).

The claim for \( b(M) \) is trivial, so it remains to consider the claim for \( a(M) \). We have
\[
R\text{Hom}(\mathcal{O}_{e_1}, \theta^{-a} \beta_* \theta^{-1} M) \cong R\text{Hom}(\mathcal{O}_{e_1}, \theta^{-a} R\beta_* \theta^{-1} M) \cong R\text{Hom}(L\beta^* \theta^a \mathcal{O}_{e_1}(-1), M)
\] (4.51)
If \( R\text{Hom}(\theta^a \mathcal{O}_{e_1}(-1), \mathcal{O}_{e_2}) = 0 \), then we have
\[
R\text{Hom}(L\beta^* \theta^a \mathcal{O}_{e_1}(-1), M) \cong R\text{Hom}(\theta^a \mathcal{O}_{e_1}(-1), R\beta_* M)
\cong R\text{Hom}(\mathcal{O}_{e_1}, \theta^{-a-1} R\beta_* M),
\] (4.52)
and thus the claim follows.

It thus remains only to show that \( R\text{Hom}(\theta^a\mathcal{O}_{e_1}(-1), \mathcal{O}_{x_2}) = 0 \), which we may rewrite using

\[
R\text{Hom}(\theta^a\mathcal{O}_{e_1}(-1), \mathcal{O}_{x_2}) \cong R\text{Hom}(\mathcal{O}_{e_1}(-1), \mathcal{O}_{\tau^{-a}x_2}).
\]

(4.53)

By assumption, \( e_1 \) is either not a component of \( C^+ \) or does not contain \( x_2 \), and thus we may choose the divisor \( C_2 \) containing \( x_2 \) so that \( e_1 \) is not a component of \( C_2 \). We then have

\[
R\text{Hom}(\mathcal{O}_{e_1}(-1), \mathcal{O}_{\tau^{-a}x_2}) \cong R\text{Hom}_{C_2}(\mathcal{O}_{e_1}(-1)|_{C_2}, \mathcal{O}_{\tau^{-a}x_2}).
\]

(4.54)

Now, \( \mathcal{O}_{e_1}(-1)|_{C_2} \) either vanishes (if \( x_1 \) and \( x_2 \) came from different components of the original curve of points) or equals \( x_1 \), in which case

\[
R\text{Hom}(\mathcal{O}_{e_1}(-1), \mathcal{O}_{\tau^{-a}x_2}) \cong R\text{Hom}_{C_2}(\mathcal{O}_{x_1}, \mathcal{O}_{\tau^{-a}x_2})
\]

(4.55)

vanishes unless \( x_2 = \tau^a x_1 \).

We then have the following immediate consequence.

**Theorem 4.25.** Let \( X \) be a Gorenstein surface containing a divisor \( C \), and let \( x_1, x_2 \) be a pair of points of \( C \) which are not in the same orbit under \( \tau \). Then the blowup of \( X \) in \( x_1 \) then \( x_2 \) (as a point in \( \widehat{C} \)) is isomorphic to the blowup of \( X \) in \( x_2 \) then \( x_1 \).

It will be useful to have an understanding of what happens when \( x_1 \) and the image of \( x_2 \) are in the same orbit. If \( x_1 \) is a fixed point, then \( e_1 \) will be an actual divisor in the first blowup \( X_1 \), and we can use its strict transform to control things. So suppose that \( x_1 \) is not a fixed point, but rather that it has an orbit of size \( r \in [2, \infty] \), and thus that the curve of points on \( X_1 \) locally agrees with \( C \), and similarly (since we are assuming \( x_2 \) in the same orbit) for the two-fold blowup. Applying a suitable equivalence of the form \( (de_2) \) then lets us assume that \( x_2 \) is equal to \( x_1 =: x \). Then there is a natural morphism \( \mathcal{O}_{e_2}(-1) \to \mathcal{O}_{e_1}(-1) \), and we define \( \mathcal{O}_{e_1-e_2}(-1) \) to be its cokernel. Note that since \( \mathcal{O}_{e_1}(-1) \) and \( \mathcal{O}_{e_2}(-1) \) both restrict to \( \mathcal{O}_x \) on \( C \), the cone of this morphism has trivial restriction to \( C \), and thus is invariant under the autoequivalence \( \_/(C) \). Since this autoequivalence is relatively ample for \( \beta \), and the direct image of the cone is the sheaf \( \mathcal{O}_{e_1}(-1) \), we conclude that the morphism is in fact injective. Note also that we have \( \theta \mathcal{O}_{e_1-e_2}(-1) \cong \mathcal{O}_{e_1-e_2}(-1)/(-C) \cong \mathcal{O}_{e_1-e_2}(-1) \). This object is readily verified to be spherical, and thus gives rise to an inverse pair of spherical twists. (This of course also makes sense when \( r = 1 \), taking the appropriate line bundle on the strict transform of \( e_1 \).

The size of the orbit plays a role via the following fact.

**Lemma 4.26.** Let \( \tilde{X} \) be the blowup of \( X \) in a point \( x \) with orbit of size \( r \in [1, \infty] \). Then for all \( 0 \leq d < r \), one has

\[
\text{Ext}^1_{\tilde{X}}(\mathcal{O}_{e_1}(-1), \mathcal{O}_{e_1}(d - 1)) = \text{Ext}^2_{\tilde{X}}(\mathcal{O}_{e_1}(-1), \mathcal{O}_{e_1}(d - 1)) = 0
\]

and \( \text{dim} \text{Hom}_{\tilde{X}}(\mathcal{O}_{e_1}(-1), \mathcal{O}_{e_1}(d - 1)) = 1 \).

**Proof.** This holds for \( d = 0 \) since \( \mathcal{O}_{e_1}(-1) \) is exceptional. We proceed by induction in \( d \). Using the short exact sequence

\[
0 \to \mathcal{O}_{e_1}(d - 1) \to \mathcal{O}_{e_1}(d) \to \mathcal{O}_{x_d} \to 0
\]

(4.57)

(where \( x_d \) is an appropriate point of \( \widehat{C} \)), we find that

\[
R\text{Hom}(\mathcal{O}_{e_1}(-1), \mathcal{O}_{e_1}(d - 1)) \cong R\text{Hom}(\mathcal{O}_{e_1}(-1), \mathcal{O}_{e_1}(d))
\]

(4.58)

unless \( R\text{Hom}(\mathcal{O}_{e_1}(-1), \mathcal{O}_{e_2}) \neq 0 \), or equivalently unless \( x_d = x_{-1} \). Since \( x_d \) ranges over consecutive points in the orbit of \( x \), this fails only when \( d + 1 \) is a multiple of \( r \).
Define a sheaf $\mathcal{O}_{X_2}(ae_1 + be_2)$ by
\[
\mathcal{O}_{X_2}(ae_1 + be_2) := \theta^b \beta^* \theta^{a-b} \alpha^* \theta^{-a} \mathcal{O}_X. \tag{4.59}
\]
(This could of course be defined using $\underline{(-C)}$ in place of $\theta$; the use of $\theta$ is only for notational convenience.) Our key result for use below can be viewed as computing certain special cases of the spherical twists of such sheaves.

**Proposition 4.27.** If $0 \leq b - a \leq r$, then there is a short exact sequence
\[
0 \to \mathcal{O}_{X_2}(-be_1 - ae_2) \to \mathcal{O}_{X_2}(-ae_1 - be_2) \to \mathcal{O}_{e_1 - e_2}(-1)^{b-a} \to 0 \tag{4.60}
\]

*Proof.* We show this by induction in $b - a$, noting that the base case $a = b$ is trivially true. Since the functor $\underline{\cdot}(e_1 + e_2)$ preserves $\mathcal{O}_{e_1 - e_2}(-1)$ (it agrees with $\underline{(-C)}$ and $\theta$ on $D^b_{\text{coh}} X$), we may as well assume that $a = 0$. We thus need to show that if the claim holds for some $b < r$, then it holds for $b + 1$.

There is certainly a natural injection $\mathcal{O}_{X_2}(-(b + 1)e_1) \to \mathcal{O}_{X_2}(-be_1)$, and composing with the already constructed map $\mathcal{O}_{X_2}(-be_1) \to \mathcal{O}_{X_2}(-be_2)$ gives an injection such that the cokernel $M_b$ is an extension of $\mathcal{O}_{e_1 - e_2}(-1)^b$ by $\beta^* \mathcal{O}_{e_1}(b)$. But
\[
\operatorname{Ext}^1(\mathcal{O}_{e_1 - e_2}(-1), \beta^* \mathcal{O}_{e_1}(b)) \cong \operatorname{Ext}^1(\theta^{-1} \mathcal{O}_{e_1 - e_2}(-1), \beta^* \mathcal{O}_{e_1}(b))
\cong \operatorname{Ext}^1(\mathcal{O}_{e_1 - e_2}(-1), \beta^* \theta \mathcal{O}_{e_1}(b))
\cong \operatorname{Ext}^1_{X_1}(\mathcal{O}_{e_1}(-1), \mathcal{O}_{e_1}(b - 1)) = 0,
\]
and thus this extension splits. Since
\[
\operatorname{Hom}(\mathcal{O}_{e_1 - e_2}(-1), \mathcal{O}_{e_2}(b)) \cong \operatorname{Hom}(\mathcal{O}_{e_1 - e_2}(-1), \mathcal{O}_{e_2}(-1)) = 0 \tag{4.62}
\]
and
\[
\operatorname{Hom}(\beta^* \mathcal{O}_{e_1}(b), \mathcal{O}_{e_2}(b)) \cong \operatorname{Hom}(\mathcal{O}_{e_1}(b), \beta^* \mathcal{O}_{e_2}(b)) \cong k \tag{4.63}
\]
(using the fact that $b < r$, so $\beta^* \mathcal{O}_{e_2}(b)$ is the direct sum of $x_0, \ldots, x_b$, only one of which has a map from $\mathcal{O}_{e_1}(b)$), we see that there is a unique morphism from $M_b$ to $\mathcal{O}_{e_2}(b)$, and thus the map $\mathcal{O}_{X_2}(-(b + 1)e_1) \to \mathcal{O}_{X_2}(-be_2)$ factors through $\mathcal{O}_{X_2}(-(b + 1)e_2)$. The cokernel of the resulting map is the sum of $\mathcal{O}_{e_1 - e_2}(-1)^b$ and the cokernel of the map $\beta^* \mathcal{O}_{e_1}(b) \to \mathcal{O}_{e_2}(b)$. Since $b < r$, we have
\[
\beta^* \mathcal{O}_{e_1}(b) \cong \theta^{-1} \beta^* \theta \mathcal{O}_{e_1}(b) \cong \theta^{-1} \beta^* \mathcal{O}_{e_1}(b - 1), \tag{4.64}
\]
and thus this cokernel is $\theta^{-1}$ of the cokernel for $b - 1$, and thus by induction is $\theta^{-b-1} \mathcal{O}_{e_1 - e_2}(-1) \cong \mathcal{O}_{e_1 - e_2}(-1)$.

**Remark.** This construction of a morphism $\mathcal{O}_{X_2}(-be_1 - ae_2) \to \mathcal{O}_{X_2}(-ae_1 - be_2)$ is somewhat reminiscent of the construction of (multivariate) operators of degree $d(s - f)$ in [40 Prop. 8.7]. This is not a coincidence, as if we blow up a point on a noncommutative $\mathbb{P}^1 \times \mathbb{P}^1$, the result is isomorphic to a two-point blowup of a noncommutative plane, and the commutation of blowups symmetry on the latter is the same as the exchange of rulings symmetry on the former.

**Remark.** When $X$ is rational or rationally quasi-ruled, we can replace $\mathcal{O}_X$ by any line bundle (see Definition 5.21 below) by applying the corresponding twist autoequivalence before blowing up. If $r = \infty$, we find that every line bundle on $X_2$ fits into such an exact sequence (and thus, modulo checking that the other Ext groups vanish, we can compute one of its two spherical twists). If $r$ is finite, this fails, but every line bundle fits into a sequence along the above lines with $\mathcal{O}_{e_1 - e_2}(-1)$ replaced by some $\mathcal{O}_{e_1 - e_2}(-1 - dr)$. 

59
For the remaining cases, showing the pseudo-canonical property will require some additional facts about sheaves, so we will postpone that to a future section and consider only the construction of the derived equivalences. The $\mathbb{P}^1 \times \mathbb{P}^1$ case can be dealt with similarly, but the other two cases (elementary transformations and $F_1$ as a blowup of $\mathbb{P}^2$) require more complicated modifications of the semiorthogonal decomposition. To deal with these cases, it will be helpful to consider different semiorthogonal decompositions. In the rational case, the object $O_X$ is exceptional, and thus induces a semiorthogonal decomposition $(O^+_X, (O_X))$, while for blowups of quasi-ruled surfaces, the image of $D^b_{\text{coh}}C_0$ is admissible, so induces a decomposition. It turns out that in each case, the orthogonal subcategory is also essentially commutative, in that it appears in the same way as a subcategory of the derived category of a commutative surface. Moreover, the gluing data can also be expressed in commutative terms.

A key observation is that when $X$ has an anticanonical curve $C$, the gluing data can be expressed as a $R\text{Hom}$ in $D^b_{\text{coh}}C$. Let $i_* : D^b_{\text{coh}}C \to D^b_{\text{coh}}X$ be the embedding, with left adjoint $Li^*$ and associated twist $(−C)$.

**Lemma 4.28.** Let $X$ be a noncommutative surface with an anticanonical divisor $C$. If $M, N \in D^b_{\text{coh}}X$ are such that $R\text{Hom}(M, N) = 0$, then $R\text{Hom}(M, N) \cong R\text{Hom}_C(Li^*N, Li^*M)$.

**Proof.** By Serre duality, we have $R\text{Hom}_X(N, M(−C)[2]) \cong R\text{Hom}_X(M, N) = 0$, so that

$$R\text{Hom}_X(N, M) \cong R\text{Hom}_X(N, i_*Li^*M) \cong R\text{Hom}_C(Li^*N, Li^*M)$$

as required. □

We need a slight variation of this in order to deal with iterated blowups of quasi-ruled surfaces.

**Lemma 4.29.** Let $X$ be a noncommutative surface with a Serre functor and a curve $C$ embedded as a divisor, and suppose that $A$ is a full subcategory of $D^b_{\text{coh}}X$ preserved by $M \mapsto SM(C)$. Then for any $A \in A, B \in A^\perp, B' \in A^\perp$,

$$R\text{Hom}(B, A) \cong R\text{Hom}_C(Li^*B, Li^*A) \quad (4.65)$$

$$R\text{Hom}(A, B') \cong R\text{Hom}_C(Li^*A, Li^*B'). \quad (4.66)$$

**Proof.** For the first claim, it again suffices to show that $R\text{Hom}(B, A(-C)) = 0$. By Serre duality, this is isomorphic to $R\text{Hom}(A, SB(C)) = R\text{Hom}(S^{-1}A(-C), B) = 0$ since $S^{-1}A(-C) \in A$. Similarly, $R\text{Hom}(A, B'(-C)) \cong R\text{Hom}(B', SA(C)) = 0$. □

**Remark.** Note that if $M \mapsto SM(C)$ preserves $A$, then it also preserves $A^\perp$ and $^\perp A$.

For a noncommutative rational surface, the curve $Q$ of points is anticanonical, and thus $M \mapsto SM(Q)$ preserves $(O_X)$. For an iterated blowup of a quasi-ruled surface, this can fail, but the functor always preserves the category $Lp^*_0D^b_{\text{coh}}C_0$.

**Theorem 4.30.** Suppose the noncommutative surface $X$ is an iterated blowup of either a noncommutative plane or a noncommutative Hirzebruch surface, with anticanonical curve $Q$. Then there is a commutative surface $X'$, an embedding $Q \subset X'$ as an anticanonical curve, and a point $q \in \text{Pic}^0(Q)$ such that there is an equivalence $\kappa : O_X^\perp \cong O_{X'}^\perp$, satisfying

$$R\text{Hom}_X(M, O_X) \cong R\text{Hom}_{X'}(\kappa(M), q) \cong R\text{Hom}_Q(\kappa(M)|_Q, q). \quad (4.67)$$
Proof. The construction of $X$ as an iterated blowup gives rise to an exceptional collection
\[ \mathcal{O}_{e_0}(-1), \alpha_m^* \mathcal{O}_{e_{m-1}}(-1), \cdots, \tag{4.68} \]
ending with an exceptional collection for the original surface, in turn ending with $\mathcal{O}_X$. The forward maps in this exceptional collection (from which we can reconstruct the full derived category via gluing) can be computed via the restrictions to $Q$. What we need to prove is that there is a line bundle $q$ in the identity component of $\text{Pic}(Q)$ such that if we tensor the restrictions with $q$ and then replace the last term by $\mathcal{O}_Q$, then the result is the sequence corresponding to an exceptional collection in some commutative $X'$ with anticanonical curve $Q$.

For $X$ a noncommutative plane, the exceptional collection is $\mathcal{O}_X(-2), \mathcal{O}_X(-1), \mathcal{O}_X$, with restrictions $\mathcal{L}_{-6}, \mathcal{L}_{-3}, \mathcal{O}_Q$ with $\mathcal{L}_{-6}, \mathcal{L}_{-3}$ line bundles of the given degree such that $\mathcal{L}_{-3}, \mathcal{L}_{-6}^{-1} \otimes \mathcal{L}_{-3}$ are effective, acyclic, and numerically equivalent. The commutative case is that $\mathcal{L}_{-6} \cong \mathcal{L}_{-3}^2$, and thus if we tensor everything with $q$ and replace the last term with $\mathcal{O}_Q$, the result will correspond to a commutative surface as long as $q \otimes \mathcal{L}_{-6} \cong q^2 \otimes \mathcal{L}_{-3}^2$; or in other words when $q \cong \mathcal{L}_{-6} \otimes \mathcal{L}_{-3}^2$. The degree condition ensures that $q$ has degree 0 on every component, so is in $\text{Pic}^0(Q)$ as required. Note that the commutative surface is the $\mathbb{P}^2$ in which $Q$ is embedded via the line bundle $q^{-1} \otimes \mathcal{L}_{-3}^2$.

For a noncommutative Hirzebruch surface, we note that $D^b_{\text{coh}}[\mathbb{P}^1]$ has an exceptional collection $\mathcal{O}_{\mathbb{P}^1}(-1), \mathcal{O}_{\mathbb{P}^1}$, and thus we can refine the semiorthogonal decomposition of Theorem 4.4 to an exceptional collection. Restricting to $Q$ gives a sequence
\[ \mathcal{L}'_{-2}, \mathcal{L}', \mathcal{L}_{-2}, \mathcal{O}_X \tag{4.69} \]
which is commutative whenever $\mathcal{L}'_{-2} \cong \mathcal{L}' \otimes \mathcal{L}_{-2}$. Moreover, intersection theory forces $q := \mathcal{L}'^{-1} \otimes \mathcal{L}'_{-2} \otimes \mathcal{L}_{-2}^{-1}$ to be degree 0 on every component, and thus be in $\text{Pic}^0(Q)$ as required. The resulting commutative Hirzebruch surface is the one obtained by using $\mathcal{L}_{-2}^{-1} \otimes q^{-1}$ to determine a degree 2 morphism $\pi : Q \to \mathbb{P}^1$ and then taking the $\mathbb{P}^1$-bundle corresponding to $\pi_*(\mathcal{L}'^{-1} \otimes q^{-1})$.

Finally, if we blow up a point, the effect on the sequence of objects in $D^b_{\text{coh}}[Q]$ is to (derived) pull back all of the existing objects to the new anticanonical curve $Q'$ and then prepend the appropriate object to the beginning of the sequence. If $p$ is a smooth point of $Q$, this is simply a point sheaf, while in general it is given by the (perfect!) complex $\mathcal{O}_Q \to \mathcal{O}_Q(c)$, which can be computed inside the commutative surface. This complex is trivial on the generic point of the blowup $\bar{Q}$, and is thus invariant under twisting by $q$, while for the other sheaves we note that tensoring by $q$ then pulling back is the same as pulling back then tensoring by the pullback of $q$ (which is again of degree 0 on every component). We thus find that the effect of blowing up $X$ is the same as that of blowing up the corresponding point of $X'$ and then pulling back $q$. \[ \square \]

Remark 1. Given any triple $(X', Q, q)$ where $X'$ is a smooth projective rational surface, $Q \subset X$ is an anticanonical curve, and $q$ is a line bundle in the identity component of $\text{Pic}(Q)$, there is a corresponding (dg-enhanced) triangulated category obtained by using $q$ to glue $\mathcal{O}_{X'}$, to $\mathcal{O}_{X'}$, such that taking $q = \mathcal{O}_Q$ recovers $\mathcal{O}_{X'}$. Of course, to obtain the noncommutative rational surfaces themselves, one needs to determine the $t$-structure, which turns out not to be possible without imposing some additional structure on $X'$. This can, however, be done inductively given a choice of blowdown structure on $X'$ (i.e., a sequence of monoidal transformations blowing it down to either a Hirzebruch surface or $\mathbb{P}^2$), by insisting that the corresponding functors be pseudo-canonical. As usual, it appears to be hard to prove independently that this gives a $t$-structure, let alone that it is the derived category of its heart. It follows, of course, from the above considerations, and thus we can use this to construct a family of noncommutative surfaces parametrized by the relative $\text{Pic}^0$ of the universal anticanonical curve of the moduli stack of anticanonical rational surfaces with blowdown structure, see below.
Remark 2. In the fully noncommutative case, the gluing data is again in the form of a pair of adjoint functors, since \( q \in \mathcal{O}_X^1 \). On the other hand, when \( q = \mathcal{O}_Q \), the above description is no longer of that form. This can be rectified, however, since for \( M \in \mathcal{O}_X^1 \), one has

\[
R \text{Hom}_{X'}(M, \omega_{X'}) \cong R \text{Hom}_{X'}(\mathcal{O}_X, M[2])^* = 0,
\]

and thus

\[
R \text{Hom}_{X'}(M, \mathcal{O}_{X'}) \cong R \text{Hom}_{X'}(M, \text{cone}(\text{tr})[-1])
\]

where \( \text{tr} \) is the trace map \( \mathcal{O}_{X'} \to \omega_{X'}[2] \). Since \( R \text{Hom}(\mathcal{O}_{X'}, \text{tr}) \) is the identity and \( \text{cone}(\text{tr})[-1] \in \mathcal{O}_X^1 \), this induces the desired functor.

Remark 3. It follows from [24, Thm. 8.5] that the Hochschild cohomology of \( \mathcal{O}_X^1 \), is the hypercohomology of \( \mathcal{O}_{X'} \oplus T_{X'} \), so that (since \( \mathcal{O}_{X'} \) is acyclic) the deformation theory of \( \mathcal{O}_X^1 \) is given by the commutative deformation theory of \( X' \). Similarly, the deformations of the gluing functor (i.e., the deformations of \( X \) with \( \mathcal{O}_X^1 \) fixed) are controlled by the deformations of the image of \( q \in \mathcal{O}_X^1 \).

Thus if \( q \not\in \mathcal{O}_Q \), then the deformation theory is controlled by the hypercohomology of \( \mathcal{O}_Q \oplus \mathcal{O}_Q(Q) \), while for \( X = X' \), the deformation theory is controlled by the hypercohomology of \( \wedge^2 T_{X'} \cong \omega_{X'}^{-1} \).

This implies at the very least that any first-order deformation of \( \text{perf}(X) \) is a noncommutative rational surface of the above form, and the agreement of obstruction spaces suggests that this should extend to arbitrary formal deformations.

In particular, any isomorphism \( X' \cong Y' \) of rational surfaces with blowdown structures induces a derived equivalence between the corresponding noncommutative surfaces, giving the desired derived equivalences corresponding to \( \mathbb{P}^1 \times \mathbb{P}^1 \cong \mathbb{P}^1 \times \mathbb{P}^1 \) and the representation of \( F_1 \) as a blowup of \( \mathbb{P}^2 \). In each case, the resulting equivalence will be an abelian equivalence as long as the functor \( R\Gamma \) is pseudo-canonical, since this functor is clearly preserved by the equivalence.

**Proposition 4.31.** The image of the restriction map \( L^*: \mathcal{O}_X^1 \to \text{perf}(Q) \) generates \( \text{perf}(Q) \).

**Proof.** Without loss of generality, \( X \) is a commutative rational surface. As in Lemma 4.20, we find that \( L^* \text{perf}(X) \) generates \( \text{perf}(Q) \), so it will suffice to show that \( \mathcal{O}_Q = L^*\mathcal{O}_X \) is in the Karoubian triangulated subcategory generated by \( L^*\mathcal{O}_X^1 \).

Define an element \( M \in \mathcal{O}_X^1 \) by the distinguished triangle

\[
M \to \mathcal{O}_X \to \theta \mathcal{O}_X[2] \to
\]

coming from the natural element of \( \text{Ext}^2(\mathcal{O}_X, \theta \mathcal{O}_X) \). Since \( \text{Ext}^2 \) vanishes for line bundles on \( Q \), this map is annihilated by \( L^* \), producing a splitting:

\[
L^* M \cong \theta \mathcal{O}_Q[1] \oplus \mathcal{O}_Q.
\]

But this is what we needed to show. \( \square \)

For quasi-ruled surfaces, we note the following.

**Lemma 4.32.** Let \( X \) be a quasi-ruled surface over \( C_0, C_1 \), and let \( Q \) be the corresponding curve of points. Then there are morphisms \( \pi_i : Q \to C_i \) such that \( L^* L\rho_0^* \cong L\pi_0^* \) and

\[
L^* L\rho_1^* \cong L^{-1}_s \otimes L\pi_1^*.
\]

for some line bundle \( L_s \) having degree 1 on every vertical component.
Proof. Let $\bar{\pi}_i : \bar{Q} \to C_i$ be the natural degree 2 morphisms, let $\pi : Q \to \bar{Q}$ be the morphism contracting the vertical fibers, and define $\pi_i = \pi \circ \bar{\pi}_i$. Then for any line bundle $L$ on $C_i$,

$$L_i^* \rho_i^* L \cong L_i^* \rho_i^* O_{C_i} \otimes \pi_i^* L,$$

(4.75)

since twisting by $L$ gives another quasi-ruled surface. The claim for $i = 0$ follows immediately, and for $i = 1$ reduces to showing that $i^* \rho_1^* O_{C_1}$ is an invertible sheaf having degree $-1$ on every vertical component. Writing this object as $M, \rho_1$ corresponds to an isomorphism $\rho_1^* O_{C_1}$, so that $\pi_1^* O_{C_1} \otimes \rho_1^* L \cong \pi_1^* O_{C_1} \otimes L$, and thus the standard spectral sequence implies that $\mathcal{L}_s$ must itself be a sheaf. We similarly find that the adjoint sheaf bimodule is given by

$$R(\pi_0 \times \pi_1)_* (\mathcal{L}_s^{-1} \otimes \pi_0^* O_{C_0}),$$

(4.76)

so that $\mathcal{L}_s^{-1}$ is also a sheaf. Thus $\mathcal{L}_s$ is reflexive, and since it has rank 1 away from the vertical fibers, must have rank 1. If $\mathcal{L}_s$ had degree $\geq 2$ on any vertical fiber, it would have a subsheaf isomorphic to the structure sheaf of that fiber, and thus its direct image would fail to be pure 1-dimensional.

On the other hand, $\mathcal{L}_s^{-1}$ must have negative degree on every vertical fiber, since the pullback of a point sheaf agrees with that point sheaf in cohomological degree $\geq 0$, and thus the corresponding map $i^* \pi_1^* O_{p_1} \to i^* \pi_0^* O_{p_0}$ must be injective with cokernel $O_p$.

Proposition 4.33. Let $X$ be an iterated blowup of a noncommutative quasi-ruled surface over $(C_0, C_1)$, with curve of points $Q$, and let $L \rho_0^* : D^b_{\text{coh}} C_0 \to D^b_{\text{coh}} X$ be the corresponding embedding. Then there is a commutative rationally ruled surface $\rho : X' \to C_1$ such that there is an equivalence

$$\kappa : (\rho_0^* D^b_{\text{coh}} C_0)^\perp \cong (\rho^* D^b_{\text{coh}} C_1)^\perp,$$

satisfying $\kappa(M)|_Q \cong i^* M$, and thus

$$R \text{Hom}(M, \rho_0^* N) \cong R \text{Hom}_Q((\kappa M)|_Q, \rho_0^* N).$$

(4.77)

Proof. If $X$ is a noncommutative quasi-ruled surface, then we can take $X'$ to be $\mathbb{P}(\pi_1_* \mathcal{L}_s)$, so that $Q$ embeds in $X'$ in such a way that $O_{X'}(s)|_Q \cong \mathcal{L}_s$. Blowups then work as in the rational case.

Remark. Note that when $X$ is rational, the commutative surface obtained in this way will not in general be isomorphic to that associated to $O_X^\perp$, although this just involves a minor twist: the above equivalence extends to an isomorphism $\rho_0^* O_{\mathbb{P}^1}(1)^\perp \cong \rho^* O_{\mathbb{P}^1}(1)^\perp$ that still respects the restriction to $Q$, and there is an abelian equivalence taking $\rho_0^* O_{\mathbb{P}^1}(1)$ to the structure sheaf of a slightly different noncommutative rational surface.

Again, this gives derived equivalences corresponding to any isomorphism of commutative ruled surfaces, giving the desired equivalences corresponding to elementary transformations. Since this respects the projection $\rho_0 \circ \alpha_s$ to $\im \rho_0$, it will be an abelian equivalence whenever that projection is pseudo-canonical.

There is a similar statement associated to iterated blowups of a noncommutative surface: if $\pi : X \to Y$ is such a blowup such that the curve of points $Q \subset Y$ is a surface curve, then there is a commutative blowup $\pi' : X' \to Y'$ with an isomorphism $(\pi^* D^b_{\text{coh}} Y)^\perp \cong (\pi'^* D^b_{\text{coh}} Y')^\perp$ respecting restriction to $Q$. Indeed, we need simply embed $Q$ in a smooth projective surface $Y'$ and then perform the corresponding sequence of blowups. In particular, the results in [39] on the category of sheaves/objects annihilated by $R\pi_*$ carry over immediately to the noncommutative case. (In fact, it suffices for $Q$ to be Gorenstein, as it still locally embeds in a surface, and the categories only depend on how $Q$ behaves near the points being blown up.)
5 Derived equivalences

Of course, we can also use these semiorthogonal decompositions to construct derived equivalences which are not abelian equivalences. The simplest instance of such a derived equivalence is the following duality. Note that in the following proposition, only the category \( D^b_{\text{coh}} X_q \) is determined by the data, as we have not chosen a blowdown structure on \( X' \). For quasi-ruled surfaces, such a duality can be obtained from the adjoint involution discussed above, and the duality we give is, in fact, closely related to that involution.

**Proposition 5.1.** Let \((X', Q)\) be an anticanonical rational surface, and for each \( q \in \text{Pic}^0(Q) \), let \( X_q \) denote the corresponding (derived) noncommutative rational surface. Then there is a family of equivalences \( \text{ad}_q : (D^b_{\text{coh}} X_q)^{\text{op}} \cong D^b_{\text{coh}} X_{q-1} \) such that \( \text{ad}_q \text{ad}_q \cong \text{id} \).

**Proof.** On \( X' \) we have the natural (Cohen-Macaulay) duality functor \( M^D := R \text{Hom}(M, \omega_{X'}) \). This takes \( \mathcal{O}_{X'} \) to \( \omega_{X'} \), and if \( M \in \mathcal{O}_{X'} \), then

\[
R \text{Hom}_{X'}(\mathcal{O}_{X'}, M^D) \cong R \text{Hom}_{X'}(M^D, \omega_{X'}[2])^* \cong R \text{Hom}(\mathcal{O}_{X'}, M[2])^* = 0,
\]

so that \( M^D \) restricts to a duality on \( \mathcal{O}_{X'}^\perp \). We claim that there is a duality \( \text{ad}_q : (D^b_{\text{coh}} X_q)^{\text{op}} \rightarrow D^b_{\text{coh}} X_{q-1} \) such that \( \text{ad}_q \mathcal{O}_{X_q} \cong \theta \mathcal{O}_{X_{q-1}} \) and

\[
\text{ad}_q \kappa_{q-1}^{-1} M = \kappa_{q-1}^{-1} M^D.
\]

This transforms the semiorthogonal decomposition as \( (\mathcal{O}_{X_q}^\perp, \mathcal{O}_{X_q}) \rightarrow (\theta \mathcal{O}_{X_{q-1}}^\perp, \mathcal{O}_{X_{q-1}}^\perp) \), so it remains only to show that it respects the gluing functor. In other words, we need to show that

\[
R \text{Hom}(\text{ad}_q \mathcal{O}_{X_q}, \text{ad}_q M) \cong R \text{Hom}(M, \mathcal{O}_{X_q})
\]

for any \( M \in \mathcal{O}_{X_q}^\perp \). Since

\[
R \text{Hom}_{X_{q-1}}(\theta \mathcal{O}_{X_{q-1}}, \kappa_{q-1}^{-1} M^D) \cong R \text{Hom}_{X_{q-1}}(\text{cone}(\text{tr}_{q-1})[-2], \kappa_{q-1}^{-1} M^D),
\]

where \( \text{tr}_{q-1} : \mathcal{O}_{X_{q-1}} \rightarrow \theta \mathcal{O}_{X_{q-1}}[2] \) is the natural trace map associated to the Serre functor, and \( \text{cone}(\text{tr}_{q-1}) \in \mathcal{O}_{X_{q-1}}^\perp \), we find that

\[
R \text{Hom}_{X_{q-1}}(\theta \mathcal{O}_{X_{q-1}}, \kappa_{q-1}^{-1} M^D) \cong R \text{Hom}_{X'}(\kappa_{q-1}^{-1} \text{cone}(\text{tr}_{q-1})[-2], M^D)
\]

\[\cong R \text{Hom}_{X'}(M, (\kappa_{q-1} \text{cone}(\text{tr}_{q-1})[-2])^D),\]

so that it remains only to compute \( \kappa_{q-1} \text{cone}(\text{tr}_{q-1})[-2] \). For any \( M \in \mathcal{O}_{X'}^\perp \), we have

\[
R \text{Hom}_{X'}(\kappa_{q-1}^{-1} M, \text{cone}(\text{tr}_{q-1})[-2]) \cong R \text{Hom}_{X'}(\kappa_{q-1}^{-1} M, \mathcal{O}_{X_{q-1}}[-1]) \cong R \text{Hom}_{X'}(M, q^{-1}[-1]),
\]

so that \( \kappa_{q-1} \text{cone}(\text{tr}_{q-1})[-2] \cong q^{-1}[-1] \) (adjusted accordingly when \( q = \mathcal{O}_Q \)) and dualizing gives \( q \) as required.

Since \( \kappa_q \text{ad}_q^{-1} \text{ad}_q \kappa_q^{-1} = \mathcal{D}^D \cong \text{id} \), to show that this is an involution it remains only to check that \( \text{ad}_q^{-1} \theta \mathcal{O}_{X_{q-1}} \cong \mathcal{O}_{X_q} \). But this follows from the fact the Serre functor is intrinsic, and thus any contravariant equivalence satisfies \( S \text{ad}_q S \cong \text{ad}_q \).

This duality respects the blowup and ruled surface decompositions.
Lemma 5.2. Let $\alpha : \tilde{X}' \to X'$ be a monoidal transformation centered at a point of $Q$, and let $\tilde{X}_q$, $X_q$ be the corresponding noncommutative families, with $\tilde{X}_q$ the blowup of $X_q$. Then $\ad_q \mathcal{O}_e(-1) \cong \mathcal{O}_e(-1)[-1]$, $\ad_q \La^* M \cong \La^1 \ad_q M$, and $\ad_q \Ra_\alpha^* M \cong \alpha_\ast \ad_q M$.

Proof. Since $\kappa_q \mathcal{O}_e(-1) \cong \mathcal{O}_e(-1)$, the action of the duality on $\mathcal{O}_e(-1)$ reduces to the commutative case. For the action on $\La^* M$, we first note that if $M \in \mathcal{O}_{\tilde{X}_q}^\perp$, then $\La^* M \in \mathcal{O}_{\tilde{X}_q}^\perp$, and thus $\ad_q \La^* M$ can be computed inside $\tilde{X}'$, giving

$$\kappa_{q-1} \ad_q \La^* M \cong \ad_q \La^* \kappa_q M \cong \La^1 \ad_q \kappa_q M \cong \La^1 \kappa_{q-1} \ad_q M \cong \kappa_{q-1} \La^1 \ad_q M.$$  \hspace{1cm} (5.7)

Since

$$\ad_q \La^* \mathcal{O}_{X_q} \cong \ad_q \mathcal{O}_{\tilde{X}_q} \cong \theta \mathcal{O}_{\tilde{X}_q-1} \cong \La^1 \theta \mathcal{O}_{X_q-1} \cong \La^1 \ad_q \mathcal{O}_{X_q},$$  \hspace{1cm} (5.8)

the action on $\La^* M$ is as described. Finally, we find

$$R \text{Hom}(N, \Ra_\alpha \ad_q M) \cong R \text{Hom}(\La^* N, \ad_q M)$$

$$\cong R \text{Hom}(M, \ad_q \La^* N)$$

$$\cong R \text{Hom}(M, \La^1 \ad_q N)$$

$$\cong R \text{Hom}(\Ra_\alpha \ad_q M, \ad_q N)$$

$$\cong R \text{Hom}(N, \ad_q \Ra_\alpha M)$$ \hspace{1cm} (5.9)

so that $\Ra_\alpha \ad_q M \cong \ad_q \Ra_\alpha M$ as required. \hfill \Box

Lemma 5.3. Let $(X', Q')$ be an anticanonical Hirzebruch surface with $\rho : X' \to \mathbb{P}^1$. Then on $X_q$ one has $\ad_q \rho_1^* M \cong \rho_1^* M^D$ and $\ad_q \rho_0^* M \cong \theta \rho_0^* \theta^{-1} M^D$.

Proof. Since $\im \rho_1^* \subset \mathcal{O}_{\tilde{X}_q}$, we can compute the duality inside in $\im \rho_1^*$ on $X'$, where it becomes

$$\ad_q (\rho^* M(-s)) \equiv \rho^* (M^D)(-s),$$  \hspace{1cm} (5.10)

easily checked on line bundles. Similarly, a commutative computation gives $\ad_q \rho_0^* \mathcal{O}_{\mathbb{P}^1}(-1) \cong \theta \rho_0^* \theta^{-1} \mathcal{O}_{\mathbb{P}^1}(-1)$, and the claim for $\mathcal{O}_{\mathbb{P}^1}$ follows from the value of $\ad_q$ on $\theta \mathcal{O}_X$. \hfill \Box

This suggests that there should be a similar duality on a general iterated blowup of a quasi-ruled surface. Although this could in principle be constructed using the $\rho_0^* D^b_{\text{coh}} C_0$-based semiorthogonal decomposition, the calculation involves some somewhat tricky adjoint computations, and thus we use an inductive approach instead.

Proposition 5.4. Let $C_0$, $C_1$ be smooth projective curves, let $\mathcal{E}$ be a sheaf bimodule of birank $(2,2)$ on $C_0 \times C_1$, and let $X$ be the corresponding noncommutative $\mathbb{P}^1$-bundle. Similarly, let $X^{\text{ad}}$ be the noncommutative $\mathbb{P}^1$-bundle associated to the sheaf bimodule $\mathcal{E} \text{Hom}_C^1(C_0 \times C_1, (\mathcal{E}, \omega_{C_0 \times C_1})$. Then $(D^b_{\text{coh}} X)^{\text{op}} \cong D^b_{\text{coh}} X^{\text{ad}}$.

Proof. Per the rational case, we want a duality defined in terms of the duality on $C_0$, $C_1$ by

$$\ad \rho_1^* M \cong \rho_1^* \text{Hom}(M, \omega_{C_1})$$

and

$$\ad \theta \rho_0^* M \cong \rho_0^* \text{Hom}(M, \omega_{C_0}).$$  \hspace{1cm} (5.11)

Since $(\im \theta \rho_0^*, \im \rho_1^*)$ gives a semiorthogonal decomposition, this certainly defines a contravariant equivalence to some glued triangulated category $X^{\text{ad}}$, so we just need to show that the gluing map corresponds to the given sheaf bimodule. We compute

$$R \text{Hom}_{X^{\text{ad}}}(\rho_1^* M, \rho_0^* N) \cong R \text{Hom}_{X^{\text{ad}}}(\ad \rho_1^* \text{Hom}(M, \omega_{C_1}), \ad \theta \rho_0^* \text{Hom}(N, \omega_{C_0}))$$

$$\cong R \text{Hom}_{X}(\theta \rho_0^* \text{Hom}(N, \omega_{C_0}), \rho_1^* \text{Hom}(M, \omega_{C_1})).$$  \hspace{1cm} (5.12)
Using the functorial distinguished triangle
\[ \theta \rho_0^* \theta^{-1} \to \rho_1^*(\text{–} \otimes_{\mathcal{O}_{C_0}} \mathcal{E}) \to \rho_0^* \to, \] (5.13)
we find that
\[ R\text{Hom}_X((\theta \rho_0^* \text{Hom}(N, \mathcal{O}_{C_0}), \rho_1^* \text{Hom}(M, \omega_{C_1}))) \]
\[ \cong R\text{Hom}_X(\rho_1^*(\text{Hom}(N, \mathcal{O}_{C_0}) \otimes_{\mathcal{O}_{C_0}} \mathcal{E}), \rho_1^* \text{Hom}(M, \omega_{C_1})) \]
\[ \cong R\text{Hom}_{C_1}((\text{Hom}(N, \mathcal{O}_{C_0}) \otimes_{\mathcal{O}_{C_0}} \mathcal{E}), \text{Hom}(M, \omega_{C_1})) \]
\[ \cong R\text{Hom}_{C_1}(M, \text{Hom}(\text{Hom}(N, \mathcal{O}_{C_0}) \otimes_{\mathcal{O}_{C_0}} \mathcal{E}, \omega_{C_1})). \] (5.14)

Using the definition of the tensor product of sheaf bimodules, the functor being applied to \( N \) has the form
\[ N \mapsto \text{Hom}(\pi_1^*(\pi_0^* \text{Hom}(N, \mathcal{O}_{C_0}) \otimes \mathcal{E}), \omega_{C_1}) \cong \pi_1^* \text{Ext}^1(\pi_0^* \text{Hom}(N, \mathcal{O}_{C_0}) \otimes \mathcal{E}, \omega_{C_0 \times C_1}) \]
\[ \cong \pi_1^*(\pi_0^* N \otimes \text{Ext}^1(\mathcal{E}, \omega_{C_0 \times C_1})) \]
\[ = N \otimes_{\mathcal{O}_{C_0}} \text{Ext}^1(\mathcal{E}, \omega_{C_0 \times C_1}) \] (5.15)
as required.

\( \square \)

**Remark.** This duality is of course related to the adjoint involution defined above in terms of the sheaf \( \mathbb{Z} \)-algebra: any module over the \( \mathbb{Z} \)-algebra has a dual which is a module over the opposite algebra, and an appropriate degree shift and twist by a line bundle recovers the duality. In particular, when applied to a 1-dimensional sheaf corresponding to a difference or differential equation, this is just a (cohomological) shift of the usual duality (i.e., coming from the dual representation of \( GL_n \) or \( \mathfrak{gl}_n \) as appropriate).

This duality also respects the curve of points, in the following way.

**Proposition 5.5.** Let \( X \) be a quasi-ruled surface with curve of points \( Q \), and let \( X^\text{ad} \) be its dual. Then the curve of points of \( X^\text{ad} \) can be identified with \( Q \) in such a way that \( \text{ad}[1] \) restricts to the Cohen-Macaulay duality on \( D^\text{coh}_0 Q \).

**Proof.** Any \( S \)-point \( p \) of \( X \) arises from a short exact sequence
\[ 0 \to \rho_1^* \mathcal{O}_p \to \rho_0^* \mathcal{O}_p \to \mathcal{O}_p \to 0. \] (5.16)
Applying \( \text{ad} \) and computing the relevant commutative duals gives a distinguished triangle
\[ \text{ad} \mathcal{O}_p \to \theta \rho_0^* \mathcal{O}_p[-1] \to \rho_1^* \mathcal{O}_p[-1] \to. \] (5.17)
It follows from this that \( (\text{ad} \mathcal{O}_p)[2] \) is an \( S \)-point sheaf on \( X^\text{ad} \), and thus that the corresponding functors (so moduli schemes) are isomorphic. Moreover, one has
\[ \text{ad} \mathcal{O}_p \cong \mathcal{O}_p[-2] \cong \text{Hom}_Q(\mathcal{O}_p, \omega_Q)[-1] \] (5.18)
so that \( \text{ad}[1] \) agrees with the Cohen-Macaulay duality on point sheaves. It then suffices to verify that it behaves correctly on the structure sheaf. We have the short exact sequence
\[ 0 \to \mathcal{O}_X(-Q) \to \mathcal{O}_X \to \mathcal{O}_Q \to 0 \] (5.19)
and the adjoint gives
\[ 0 \to \theta \mathcal{O}_{X^\text{ad}} \to \theta \mathcal{O}_{X^\text{ad}}(Q) \to \text{ad} \mathcal{O}_Q[1] \to 0, \] (5.20)
but \( \theta \mathcal{O}_X(Q)|_Q \cong \omega_Q \) by Proposition 1.17. \( \square \)
This claim about the restriction is crucial to let us make blowups work.

Lemma 5.6. Let $X$ be a noncommutative surface with curve of points $Q$ such that $X$ is generated by weak line bundles along $Q$, and let $\tilde{X}$ be the blowup of $X$ at $p$. If $X^\text{ad}$ is another noncommutative surface with the same curve of points and there is a duality $\text{ad} : (D^b_{\text{coh}}X)^{\text{op}} \to D^b_{\text{coh}}X^\text{ad}$ such that $\text{ad}(M(-Q)) \cong (\text{ad} M)(Q)$ and $\text{ad}[1]$ restricts to the Cohen-Macaulay duality on $Q$, then there is a duality $\text{ad} : (D^b_{\text{coh}}\tilde{X})^{\text{op}} \to D^b_{\text{coh}}\tilde{X}^\text{ad}$, where $X^\text{ad}$ is the blowup of $X^\text{ad}$ at $p$, and $\text{ad}[1]$ satisfies the same conditions with respect to the new curve of points.

Proof. Following the rational case, we aim to define $\tilde{\text{ad}}$ so that

$$\tilde{\text{ad}}O_e(-1) \cong O_e(-1)[1] \quad \text{and} \quad \tilde{\text{ad}}L^aM \cong L^a\text{ad}M.$$ (5.21)

Consistency of the gluing reduces to computing $\text{ad}$ on the appropriate point sheaf, which follows by a computation in $Q$.

It remains only to show that $\tilde{\text{ad}}[1]$ interacts correctly with the new curve of points $Q^+$. That $\tilde{\text{ad}}(M(-1)) \cong (\text{ad} M)(1)$ follows from the description of $M \mapsto \theta M(1)$ in terms of $\theta M(-Q)$ and the fact that $\text{ad}$ and $\text{ad}$ both invert $\theta$ while $\text{ad}$ inverts $\theta(-Q)$. Any line bundle on $Q$ pulls back via $\alpha^*$ to a line bundle on $Q^+$, and one has

$$(\text{ad} \alpha^*L)[1] \cong \alpha^*(\text{ad} L)[1] \cong \alpha^*(\text{Hom}(L,\omega_Q) \cong \alpha^*\text{Hom}(L,\omega_Q) \otimes O_{Q^+}(e)).$$ (5.22)

This depends only on the commutative morphism $\alpha : Q^+ \to Q$, and may thus be computed inside a commutative surface, where it reduces to the corresponding fact for the Cohen-Macaulay dual.

It follows more generally that for any $d \in \mathbb{Z}$, one has

$$\text{ad}(\alpha^*L(d))[1] \cong \text{Hom}(\alpha^*L,\omega_{Q^+})(-d) \cong \text{Hom}(\alpha^*L(d),\omega_{Q^+})$$ (5.23)

But the line bundles on $Q^+$ of this form are ample, and thus any object $M$ in $D^b_{\text{coh}}Q^+$ is quasi-isomorphic to a right-bounded complex in which the terms are sums of such line bundles. This complex is acyclic for $\text{ad}[1]$, so $\text{ad} M[1]$ is quasi-isomorphic to the left-bounded complex obtained by applying $\text{ad}[1]$ term-by-term. It follows that $\text{ad} M[1] \cong \text{Hom}_{Q^+}(M,\omega_{Q^+})$ as required. \hfill \Box

This gives rise to an inductive construction of a duality $\text{ad}$ on any iterated blowup of a quasi-ruled surface or noncommutative plane, which agrees with the previous definition in the rational surface case.

Although this duality cannot be expected to be exact (any more than the Cohen-Macaulay duality it deforms), we can in fact control fairly well how it interacts with the $t$-structure. The key idea is that there is a particularly nice class of generators of $\text{qcoh} X$ that is preserved by duality.

Definition 5.1. A line bundle on a rational or rationally quasi-ruled surface is a member of the smallest class of sheaves on such surfaces such that (a) any sheaf isomorphic to a line bundle is a line bundle, (b) on a noncommutative plane, $\mathcal{O}_X, \mathcal{O}_X(-1)$ and $\mathcal{O}_X(-2)$ are line bundles, (c) on a quasi-ruled surface, $\rho_\theta^*L$ is a line bundle for any line bundle $L \in C_d$, and (d) the image of a line bundle under $\theta$ or $\alpha^*_t$ is a line bundle.

Remark. This differs from other notions of line bundles in the literature; in addition to the weak notion considered above (the restriction to $Q$ is a line bundle), one might also consider those weak line bundles which are reflexive under $\theta^0 \text{ad}$ (this was considered in \cite{30} for noncommutative planes). The above notion has the merit that the corresponding family of moduli spaces is flat; in particular, in a sufficiently large family of rationally ruled surfaces, the line bundles are deformations of line...
bundles on the commutative fibers of the family. Although it in principle depends on the way
in which we described the surface as an iterated blowup, this is not the case, see Corollary [10.15]
below. It is unclear whether there is a corresponding notion for vector bundles (i.e., as a subclass
of reflexive coherent sheaves).

One key fact about line bundles is that there is a notion of twi
sting by line bundles. To be
precise, for any line bundle \(L\) on \(X\), there is another rational (resp. rationally quasi-ruled) surface
\(X'\) such that there is a Morita equivalence \(\text{coh} X \cong \text{coh} X'\) taking \(L\) to \(\mathcal{O}_{X'}\), taking point sheaves to
point sheaves, and taking line bundles to line bundles. This is trivial for noncommutative planes, is
straightforward for quasi-ruled surfaces, and follows by an easy induction in general. (For a blowup,
we simply take the composition of a power of \(\theta\) with the result of applying such an equivalence to the
original surface, making sure to keep track of the point being blown up.) When \(X\) is commutative,
this is agrees with the usual notion of twisting by a line bundle, but in general this twist is not an
autoequivalence.

Line bundles give an alternate description of the \(t\)-structure.

**Lemma 5.7.** An object \(M \in D_{\text{qcoh}}(X)\) is in \(D_{\text{qcoh}}(X)_{\geq 0}\) iff \(\text{Hom}(L[p], M) = 0\) whenever \(p\) is a
negative integer and \(L\) is a line bundle.

**Proof.** This is automatic for a plane, while on a quasi-ruled surface, this follows via adjunction from
the corresponding fact for line bundles on commutative curves; for rationally quasi-ruled surfaces,
it follows by an easy induction. \(\square\)

We also have the following important fact, which in particular shows that line bundles generate
\(\text{coh} X\), so \(\text{qcoh} X\).

**Proposition 5.8.** If \(M \in \text{coh}(X)\), then there is a line bundle \(L\) such that \(\text{Ext}^p(L, M) = 0\) for
\(p > 0\) and \(L \otimes \text{Hom}(L, M) \to M\) is surjective.

**Proof.** This is certainly true by construction for planes and quasi-ruled surfaces and for blowups
follows by an easy induction from the fact that for \(l \gg 0\), \(\alpha_m \theta^{-l} M\) is a sheaf and \(\alpha_m^* \alpha_m \theta^{-l} M \to M\)
is globally generated. Indeed, if \(L'\) is the line bundle satisfying the conclusion for the sheaf \(\alpha_m \theta^{-l} M\)
on \(X_{m-1}\), then we may take \(L = \theta^l \alpha_m^* L'\). \(\square\)

**Remark.** We will prove a number of refinements of this fact below. One easy refinement is that
we need not use every line bundle here; in particular, if we fix points \(x_0 \in C_0, x_1 \in C_1\), we need
only use those bundles coming from \(\mathcal{O}_{C_d}(nx_d)\) for \(d, n \in \mathbb{Z}\). (This refinement also applies to the
description of the \(t\)-structure.)

**Remark.** More generally, given a finite collection of coherent sheaves, we can find a single line
bundle that acyclically globally generates all of them: simply apply the Proposition to the direct
sum.

Since \(\text{ad} \theta \cong \theta^{-1} \text{ad} \) and \(\text{ad} \alpha^* \cong \alpha^1 \text{ad} \), it is easy to verify that for any line bundle \(L\), \(\text{ad} L\) is also
a line bundle. We may thus view the above derived duality as the derived functor of a contravariant
functor \(\text{ad}\) of abelian categories, and will thus in the sequel denote it as \(R\text{ad}\), particularly when
applying it to sheaves.

**Corollary 5.9.** The duality \(\text{ad}\) is left exact of homological dimension \(\leq 2\).

**Proof.** Since line bundles generate \(\text{coh} X\) and \(\text{ad}\) takes line bundles to line bundles, it is left exact.
Now, for any line bundle \(L\) and coherent sheaf \(M\), we have
\[
R\text{Hom}(L, R\text{ad} M) \cong R\text{Hom}(M, \text{ad} L) \cong R\text{Hom}(\text{ad} L, \theta M[2])^*, \quad (5.24)
\]
and thus $h^p R \text{Hom}(L, R \text{ad} M) = 0$ for $p \notin \{0, 1, 2\}$. For each $p'$, we may choose $L$ so that the first $p' + 1$ cohomology sheaves of $R \text{ad} M$ are acyclically globally generated by $L$. But then the spectral sequence gives $h^i R \text{Hom}(L, R \text{ad} M) = \text{Hom}(L, R^i \text{ad} M)$ for $0 \leq i < p'$, and thus $R^i \text{ad} M = 0$ for $2 \leq i < p'$. Since this is true for all $p'$, we conclude that $\text{ad}$ has homological dimension 2 as required.

The other family of true derived equivalences we consider are related to derived autoequivalences of commutative elliptic surfaces. If $C$ is a smooth curve and $X/C$ is the minimal proper regular model of an elliptic curve over $k(C)$, then there is an associated action of $SL_2(\mathbb{Z})$ on $D^b_{\text{coh}} X$. If $X$ has only smooth fibers, this is just a relative version of the action of $SL_2(\mathbb{Z})$ on the derived category of an elliptic curve, and in general a similar construction works (albeit with some issues of nonuniqueness when $X$ has reducible fibers).

Since the deformation theory of an abelian category depends only on the associated derived category, the autoequivalences of the derived category act on the space of infinitesimal deformations. It is therefore not unreasonable to expect this to extend to an action on algebraic deformations, such that two deformations in the same orbit should be derived equivalent. This is of course purely heuristic, but works for both types of elliptic surface that have a rational ruling, and thus admit noncommutative deformations via the above construction.

A rationally ruled surface over a curve of genus $> 1$ does not contain any curves of genus 1 (a vertical curve has genus 0, while a horizontal curve maps to the base of the ruling, so has genus $> 1$). If the base curve has genus 1, then every fiber of the elliptic surface contains a smooth genus 1 curve isogenous to the base, and thus the minimal proper regular model must be a constant family, so that the only rationally ruled case is $E \times \mathbb{P}^1$. In the genus 0 case, we have a rational elliptic surface, and it is well-known that such a surface, if relatively minimal, must have $K^2 = 0$, with the elliptic fibration given by the anticanonical pencil $| - K|$. These cases then deform to (a) noncommutative ruled surfaces over $E$ in the same component of the moduli stack as $E \times \mathbb{P}^1$, and (b) noncommutative rational surfaces with $\theta \mathcal{O}_Q \in \text{Pic}^0(Q)$.

For the genus 1 case, we recall that a sheaf bimodule on $E \times E$ corresponding to a noncommutative ruled surface necessarily has reducible (or nonreduced) support, and thus may be viewed as an extension of two rank $(1, 1)$ sheaf bimodules, both algebraically equivalent to the diagonal. The moduli space of such rank $(1, 1)$ sheaf bimodules can itself be identified with $E \times \text{Pic}(E)$: the bimodule is given by a line bundle in $\text{Pic}^0(E) \cong E$ supported on the graph of a translation. So as to obtain a surface sufficiently similar to $E \times \mathbb{P}^1$, we insist that the line bundle be degree 0, so that the moduli space is $E \times E$. This moduli space has a universal family, which in turn induces a Fourier-Mukai functor $D^b_{\text{coh}}(E \times E) \to D^b_{\text{coh}}(E \times E)$ taking point sheaves to their corresponding sheaf bimodules. This is actually an equivalence, allowing us to identify the relevant component of the moduli stack of rank $(2, 2)$ sheaf bimodules with the moduli stack $(E \times E)^{(2)}$ of 0-dimensional sheaves on $E \times E$ of Euler characteristic 2. (This stack is a mild thickening of the 2-point Hilbert scheme of $E \times E$, gluing in sheaves of the form $\mathcal{O}_p^2$.)

We thus obtain a family of noncommutative ruled surfaces over this stack. Any automorphism of the scheme $E \times E$ has an induced action on the stack, and we see that the translation subgroup does not actually change the noncommutative ruled surface. (The effect on the sheaf bimodule is to modify the identification between the two copies of $E$ by a translation, and then twist by the pullback of a line bundle on $E$.) Thus we should really view this as a family of noncommutative ruled surfaces over the quotient $(E \times E)^{(2)}/E \times E$. There still remains a group $\text{Aut}(E \times E)$, and the subgroup $U(E \times E)$ (automorphisms which are unitary with respect to the involution induced by the Poincaré bundle), which is generically $SL_2(\mathbb{Z})$, acts as derived equivalences on the fiber $E \times \mathbb{P}^1$ over the point corresponding to $\mathcal{O}_p^2$.  

69
Proposition 5.10. The action of \( U(E \times E) \) on \((E \times E)^{(2)}/E \times E \) lifts to an action by equivalences on the derived categories of the corresponding noncommutative ruled surfaces.

Proof. By \([37]\), there is an action of \( U(E \times E) \) on \( D_{\text{coh}}^b E \), and thus on both subcategories in the semiorthogonal decomposition. One thus obtains a derived equivalence to a glued category in which the gluing functor has been conjugated by the given element of \( \text{Aut}(D_{\text{coh}}^b E) \). This reduces to computing the action on the sheaf bimodules corresponding to \( E \times E \), which again follows by \([37]\).

Remark. More generally, if \( A \) is an abelian variety, the same argument gives a family of rank \((2,2)\) sheaf bimodules on \( A \times A \) parametrized by the stack analogue \((A \times A^*)^{(2)}\) of the 2-point Hilbert scheme, and the action of \( U(A \times A^*) \) on \( D_{\text{coh}}^b A \) induces derived equivalences between the corresponding noncommutative \( \mathbb{P}^1 \)-bundles, deforming the action on \( A \times \mathbb{P}^1 \).

In the rational case, the elliptic surfaces we consider are obtained by blowing up the base points of a pencil of cubic curves on \( \mathbb{P}^2 \). (We say “base points” rather than “base locus”, as the latter will in general be singular; to obtain an elliptic surface, we should repeatedly blow up a base point of the pencil until the resulting anticanonical pencil is base point free.) If we instead blow up only 8 of the base points, the result is a (possibly degenerate) del Pezzo surface \( Y \) of degree 1, and the elliptic surface is obtained by blowing up the unique base point of the anticanonical pencil on \( Y \). If we fix an anticanonical curve \( Q \) on \( Y \), then \( Q \) blows up to a fiber of the elliptic surface. Since \( Q \) comes equipped with a choice of smooth point (the base point of the anticanonical pencil), we can identify the corresponding component of the smooth locus of \( Q \) with \( \text{Pic}^0(Q) \). This, then, lets us construct a family of deformations parametrized by \( \text{Pic}^0(Q)^2 \): we first blow up a point \( z \in \text{Pic}^0(Q) \) viewed as the “identity” component of the smooth locus of \( Q \), and then take the noncommutative deformation corresponding to \( q \in \text{Pic}^0(Q) \). As a family of noncommutative surfaces, this depends on a choice of blowdown structure on \( Y \), but the corresponding derived categories do not, as we have a semiorthogonal decomposition

\[
((\mathcal{O}_{e}(-1)), \mathcal{O}_{Y}^\perp, (\mathcal{O}_{X}))
\]

in which the gluing data is determined by \( z \) and \( q \), with \( \mathcal{O}_{e}(-1)|_{Q} \cong \mathcal{O}_{z} \).

If we consider the family of all such surfaces (i.e., a 2-dimensional fiber bundle over the stack of degenerate del Pezzo surfaces with blowdown structure), we expect that any derived equivalence of the generic elliptic fiber should extend to the full family. The relevant group has the form \( \mathbb{Z}^2.\Lambda_{E_8}^2 \times \text{SL}_2(\mathbb{Z}) \), where the center \( \mathbb{Z}^2 \) is generated by the shift and the Serre functor, one copy of \( \Lambda_{E_8} \) is translation by the Mordell-Weil group, and the other is the quotient by the canonical bundle of the group of line bundles on \( X \) that have degree 0 on \( Q \). The action of \( \text{SL}_2(\mathbb{Z}) \) intertwines these two actions, and one of its generators is the twist by \( \mathcal{O}_{X}(e) \) where \( e \) is the built-in section (the exceptional curve of the final blowup). We have already seen that twists by line bundles extend to the full family (with a nontrivial \( q \)-dependent action on the base of the family), and thus need only one more generator to generate the full group. One should note here that the “correct” group is really \( \mathbb{Z}^2.\Lambda_{E_8}^2 \rtimes W(E_8) \times \text{SL}_2(\mathbb{Z}) \), since we should include the action of \( W(E_8) \) by changing the blowdown structure of the del Pezzo surface. Also, though every element of this group extends, the group itself does not; even for \( W(E_8) \), the extension to fibers with \(-2\)-curves involve a spherical twist, and there are choices involved which cannot be made in a uniformly consistent fashion.

To get the other generator, we will need to consider how modifications of the semiorthogonal decomposition interact with the restriction to \( Q \). Given objects \( M \) and \( N \), let \( T_{M}(N) \) be the cone

\[
M \otimes R\text{Hom}(M, N) \to N \to T_{M}(N) \to .
\]

(5.26)
If $M$ is exceptional, this is precisely the operation appearing in modifications of semiorthogonal decompositions involving $(M)$ (more precisely, those modifications not changing $M$), while if $M$ is spherical, this is an autoequivalence (the spherical twist). (Since we are really working with a dg-enhanced triangulated category, we can compute the cone functor $T_M$ inside the dg-category, and thus sidestep the fact that cones of natural transformations of triangulated functors need not exist.)

**Lemma 5.11.** Let $X$ be a noncommutative surface with a Serre functor and a curve $C$ embedded as a divisor, and let $E \in D^{b}_{\text{coh}} X$ be an exceptional object such that $SE \cong E(-C)[d]$ for some $d \in \mathbb{Z}$. Then for $M \in \mathcal{D}E$, one has

$$T_E(M)|_C \cong T_{E|_C}(M|_C).$$  

(5.27)

**Proof.** We recall that $R\text{Hom}(E,M) \cong R\text{Hom}_C(E|_C,M|_C)$, and thus one can restrict the distinguished triangle defining $T_E(M)|_C$ to $C$ to obtain

$$E|_C \otimes R\text{Hom}_C(E|_C,M|_C) \to M|_C \to T_E(M)|_C \to,$$

(5.28)

which is precisely the distinguished triangle defining $T_{E|_C}(M|_C)$. □

**Remark 1.** If $X$ is generated by weak line bundles along $C$, then one can compute the functor $T_{E|_C}$ on $D^{b}_{\text{coh}} C$ by computing it on sheaves $M|_C$. In particular, the fact that we can undo the modification forces $T_{E|_C}$ to be an autoequivalence, and thus makes $E|_C$ a spherical object. Something similar holds for more general subcategories in a semiorthogonal decomposition: as long as the corresponding restriction-to-$C$ functor has adjoints, it will be spherical, and the modification acts as the corresponding twist. This is primarily of interest for quasi-ruled surfaces, where the corresponding spherical twists are essentially given by the involutions corresponding to double covers $Q \to C_i$.

Let $X_{z,q}$ be the family defined above associated to some fixed degenerate del Pezzo surface $Y$. Note that by construction, any object in $D^{b}_{\text{coh}} X_{z,q}$ restricts to a perfect object in $D^{b}_{\text{coh}} Q$, and thus there is a well-defined map $K_0(X_{z,q}) \to \text{Pic}(Q)$ given by $[M] \mapsto \det(M|_Q)$. This gives us the following identification.

**Proposition 5.12.** We have $\det(O_Q|_Q) \equiv z$, $\det(O_x|_Q) \equiv q$.

**Proof.** For $\det(O_x|_Q)$, we first observe that all point sheaves are equivalent in $K_0(X_{z,q})$: indeed, a numerically trivial class in $K_0(X_{z,q})$ is trivial (since the Mukai pairing is independent of $q$ and this is true for commutative rational surfaces), and any two point sheaves are algebraically equivalent. We may thus assume that $x$ does not lie on any of the exceptional curves, and thus reduce to a calculation in $\mathbb{P}^2$ or a Hirzebruch surface, where we can compute it via numerical considerations. Similarly, for $\det(O_Q|_Q)$, we can replace $O_Q$ by any sheaf $w \in \text{Pic}^0(Q)$, and in particular may assume that $w$ has no global sections, so lies in $O_X$. Since $w|_Q$ has rank 0, we find that $\det(w|_Q)$ is independent of $q$, so equals $z$ by a commutative calculation. □

Now, starting with the semiorthogonal decomposition $(O^+_X, O_X)$ of $D^{b}_{\text{coh}} X_{z,q}$, let us first modify it to $(O_X, \mathcal{O}_Q)$ and then rotate to obtain the semiorthogonal decomposition $(\mathcal{O}_X, \theta^{-1}\mathcal{O}_X)$. Let $\nu: O^+_X \to \mathcal{O}_X$ be the corresponding inclusion functor, and note that

$$\nu(M)|_Q \cong T^{-1}_q(M|_Q) \otimes q^{-1}.$$  

(5.29)

Moreover, we have

$$\theta^{-1}\mathcal{O}_X|_Q \cong \mathcal{O}_X(Q)|_Q \cong \det(O_Q(Q)) \cong \det(O_Q|_Q) \cong z,$$

(5.30)
since $\mathcal{O}_X(Q)|_Q$ is a line bundle, $\det(\mathcal{O}_Q) \cong \mathcal{O}_Q$, and $\mathcal{O}_Q(Q) \in \text{Pic}^0(Q)$. We have thus changed the gluing data (as functors to $D^b_{\text{coh}}Q$) from $(M \mapsto M|_Q, q)$ to $(M \mapsto T_q^{-1}(M|_Q), qz)$. Composing both functors with the autoequivalence $T_q$ gives the equivalent data $(M \mapsto M|_Q, T_q(qz))$. But $T_q(qz) \cong qz$: this is true if $z \not\in \mathcal{O}_X$ since then $R\text{Hom}(\mathcal{O}_q, \mathcal{O}_{qz}) = 0$, and if $z \cong \mathcal{O}_X$ since $T_q(q) \cong q \otimes \text{Ext}^1_q(q, q) \cong q$. In other words, the resulting gluing data has the form $(M \mapsto M|_Q, qz)$, which is precisely the gluing data associated to $X_{z,qz}$. Since $\theta$ is an autoequivalence, we obtain the following generalization of a special case of [22] Thm. 12.3 (which dealt with the case $Q$ smooth).

**Theorem 5.13.** There is a derived equivalence $\Phi : D^b_{\text{coh}}X_{z,q} \cong D^b_{\text{coh}}X_{z,qz}$ acting on $D^b_{\text{coh}}Q$ as the spherical twist $T_q$. Moreover, this equivalence fixes $\mathcal{O}_X$ and takes $\mathcal{O}_e(-1)$ to $\theta \mathcal{O}_X(e)$.

**Proof.** Everything except for the action on $\mathcal{O}_e(-1)$ is immediate from the above discussion, which also shows that for $M \in \mathcal{O}^+_X$, there is a distinguished triangle

$$\theta^{-1}\Phi(M) \rightarrow M \rightarrow R\text{Hom}(R\text{Hom}(M, \mathcal{O}_X), \mathcal{O}_X) \rightarrow$$

from which it follows that $\theta^{-1}\Phi(\mathcal{O}_e(-1))$ is the unique non-split extension of $\mathcal{O}_e(-1)$ by $\mathcal{O}_X$. \[\square\]

We of course also have an equivalence $M \mapsto \theta^{-1}M(e)$ taking $D^b_{\text{coh}}X_{z,q}$ to $D^b_{\text{coh}}X_{qz,q}$, fixing $\mathcal{O}_e(-1)$ and taking $\mathcal{O}_X$ to $\theta^{-1}\mathcal{O}_X(e)$. As in the case $Q$ smooth, these generate a faithful action of $\text{SL}_2(\mathbb{Z})$ on $K_0^{\text{perf}}(Q)$, and thus $\Phi$ provides the desired extensions of derived autoequivalences of elliptic surfaces.

In particular, there is a derived equivalence $D^b_{\text{coh}}X_{z,1} \cong D^b_{\text{coh}}X_{1,z}$ for any $X$. By Theorem [11.19] below, $X_{z,1}$ may be interpreted (in a countably infinite number of different ways) as a moduli space of difference or differential equations, while the equation to have singularities, not necessarily Fuchsian, with total complexity corresponding to four Fuchsian singularities). This suggests that our $\text{SL}_2(\mathbb{Z})$ of derived equivalences is the shadow of a more general theory which would extend the geometric Langlands correspondence to difference or differential equations, while $\text{SL}_2(\mathbb{Z})$ is smooth, since $X_{z,1}$ is a noncommutative deformation of the corresponding moduli space $X_{1,1}$ of “Higgs bundles” (or analogues thereof). In the differential case, this is thus precisely the sort of derived equivalence arising in geometric Langlands theory, and is indeed a nontrivial special case thereof (with nonabelian structure group $\text{GL}_2$ and allowing the equation to have singularities, not necessarily Fuchsian, with total complexity corresponding to four Fuchsian singularities). This suggests that our $\text{SL}_2(\mathbb{Z})$ of derived equivalences is the shadow of a more general theory which would extend the geometric Langlands correspondence to difference equations.

Theorem 5.13 is more difficult to apply than the corresponding result when $Q$ is smooth, since the derived autoequivalences of $Q$ are ill understood in more degenerate cases. We can, however, obtain the following result, which extends [11] Thm. 7.1 to the case of nonreduced special fiber (and general $d$).

**Corollary 5.14.** Let $z$ be an $l$-torsion point of $\text{Pic}^0(Q)$ and let $d$ be an integer. Then the minimal proper regular model of the relative $\text{Pic}^d$ of the (quasi-)elliptic fibration $X_{z,1}$ is isomorphic to the center of $X_{z^a,z^{1/l}/\gcd(l,d)}$, where $a$ is such that $ad \equiv \gcd(l,d) \bmod l$.

**Proof.** Set $b = \left(\frac{a}{l/\gcd(l,d)} \ b \frac{d}{\gcd(l,d)}\right) \in \text{SL}_2(\mathbb{Z})$. Then $\text{Theorem 5.13}$ induces a derived equivalence between $X := X_{z,1}$ and $Y := X_{z^a,z^{1/l}/\gcd(l,d)}$. Moreover, since derived equivalences respect Serre functors, it follows that the (quasi-)elliptic fibration of $X$ induces a pencil of natural transformations $\theta^l \rightarrow \text{id}$, and equivalences between the triangulated categories of perfect objects on the respective fibers. In particular, a 0-dimensional sheaf on $Y$
of degree $\gcd(l,d)$ and disjoint from $Q$ maps to a perfect complex of rank 1 and degree $d$ on the corresponding fiber of $X$. If the fiber on $X$ is smooth, then this perfect complex is itself a shifted simple sheaf, so necessarily a line bundle; since this is a derived equivalence, it follows that line bundles of degree $d$ on smooth fibers of $X$ map to 0-dimensional sheaves on $Y$ of degree $\gcd(l,d)$. Such a sheaf is supported on a unique point of the center $Z$ of $Y$, so that smooth fibers of $Z$ map to 0-dimensional sheaves on $Y$ of degree $\gcd(l,d)$. The claim is obvious for $d = 1$ (the relative Pic$^1$ of $X$ is always $X$!), while for $d = 0$, it remains only to show that the minimal proper regular model of the relative Jacobian is the center of $X_{1,z}$. But in that case the derived equivalence is simple enough that we can directly check that it generically takes line bundles on fibers to sheaves. Indeed, it suffices to consider the image of the structure sheaf of a fiber, which reduces (since the derived equivalence respects restriction to a fiber) to showing that the derived equivalence takes $\mathcal{O}_X$ to $\mathcal{O}_{e_8}(-1)$. Up to a shift, this is precisely [42, Lem. 12.5], the proof of which does not use smoothness of $Q$.

Remark. If $Q$ is reduced, then the center of $Y$ may be obtained by taking the images of the various parameters under the isogeny with kernel generated by $z$. In general, the center can in principle be made explicit via our understanding of blowups of maximal orders: we need simply keep track of the morphism of anticanonical curves as we blow up points.

6 Families of surfaces

For a number of purposes, we will need to consider not just individual noncommutative surfaces but also families; e.g., even for results purely over fields, some of the results below require us to work over dvrs. The most satisfying theory applies in the case of a Noetherian base, although again for technical reasons we will need to consider more general bases.

Here the main technical issue in the direct approach is that the theory of blowups has only been developed over a field. Indeed, there are a number of places in van den Bergh’s arguments where he does a case-by-case analysis depending on the multiplicity of the point in the curve $Y$ or on the size of its orbit under $\theta$, and neither of these is well-behaved in families. And, of course, there are further issues even over fields, since one might wish to blow up a Galois cycle of points. (One might also consider the $p^l$-fold blowup of a point defined over an inseparable extension, but even in the commutative case, there’s no way to resolve the singularity without a field extension.) Further issues over fields already arising in the commutative case are that geometrically ruled surfaces might only be conic bundles and geometrically rational surfaces might not have a rational ruling; one must also consider Brauer-Severi schemes of relative dimension 2.

Most of these issues can be dealt with via descent, so we can at least initially consider only $\mathbb{P}^1$-bundles, blowups in single points, etc. Thus for the moment, let $R$ be a general commutative ring. A split noncommutative plane over $R$ will be a category $\text{qcoh} X$ with choice of structure sheaf $\mathcal{O}_X$, defined in the following way. Let $Q \subset \mathbb{P}^2_R$ be a cubic curve, and let $q$ be an invertible sheaf on $Q$ which on every geometric fiber is in the identity component of Pic$^0(Q)$. Then we can

\footnote{We will eventually be gluing over the étale topology, so there is no need to leave the affine case yet.}
define a \( \mathbb{Z} \)-algebra over \( R \) as in \( \text{[ ]} \), and can take \( \text{qcoh} \, X \) to be the appropriate quotient of the category of modules over that \( \mathbb{Z} \)-algebra.

One difficulty that arises is showing that the result is actually flat. The main issue is that since the \( \mathbb{Z} \)-algebra is defined via a presentation, there is no a priori reason why the \( \mathbb{Z} \)-algebra should be flat. We would also like to have the semiorthogonal decomposition, which reduces to establishing an exact sequence of the form

\[
0 \to \mathcal{O}_X(d-3) \otimes_R L_d \to \mathcal{O}_X(d-2) \otimes_R V_d \to \mathcal{O}_X(d-1) \otimes_R \Gamma(q^{d+1}(1)) \to \mathcal{O}_X(d) \to 0 \quad (6.1)
\]

where \( V_d, L \) are determined by exact sequences

\[
0 \to V_d \to \Gamma(q^d(1)) \otimes_R \Gamma(q^{d+1}(1)) \to \Gamma(q^{2d+1}(2)) \to 0 \quad (6.2)
\]

and

\[
0 \to L_d \to \Gamma(q^{d-1}(1)) \otimes_R \Gamma(q^d(1)) \otimes_R \Gamma(q^{d+1}(1)) \\
\to \Gamma(q^{2d+1}(2)) \otimes_R \Gamma(q^{d+1}(2)) \otimes_R \Gamma(q^{2d+1}(2)). \quad (6.3)
\]

If \( R \) is Noetherian, we can establish both facts by a common induction. Indeed, the \( R \)-module \( \text{Hom}(\mathcal{O}_X(-n), \mathcal{O}_X(d)) \) is defined inductively as the cokernel of the map

\[
\text{Hom}(\mathcal{O}_X(-n), \mathcal{O}_X(d-2)) \otimes_R V_d \to \text{Hom}(\mathcal{O}_X(-n), \mathcal{O}_X(d-1)) \otimes_R \Gamma(q^{d+1}(1)) \quad (6.4)
\]

(with \( \text{Hom}(\mathcal{O}_X(-n), \mathcal{O}_X(d)) = 0 \) for \( d < -n \) and \( \text{Hom}(\mathcal{O}_X(-n), \mathcal{O}_X(-n)) = R \)), and thus flatness and exactness reduce to showing that the complex

\[
\text{Hom}(\mathcal{O}_X(-n), \mathcal{O}_X(d-3)) \otimes_R L_d \to \text{Hom}(\mathcal{O}_X(-n), \mathcal{O}_X(d-2)) \otimes_R V_d \\
\to \text{Hom}(\mathcal{O}_X(-n), \mathcal{O}_X(d-1)) \otimes_R \Gamma(q^{d+1}(1)) \quad (6.5)
\]

represents a flat \( R \)-module. By induction, this is a complex of finitely generated flat \( R \)-modules, and thus represents a (finitely generated) flat \( R \)-module if it represents a vector space over every closed point. We may thus reduce to the case of a field, which we can even assume is algebraically closed (since the desired claim descends through fpqc base change), and thus reduce to the known case. Similarly, the requisite vanishing of Ext spaces reduces to considerations of complexes of f.g. flat \( R \)-modules, so again can be checked on geometric fibers. In this way, we find that \( \mathcal{O}_X(-2), \mathcal{O}_X(-1), \mathcal{O}_X \) is still a full exceptional collection, with gluing functors as expected.

More generally, this property is inherited by any base change, and as already mentioned descends through fpqc, and thus smooth base change. Thus if there is a smooth cover \( R' \) of \( R \) such that \( (C_{R'}, q_{R'}) \) is a base change of a family over a locally Noetherian family, then we still obtain a flat family of categories, and the derived category still has the expected exceptional collection. But any family has this property! Indeed, cubic curves in a fixed \( \mathbb{P}^2 \) are classified by a projective fine moduli space (isomorphic to \( \mathbb{P}^9 \), to be precise), and thus pairs \((C, q)\) are classified by a smooth group scheme over that moduli space. The latter is not quite a fine moduli space (there is a Brauer obstruction to a point of \( \text{Pic}^0 \) being represented by a line bundle), but this can be resolved by an étale base change. We thus see that any family of pairs \((C, q)\) is étale-locally given by a base change from the universal family over the Noetherian moduli stack of such pairs, and thus inherits flatness and the exceptional collection.

We can also recover the embedding of \( Q \) in \( X \) by considerations from geometric fibers. The existence of a map \( \text{Hom}_X(\mathcal{O}_X(d'), \mathcal{O}_X(d)) \to \text{Hom}_Q(q^{d(d+3)/2}(d'), q^{d(d+3)/2}(d)) \) is immediate from the construction, and when \( d' = d - 3 \) is surjective with invertible kernel (since on geometric fibers
it is surjective with 1-dimensional kernel). This establishes the requisite natural transformation \(\mu(-Q) \to \id\), and we easily see that \(\Hom_X(L, L'|_Q)\) behaves as expected when \(L, L'\) are line bundles, so recovers a twisted homogeneous coordinate ring of \(Q\).

For inductive purposes, we would like to know that the resulting category \(\text{qcoh} X\) is locally Noetherian. Unfortunately, the proof of \([6]\) for the field case does not quite carry over, as it uses valuations on the field in a significant way (in particular, \([6\text{ Lem. 8.9}]\)). Luckily, those parts of the argument are in service of showing that the quotient of the graded algebra by the normalizing element of degree 3 is Noetherian; we now recognize that quotient as a twisted homogeneous coordinate ring \([7]\), and thus it is Noetherian since its Proj is Noetherian. We thus conclude that any “split” noncommutative plane over a Noetherian base ring is locally Noetherian. (This is a stronger form of the “strongly Noetherian” condition: any Noetherian base change is still a family over a Noetherian base, so remains Noetherian.)

The argument for quasi-ruled surfaces is analogous. Given a pair of projective smooth curves \(C_0/R, C_1/R\) with geometrically integral fibers and a sheaf \(E\) on \(C_0 \times_R C_1\) which is a sheaf bimodule on every geometric fiber, we can use the construction of van den Bergh to get a global sheaf \(\mathbb{Z}\)-algebra, and flatness, the semiorthogonal decomposition, and the embedding of \(Q\) as a divisor follow over a Noetherian base using the analogue of the exact sequence of Lemma \([4,1]\). (Here when checking that the \(R\Hom\) complexes behave correctly, we need only check sheaves of the form \(\rho^* L\) and can further arrange for the line bundle on the source side to be arbitrarily negative, since it suffices to check generators; this lets us reduce to cases in which there is a single cohomology sheaf.) Again, the corresponding moduli stack is itself locally Noetherian, so the claims follow in general. Moreover, over a Noetherian base, the category is again locally Noetherian; in this case, the argument from the literature \([15]\) can be adapted with no difficulty (since they were already considering constant families over general Noetherian \(k\)-algebras). For technical reasons, we will define a “split” family of quasi-ruled surfaces to be a surface obtained from the above data in which we have also marked points \(x_i \in C_i(R)\). (This ensures that every component of the moduli space of line bundles on \(X\) has a point. Of course, this is only relevant data for quasi-ruled surfaces themselves; on blowups, we can simply take the images of the first point to be blown up!)

The case of blowups is somewhat trickier, as the relevant graded bimodule algebra is no longer given by a presentation. However, we can show by a similar induction (again for \(R\) Noetherian) that for any line bundle \(L\) on \(X\), \(\alpha_*(L(d))\) is \(R\)-flat, and thus since line bundles generate \(\text{coh}\ X\), the bimodule algebra is again \(R\)-flat. (For the inductive argument, we need to represent \(\alpha_*(L(d))\) by a complex of finite sums of line bundles, apply the appropriate functor to obtain \(R\alpha_* L(d + 1)\), and observe by checking geometric fibers that the cone of the natural transformation \((R\alpha_* L(d + 1))(-Q) \to \alpha_*(L(d))\) is an \(R\)-flat coherent sheaf, and thus so is \(R\alpha_* L(d + 1)\).) The semiorthogonal decomposition is similar, although now we need analogues of the two triangles

\[
L \alpha^* L \to L \alpha^! L \to \mathcal{O}_e(-1) \to \quad (6.6)
\]

and

\[
\mathcal{O}_e(-1)[1] \to L \alpha^* \mathcal{O}_{\tau p} \to \mathcal{O}_e \to \quad (6.7)
\]

in order to establish that \(L \alpha^* \text{coh}\ X\) and \(\mathcal{O}_e(-1)\) generate the derived category. Here the sheaf \(\mathcal{O}_e(-1)\) is essentially defined by the special case \(L = \mathcal{O}_X\) of the first triangle (with \(\mathcal{O}_e := \mathcal{O}_e(-1)(1)\)), and is an \(R\)-flat sheaf since it is a sheaf on every geometric fiber. Moreover, semi-continuity shows that \(\Hom(\alpha^! L / \alpha^* L, \mathcal{O}_e(-1))\) is a line bundle on \(R\) (presumably the fiber of \(L\) over the appropriate point of \(Q\)), and we may verify that

\[
(\alpha^! L / \alpha^* L) \otimes_R \Hom(\alpha^! L / \alpha^* L, \mathcal{O}_e(-1)) \to \mathcal{O}_e(-1) \quad (6.8)
\]
is an isomorphism by checking geometric fibers. The second triangle is somewhat trickier, but we may rewrite it (up to line bundles on $R$) as

$$O_e(-1)[1] \to L\alpha^*R\alpha_*O_e \to O_e \to (6.9)$$

and represent the latter map as a chain map of complexes of finitely generated $R$-flat modules, and thus again reduce to checking things geometrically. And once more the relevant moduli stack is locally Noetherian (see Proposition 6.8 below), so the general case follows from the Noetherian case.

Inducting along blowups requires that we show that the blowup is again locally Noetherian as long as the base ring is Noetherian. Here the argument of [51] is more difficult to adapt, as it involves the quotient by a certain invertible ideal that depends on the multiplicity of the point being blown up in the ambient curve, and this is not flat. Luckily, there is a different (and in many ways more natural) ideal we can use instead, which being flat allows the argument to carry over.

**Proposition 6.1.** Let $X/R$ be a split family of noncommutative rational or rationally quasi-ruled surfaces over a Noetherian ring $R$. Then $\text{qcoh}(X)$ is locally Noetherian.

**Proof.** Per the above discussion, it remains only to show that this is inherited by blowups. We use the notation of [51], and note that the basic properties we need are easily deduced from the fact that they hold on geometric points. Thus $\text{qcoh}(\tilde{X})$ has been represented as $\text{Proj}(D)$, where $D$ is a suitable “graded bimodule algebra on $X$”, and the main missing ingredient in the argument is an invertible ideal in $D$ defined over $S$ such that the quotient is Noetherian. Consider the invertible ideal $D(-1)$. If we can show that the Proj of the quotient is a commutative curve over $S$, then the Proj will be Noetherian. On any geometric fiber, this follows from Proposition 4.18, and thus is true globally. To lift to the graded quotient itself, we need simply observe that since $S$ is Noetherian, there is a maximum degree in which the graded algebra on any fiber differs from its saturation. The saturation is certainly Noetherian, and every homogeneous component where there is a difference is Noetherian, and thus the original graded algebra is Noetherian. □

**Remark.** In fact, one can check more directly that the quotient by $D(-1)$ is equal to its saturation in all but degree 0, where the saturation has $o_Y$ in place of $o_X$. Furthermore, the saturation (which since $Y$ is commutative may be rephrased in terms of graded coherent sheaves on $Y \times Y$) is essentially a relative version of a twisted homogeneous coordinate ring (based on the fact that the autoequivalence $M \mapsto M(Y^+) = M(1)$ is relatively ample for $Y^+ \to Y$).

**Remark.** In general, the ideal van den Bergh uses is one of the sequence of invertible ideals $D(-m)((m - 1)Y)$. This is essentially ascending, as there is only one degree where $D(-m)((m - 1)Y) \not\subset D(-m - 1)(mY)$. It thus describes a descending chain of closed subschemes, the limit of which is $\tilde{Y}$. (For general $m$, the quotient is obtained by removing $\min(m - 1, \mu - 1)$ copies of the exceptional curve from $Y^+$.) Only the case $m = 1$ is flat, however.

**Remark.** Considering the commonalities between the proofs in the different cases, it seems likely that it should be possible to prove a quasi-scheme is Noetherian whenever it has a morphism to a Noetherian quasi-scheme, a relatively ample autoequivalence $\tau$, and a natural transformation $T : \text{id} \to \tau$ such that the category of sheaves with $T_M = 0$ is also Noetherian. (It may also be necessary to have $T_{\tau M} = \tau T_M$.) In the three cases, $\tau(M) = M(Q)$, $T$ is the obvious natural transformation, and the first morphism is $\Gamma$, $\rho_\ast$, or the blow-down respectively.

Since in each case we retain the semiorthogonal decomposition over a general base, we can give an alternate description of these categories as $t$-structures on derived categories of suitable dg-algebras. Consider the quasi-ruled case. For each $i$, the category $\text{perf}(C_i) = D^b_{\text{coh}} C_i$ is generated
by $G_i := \mathcal{O}_{C_i} \oplus \mathcal{O}_{C_i}(-x_i)$. This lets us represent $D_{\text{qcoh}}(C_i)$ as (the homotopy category of) the category of right modules over the finite type dg-algebra $R\text{End}(G_i)$ (which we think of as acting on $G_i$ on the left). Then $\rho_0^*G_0 \oplus \rho_1^*G_1$ is a compact generator of the quasi-ruled surface, and has endomorphism dg-algebra of the form

$$
\begin{pmatrix}
R\text{End}_{C_0}(G_0) & R\text{Hom}_{C_0 \times C_1}(\pi_1^*G_1, \pi_0^*G_0 \otimes \mathcal{E}) \\
0 & R\text{End}_{C_1}(G_1)
\end{pmatrix}.
$$

(6.10)

In particular, the derived category of modules over this dg-algebra agrees with $D_{\text{qcoh}}(X)$, with the best analogue of $D_{\text{coh}}^b(X)$ being the category of perfect modules over the dg-algebra. (Over a general base, “coherent” is not very well-behaved.)

We may deal with blowups similarly; if we have already constructed a sheaf of dg-algebras $A_{m-1}$ corresponding to a family of surfaces $X_{m-1}$, then any object $\mathcal{O}_{x_m}$ in $\text{perf}(A_{m-1})$ gives rise to a new sheaf of dg-algebras of the form

$$
A_m = \left( A_{m-1} \quad R\text{Hom}(\mathcal{O}_{x_m}, R)[-1] \quad R \right),
$$

(6.11)

with associated family $X_m$. (This corresponds to the gluing functor $R\text{Hom}_{X_m}(\mathcal{O}_{x_m}(-1), L\alpha_m^*M) \cong R\text{Hom}_X(M, \mathcal{O}_{x_m}[1])^*$ for $M \in \text{perf}(X_{m-1})$.) If every geometric fiber of $\mathcal{O}_{x_m}$ is the structure sheaf of a point on a divisor on the corresponding fiber of $X_{m-1}$, then this dg-algebra is again Morita-equivalent to the blown up surface.

We can again recover the t-structure without reference to the original abelian category. Indeed, the definition of line bundles extends easily from the field case (the only change being that anything étale locally isomorphic to a line bundle should be considered a line bundle), and we see that line bundles generate the abelian category, and further that $M \in D_{\text{qcoh}}(X)^{\geq 0}$ iff $R\text{Hom}(L, M) \in D_{\text{qcoh}}(R)^{\geq 0}$ for all line bundles $L$ (or, say, only those coming from line bundles $\mathcal{O}_{C_i}(nxx_i)$). Equivalently, $D_{\text{qcoh}}(X)^{\leq 0}$ is the smallest “cocomplete preisle” containing the given set of line bundles; that is, it is the smallest subcategory containing $L[p]$ for all $p < 0$ and closed under extensions and arbitrary direct sums. By [1, Thm. A.1], a cocomplete preisle generated by a set of compact generators is an “isle” (the negative part of an actual t-structure), and thus in particular this holds for the isle generated by line bundles. (Of course, we already knew this, but this argument does not require that we have a direct construction of the abelian category.)

One useful consequence (which again could be shown using the construction of the abelian category, but is particularly simple using the dg-algebra description) is that if $M, N \in \text{perf}(X)$, then $R\text{Hom}(M, N) \in \text{perf}(R)$, and thus satisfies semicontinuity.

**Proposition 6.2.** Let $\text{perf}(X)$ be the dg-category of perfect complexes on a flat family of rational or rationally quasi-ruled surfaces over $R$. Then for any $M, N \in \text{perf}(X)$ and any integer $p$, the map

$$
s \mapsto \dim \text{Ext}^p_{X_s}(M \otimes^L k(s), N \otimes^L k(s))
$$

(6.12)

is an upper semicontinuous function of $s \in \text{Spec}(R)$. Moreover, if $\text{Ext}^q(M, N) = 0$ for $q > p$ and $\dim \text{Ext}^p_{X_s}(M \otimes^L k(s), N \otimes^L k(s))$ is constant, then $\text{Ext}^p(M, N)$ is a locally free $R$-module.

**Proof.** We need simply note that

$$
\text{Ext}^p_{X_s}(M \otimes^L k(s), N \otimes^L k(s)) \cong \text{Ext}^p_X(M, N \otimes^L k(s)) \cong h^p(R\text{Hom}(M, N) \otimes^L k(s)),
$$

(6.13)

and thus reduce to standard semicontinuity results in $\text{perf}(R)$. \hfill \square

77
Of course, this is only useful when combined with an understanding of the perfect objects. An object \( M \in D_{\text{qcoh}}(X) \) is perfect iff its projections to the various pieces of the semiorthogonal decomposition are perfect. Each of these lives on a scheme which is smooth and projective over \( R \), and thus we may apply the following.

**Proposition 6.3.** Let \( Y \) be a smooth projective scheme over \( R \) of relative dimension \( n \). An object \( M \in D_{\text{qcoh}}(Y) \) is perfect iff there are integers \( [a, b] \) such that for any point \( s \in \text{Spec}(R) \), \( M \otimes_k^L k(s) \) has coherent cohomology supported on the interval \( [a, b] \).

**Proof.** An object is perfect iff \( M \otimes_{\mathcal{O}_Y}^L k(y) \) has coherent cohomology of uniformly bounded amplitude as \( y \) ranges over points of \( Y \). If \( \pi : Y \to \text{Spec}(R) \) is the structure map, then we may write

\[
M \otimes_{\mathcal{O}_Y}^L k(y) \cong M \otimes_R^L k(\pi(y)) \otimes_{\mathcal{O}_{Y/s}(y)}^L k(y).
\]

(6.14)

Since \( Y_s \) is a projective scheme over a field, \( k(y) \) has Tor dimension at most \( n \). Thus if \( M \otimes_R^L k(\pi(y)) \) has coherent cohomology supported on \( [a, b] \), then \( M \otimes_{\mathcal{O}_Y}^L k(y) \) has coherent cohomology supported on \( [a - n, b] \), giving one implication. For the converse, note that for any point \( s \in \text{Spec}(R) \), if \( h^p(M \otimes_R^L k(s)) \) is the nonzero cohomology sheaf of lowest degree and \( y \) is a generic point of a component of its support in \( Y_s \), then \( h^{p-\text{codim}(y)}(M \otimes_{\mathcal{O}_Y}^L k(y)) \neq 0 \).

In our case, every fiber has a \( t \)-structure, and we have the following.

**Proposition 6.4.** Let \( X/R \) be a family of noncommutative rational or rationally quasi-ruled surfaces as above. Then an object \( M \in D_{\text{qcoh}}(X) \) is perfect iff there are integers \( [a, b] \) such that \( M \otimes_R^L k(s) \in D_{\text{qcoh}}(X_s) \) has coherent cohomology supported on the interval \( [a, b] \) for all \( s \in \text{Spec}(R) \).

**Proof.** On each fiber and for each piece of the semiorthogonal decomposition, the projection and the inclusion functors have finite cohomological amplitude, and this amplitude is uniformly bounded on \( \text{Spec}(R) \). Thus \( M \otimes_R^L k(s) \) has uniformly bounded amplitude iff its projections have uniformly bounded amplitude.

**Corollary 6.5.** If \( M \in D_{\text{qcoh}}(X) \) is a flat family of coherent sheaves (i.e., \( M \otimes_R^L k(s) \) is a coherent sheaf for all \( s \in \text{Spec}(R) \)), then \( M \in \text{perf}(X) \).

**Remark.** In particular, flat families of coherent sheaves satisfy semicontinuity. When \( R \) is Noetherian, \( \text{qcoh}(X) \) is locally Noetherian, and thus we can define \( \text{coh}(X) \) to be the subcategory of Noetherian objects, and automatically have \( \text{perf}(X) \subset D^b_{\text{coh}}(X) \). Over a more general base, “coherent” is both tricky to define and of unclear use.

There is of course no real difficulty in gluing the above construction in the Zariski topology. We thus make the following definition. Note that the data we used to construct a family of noncommutative planes came with a choice of curve \( Q \), and we make a similar choice as necessary for quasi-ruled surface, which we include as part of the data. On fibers which are not commutative, we can recover \( Q \) from the surface, so it does not give extra data, but commutative fibers come with a choice of anticanonical curve.

**Definition 6.1.** A split family of noncommutative rationally quasi-ruled surfaces over a scheme \( S \) is an \( \mathcal{O}_S \)-linear category \( \text{qcoh}(X) \) (or \( D_{\text{qcoh}}(X) \) with a \( t \)-structure) which is Zariski locally of the above form.

**Definition 6.2.** A split family of noncommutative rationally ruled surfaces is a split family of noncommutative rationally quasi-ruled surfaces equipped with an isomorphism \( C_0 \cong C_1 \) identifying \( x_0 \) with \( x_1 \) and making \( Q \) algebraically equivalent to the double diagonal; in addition, \( Q \) may not be geometrically integral on any fiber such that \( g(C_0) = 1 \).
Definition 6.3. A split family of noncommutative rational surfaces is either an iterated blowup of a family of noncommutative planes as constructed above, or a split family of noncommutative rationally ruled surfaces such that \( g(C_0) = 0 \).

Remark. Since we do not deal with any other kind of noncommutative surface, we will feel free to abbreviate this to “split family of noncommutative surfaces”, only adding “rational”, “ruled”, or “quasi-ruled” when we are imposing further restrictions.

Remark. As we have already mentioned, we will show below that a blowup of a noncommutative plane is a noncommutative Hirzebruch surface, and thus a noncommutative rational surface is either a noncommutative rationally ruled surface over \( \mathbb{P}^1 \) or a noncommutative plane.

As we have already discussed, the above construction is clearly too restrictive to be the right notion of family. An obvious further approach is to consider surfaces that can locally be put in the above form relative to some suitable topology. To ensure we make the correct choice of topology here, we should first determine the correct choice in the commutative case.

We first observe that \( C_0 \) and \( C_1 \) have sections étale locally (indeed, any smooth surjective morphism has a section étale locally), so that \( x_0 \) and \( x_1 \) can be chosen étale locally. Moreover, they only played a role in constructing a set of generating line bundles on the surface, and thus the \( t \)-structure, but the resulting \( t \)-structure was independent of the choices, so descends. For the same reason, a flat family of smooth surfaces geometrically isomorphic to \( \mathbb{P}^2 \) again has an étale local section, and is thus étale locally isomorphic to \( \mathbb{P}^2 \), and the \( t \)-structure defined using that isomorphism descends.

A somewhat more subtle question has to do with the fact that a geometrically ruled surface need not be a projective bundle. Note that although we are assuming a particular choice of ruling, there is no loss of generality when \( g(C) > 0 \), since then the canonical map \( X \to \text{Alb}^1(X) \) to the Albanese torsor factors through \( C \) on any geometric fiber, so that we actually have a canonical ruling.

Proposition 6.6. Let \( C/S \) be a smooth proper curve, and let \( \rho : X \to C \) be a smooth proper curve which over geometric points of \( C \) is isomorphic to \( \mathbb{P}^1 \). Then any geometric point \( s \in S \) has an étale neighborhood over which \( X \) is isomorphic to a projective bundle.

Proof. First note that \( C \) étale locally has a section, so may be assumed projective, and \( -K_X \) is relatively ample over \( C \), so that \( X \) is then also projective. The anticanonical embedding of \( X_s/C_s \) is a conic, and thus by Tsen’s Theorem has a section \( \sigma : C_s \to X_s \). This induces a line bundle \( \mathcal{O}_{X_s}(\sigma(C_s)) \) such that \( X_s \cong \mathbb{P}(\rho_* \mathcal{O}_{X_s}(\sigma(C_s))) \). Let \( \text{Pic}^\sigma_{X/S} \) denote the component of the Picard scheme \( \text{Pic}_{X/S} \) containing the isomorphism class of this line bundle. This is a torsor over \( \text{Pic}^0_{C/S} \), thus smooth and surjective, so has a section over an étale neighborhood \( S' \) of \( s \) in \( S \), and the isomorphism class of line bundles has a representative \( \mathcal{L} \) defined over an étale neighborhood \( T \) of \( s \) in \( S' \). The sheaf of graded algebras over \( C \) corresponding to \( \mathcal{L} \) is naturally isomorphic to the symmetric algebra of \( \rho_* \mathcal{L} \), so that \( X_T \cong \mathbb{P}_C(\rho_* \mathcal{L}) \) as required.

Remark. It is tempting to simply specify the component \( \text{Pic}^\sigma(X/S) \) by numerical considerations (i.e., specifying the Hilbert polynomials of \( \mathcal{L} \) and \( \mathcal{L}(f) \)). The issue is that the resulting component could be (and, half the time, is!) empty; we need a splitting over some geometric point to pick out a good component.

The hardest case is when there is no longer a unique way to interpret the commutative surface as an iterated blowup of a ruled surface. This is likely to be especially difficult to deal with for rational surfaces, as in that case there may in fact be infinitely many such interpretations, and thus
the moduli stack of anticanonical rational surfaces is not algebraic! (If one imposes a blowdown structure, this is no longer an issue, see [111], generalizing a construction of [17].) To get a feel for the issue, consider the case of a projective family over a connected base with generic geometric fiber $\mathbb{P}^1 \times \mathbb{P}^1$. If the family has geometric fibers of the form $F_d$ for $d > 0$, then the ample bundle must have bidegree $(d, d')$ with $d > d'$, and this distinguishes the two rulings on the generic fiber, so that there is a unique choice of global ruling. If all fibers are $\mathbb{P}^1 \times \mathbb{P}^1$, then the line bundle of bidegree $(1, 1)$ extends étale locally, and gives an embedding of the surface as a smooth quadric surface. Over a non-closed field, a typical such surface has no ruling, and thus the only rational line bundles are multiples of the bidegree $(1, 1)$ bundle. However, the family has a natural double cover over which it has a ruling, which in odd characteristic simply takes the square root of the determinant. In particular, by removing the singular surfaces (which correspond to smooth surfaces on which the given bundle is not ample), we have made this cover étale. (If we had not removed the singular surfaces, the cover would be ramified, but the family would not be smooth, and does not have a global desingularization.) Over the cover, the surface is isomorphic to a product of two conics, and thus at worst two further étale covers make it globally $\mathbb{P}^1 \times \mathbb{P}^1$.

More generally, as long as the family is projective, the ample divisor $D_a$ cuts out a finite set of blowdown structures on the geometric fibers of $X$, namely those for which $D_a$ is in the fundamental chamber (see the discussion in Section 9 below). Moreover, the resulting set of blowdown structures is a torsor over an appropriate finite Coxeter group, and thus a blowdown structure exists étale locally.

With the above discussion in mind, we define a family of noncommutative rational or rationally quasi-ruled surfaces (again abbreviated to “family of noncommutative surfaces”) over $S$ to be a family $D_{\text{qcoh}}(X)$ of dg-categories over $S$ such that (a) the dg-category is étale locally a split family of noncommutative surfaces, and (b) the associated $t$-structures are compatible, in that the two ways of pulling back to the fiber square of the cover agree.

Note that the locally Noetherian condition easily descends through étale covers, and thus we have the following, over a Noetherian base.

**Theorem 6.7.** Let $X/S$ be a family of noncommutative rational or rationally quasi-ruled surfaces over a Noetherian base. Then $\text{qcoh}(X)$ is locally Noetherian.

In principle, we could construct such a category by specifying the specific data $(C_0, C_1, \ldots)$ on each piece of the étale cover, and giving suitable gluing data. (Indeed, by fpqc descent, quasicoherent sheaves can always be glued along étale covers.) For rational or rationally ruled surfaces, this is not too difficult: we have an associated family of commutative surfaces, so as long as that family is projective, there is an étale cover $T/S$ over which there is a global choice of blowdown structure. Since the associated tuple $(C_0, C_1, \ldots)$ over $T$ satisfies the natural compatibility conditions, the result indeed glues to give a dg-category with $t$-structure over $S$.

It turns out that the dg-category itself is easy enough to construct directly. Let us consider first the case that $X$ is rational. Then the exceptional object $O_X$ of $\text{perf}(X \times_S T)$ certainly descends, and thus induces a semiorthogonal decomposition over $S$, suggesting the following construction. Given a family $Y/S$ of commutative rational surfaces (i.e., $Y$ is smooth and proper over $S$ of relative dimension 2, and its fibers are geometrically rational), not only does $\text{perf}(Y)$ have a generator over $S$, but so does the subcategory $O_Y^{\perp}$; indeed, if $G$ generates $Y$, then the cone $G^0$ of $\mathcal{O}_Y \otimes R\text{Hom}(\mathcal{O}_Y, G) \to G$ generates $O_Y^{\perp}$. If $Q$ is an anticanonical divisor on $Y$ and $q \in \text{Pic}^0(Q)$ (that is, $q$ is a line bundle on $Q$ which has degree 0 on every component of every geometric fiber of $Q$), then
we may consider the sheaf of triangular dg-algebras

\[
\begin{pmatrix}
\mathcal{O}_S & R\text{Hom}_Q(G'_L|_{Q'}, q) \\
0 & R\text{End}(G')
\end{pmatrix}
\] (6.15)

This almost gives a fully general construction of \( D_{\text{qcoh}}(X) \) for noncommutative rational surfaces. The only remaining issue is that all we actually obtain from the étale local description is a point of \( \text{Pic}(\mathcal{Q}/S)(\text{ét}) \) which is in the identity component of every fiber; in particular, it defines a line bundle on the base change to some étale cover such that the two pullbacks are isomorphic, but the isomorphisms need not be compatible. (Basically, the problem is that \( q \) is normally given as the determinant of a point on the noncommutative surface, but \( Q \) may not have rational points, so we only know \( q \) up to isomorphism!) This is not too hard to fix as long as \( Q \) is projective (e.g., if \( Y \) is projective); the idea is that although \( q \) may not descend, the objects \( q \otimes R\Gamma(q^{-1}(d)) \in \text{perf}(Q_T) \) and \( R\text{End}(R\Gamma(q^{-1}(d))) \) descend for any \( d \). Taking \( d \gg 0 \) gives a well-defined sheaf of dg-algebras

\[
\begin{pmatrix}
\mathcal{O}_S & R\text{Hom}(G'_L|_Q, q \otimes \Gamma(q^{-1}(d))) \\
0 & R\text{End}(G') \otimes R\text{End}(\Gamma(q^{-1}(d)))
\end{pmatrix}
\] (6.16)

This is clearly Morita-equivalent to the original dg-algebra over \( T \), and thus the category of (perfect) modules over this dg-algebra may indeed be viewed as a family of (derived categories of) noncommutative rational surfaces, in that every geometric fiber is such a surface. Moreover, any category \( \text{perf}(X) \) which is étale locally equivalent to the category of perfect objects on an iterated blowup of a noncommutative Hirzebruch surface (or noncommutative plane) can be obtained via the above construction.

So we may instead construct families of noncommutative rational surfaces by specifying a triple \((Y, Q, q)\) (with \( q \in \text{Pic}(\mathcal{Q}/S)(S) \)) along with a splitting over some étale cover \( T/S \) such that both pullbacks of the \( t \)-structure agree. If \( T \) is Noetherian, then we will see below that \( \text{qcoh}(X) \) is equivalent to the Proj of a sheaf of \( \mathbb{Z} \)-algebras.

For ruled surfaces which are not rational, Proposition 8.12 below tells us that the functor \( \alpha^* \cdots \alpha^*_m \rho^*_0 \) descends (i.e., noncommutative ruled surfaces of genus \( > 0 \) also have canonical rulings), and thus we may use the corresponding semiorthogonal decomposition to construct \( \text{perf}(X) \) from a commutative family \( Y \) of geometrically rationally ruled surfaces over a curve \( C \) of genus \( > 0 \), an anticanonical divisor \( Q \), and a morphism \( Q \to C \) which contracts vertical fibers and is in the same component of the moduli stack of such morphisms as the morphism coming from the ruling on \( Y \).

We should note that even when \( Y \) is geometrically ruled, the subcategory \( \text{perf}(C)^\perp \) is not in general equivalent to \( \text{perf}(C) \). Indeed, if \( Y/C \) is a nonsplit conic bundle, then \( \text{perf}(C)^\perp \) is the category of perfect objects in the derived category of the corresponding (quaternion) Azumaya algebra over \( C \).

We ignore families of surfaces which are rationally quasi-ruled but not rationally ruled, as the fibers themselves are not particularly interesting as noncommutative surfaces (and there is no intrinsic difficulty in constructing them in any case; Proposition 8.12 implies that the ruling is again canonical (though the fibers may only be conics)). Note that we cannot quite dismiss these as being maximal orders on families of rationally ruled commutative surfaces, as the degree over the center can fail to be constant: see the discussion above of quasi-ruled surfaces of “2-isogeny” type.

The one issue with the above notion of family, though more natural than the split case, is that the corresponding moduli problem is not well-behaved. We can resolve this by putting back part
of the splitting data. A blowdown structure on a family $X/S$ of noncommutative ruled surfaces is an isomorphism class of sequences

$$X = X_m \to X_{m-1} \to \cdots \to X_0 \to C$$

(6.17)
of morphisms of families, in which all but the last map is a blowdown, and $X_0 \to C$ is a ruling. (Note that when $C$ has genus 1, it might only be an algebraic space.) This is essentially combinatorial data; as we will see, the blowdown structures on a noncommutative ruled surface over an algebraically closed field form a discrete set. Note however, that in the rational case, this set can be infinite, and in general, the set is far from flat (in a typical family, the size changes on dense subsets!).

**Proposition 6.8.** The moduli stack of noncommutative rationally ruled surfaces with blowdown structures is an algebraic stack locally of finite type over $\mathbb{Z}$, and the components classifying $m$-fold blowups of ruled surfaces of genus $g$ have dimension $m + 3$ if $g = 0$, $m + 1$ if $g = 1$, and $m + 2g − 2$ otherwise.

**Proof.** We first note that if $X/S$ is a family of noncommutative rationally ruled surfaces with a blowdown structure, then the splittings of $X$ compatible with the blowdown structure are essentially classified by a smooth scheme over $S$. More precisely, the splittings are classified by $C \times_S \text{Pic}(C)$, with $C$ recording the marked point and Pic$(C)$ capturing the fact that the sheaf bimodule is only determined modulo $\pi_1^*\text{Pic}(C)$. If we insist that the Euler characteristic of the bimodule be 0 or $-1$, then this eliminates all but one component. Thus it will suffice to construct the corresponding stack for split surfaces.

For ruled surfaces, we first note that the curve $C$ is classified by the union over $g$ of the classical moduli stacks $M_g$ of smooth genus $g$ curves with a marked point.

Relative to the ample divisor $O_C((−dx)) \boxtimes O_C((−dx))$ on $C \times C$, a sheaf bimodule of rank 2 has Hilbert polynomial $2t + \chi$ for some $\chi$. The condition for a sheaf on $C \times C$ with that Hilbert polynomial to have Chern class algebraically equivalent to the double diagonal is open and closed, while having no subsheaf support on a fiber of $\pi_1$ or $\pi_2$ is open. We thus find that the stack $M_{sb}$ of sheaf bimodules corresponding to ruled surfaces is smoothly covered by open substacks of

$$\text{Quot}_{C \times C/M_{sb}}(O_C(−dx) \boxtimes O_C(−dx), 2t + \chi).$$

(6.18)

For a family without commutative fibers, we can recover the anticanonical curve as the Quot scheme $\text{Quot}_{C \times C/M_{sb}}(\mathcal{E}, 1)$. Over commutative fibers, this is not a curve, but we can resolve this as follows. The condition that $\mathcal{E}$ be a vector bundle of rank 2 on a curve is a closed condition, and thus we may blow this up to obtain a new stack $M_0$. The Quot scheme classifying the anticanonical curve is still badly behaved over the exceptional locus, but now the bad behavior comes in the form of an extra component that we can remove to obtain a family of curves of genus 1. We thus find that $M_0$ is the desired moduli stack of noncommutative ruled surfaces. (We easily check that when $g = 1$, the anticanonical curve is either two disjoint copies of $C$ or a double copy of $C$ with some number of fibers, so in either case is not integral.)

The universal anticanonical curve over $M_0$ embeds in the commutative ruled surface

$$X' := \text{Quot}_{C/M_0}(π_1^*\mathcal{E}, 1),$$

(6.19)

which lets us construct the moduli stack in general. For each $m > 0$, $M_m$ is the universal anticanonical curve over $M_{m−1}$, and the universal anticanonical curve on $M_m$ is obtained by blowing up the corresponding point of the universal commutative ruled surface and then removing one copy of the exceptional curve from the pullback of $Q$. 

82
To compute the dimension, we first note that each blowup adds 1 to the dimension, so it suffices to consider the ruled surface case, and for \( g \geq 1 \) since the dimension for \( g = 0 \) was effectively computed in [41, Thm. 5.8]. We may also compute the dimension for \( C \) fixed and add \( 3g - 3 \). For \( g \geq 2 \), the sheaf bimodule is supported on the double diagonal, and is either invertible (a 0-dimensional stack since the double diagonal has trivial dualizing sheaf), a torsion-free sheaf determined by where it fails to be invertible, or a vector bundle. The invertible case has dimension 0, but we must the mod out by the action of the Picard stack of \( C \) (twisting by \( \rho_1^* \mathcal{L} \)), so the correct dimension is \( 1 - g \), giving the total \( 2g - 2 \) as stated.

For the non-invertible cases, pick a point where \( \mathcal{E} \) is not invertible (there being only finitely many such points on non-commutative geometric fibers). Then \( Q \) has a component lying over that point, and thus we obtain a 1-parameter family of blowups in a point of that component and not on any other component. Each of those blowups has a unique blowdown (using Theorem 5.1) to a surface with one fewer point of non-invertibility. We can recover the original surface and its blowup from the resulting \( Q' \) along with the point that got blown up, and thus we find that the two pieces of the moduli stack have the same dimension.

In the genus 1 case, the nonreduced support case picks up an additional dimension (which reduced curve it is supported on) which is then cancelled out by the fact that \( C \) has infinitesimal automorphisms, and we need to mod out by the choices of isomorphism \( C_1 \cong C_0 \). A bimodule with reduced support is supported on the union of two graphs of translations (2 dimensions), is a line bundle on each (2 - 2 more dimensions), modulo a line bundle on \( C_1 \) (1 - 1 fewer dimensions) and automorphisms of \( C_1 \) (-1 dimensions).

Remark. In the rational case, we could also construct this as the relative Pic\(^0\)(\( Q \)) (the scheme, not the stack!) over the moduli stack of commutative rational surfaces (with blowdown structure), which also deals with the case of noncommutative planes. It follows from [41, Thm. 5.8] that the stack of noncommutative rational surfaces is a local complete intersection. Something similar is true in higher genus, though the fibers are more complicated to describe; we omit the details. In either case, we find that the moduli stack of noncommutative surfaces retracts to the substack of anticanonical commutative surfaces via a smooth morphism.

Remark. One can also compute the expected dimension of this moduli stack, and find that it is highly obstructed for \( g \geq 2 \). (That there are some obstructions should not be surprising: for \( g \geq 2 \), the moduli stack has nonreduced components!) Indeed, the moduli stack of sheaf bimodules has expected dimension \((2\Delta_{G \times C})^2 = 8 - 8g\), and thus for \( g \geq 2 \), the expected dimension is \( m + (8 - 8g) + (1 - g) + (3g - 3) = m + 6 - 6g \); thus there must be at least \( 8g - 8 \) obstructions. (For \( g = 1 \), we should subtract one to get the expected dimension, and thus see that despite the moduli stack being reduced, there are still at least 2 obstructions.) This suggests (along with the fact that we are already working with dg-algebras) that one should consider the derived moduli stack of noncommutative surfaces. It should be possible to construct this: the moduli stack of commutative rational or rationally ruled surfaces is smooth if we do not choose an anticanonical curve, and thus one could consider the derived linear system \( |-K_X| \) over this stack. The derived moduli stack of noncommutative surfaces would then presumably be some sort of smooth 1-dimensional fiber bundle over this stack.

In [41], we considered a decomposition of the moduli stack of rational surfaces based on the structure of the anticanonical curve (i.e., the divisor classes and multiplicities of the components along with whether \( \text{Pic}^0(Q) \) is elliptic, multiplicative, or additive), and showed that in each case, the corresponding substack was irreducible and smooth. (Indeed, there is an étale covering making it a smooth scheme, in which we specify an ordering within each set of components of \( Q \) with the
same divisor class and multiplicity.) This of course carries over immediately to the moduli stack of noncommutative rational surfaces, since $\text{Pic}^0(Q)$ is also irreducible and smooth.

The basic idea also works for noncommutative rationally ruled surfaces of higher genus. There is an easy induction reducing to $X_0$: each time we blow up a point, the new combinatorics either determines the multiplicity with which each component contained that point or gives a smooth open curve over which the point varies. For $X_0$ itself, if $g = 1$ and $Q$ is smooth, then we need simply specify the pair of line bundles and translations, and otherwise we are in the differential case, so need simply specify the torsion-free sheaf on the double diagonal. Such a sheaf is either invertible, so by the constraint on the Euler characteristic is classified by $\text{Pic}^0(Q) \cong \mathbb{G}_a$, or strictly torsion-free, in which case it is uniquely determined by the divisor on which it fails to be torsion-free, or equivalently the points of $C_0$ (with multiplicities) over which the components of $Q$ of class of $f$ lie. In addition, we note that the degree of the Fitting scheme of the sheaf bimodule is semicontinuous, so for $g > 1$ each subfamily is locally closed, and the same follows for $g = 1$ once we observe that the support being reduced is an open condition.

One immediate consequence is that characteristic 0 points are dense in the moduli stack of noncommutative surfaces; i.e., that any surface over a field of characteristic $p$ can be lifted (possibly after a separable field extension) to characteristic 0. Another is that for any family $X/S$, there is an induced decomposition of $S$ into locally closed subsets, which must be finite if the base is Noetherian.

A natural further question is how the closures of these substacks interact. Over $\mathbb{Z}$, there are already examples showing in the rational case that this is not a stratification in general, though it is still open whether this phenomenon can occur if one excludes points of finite characteristic. Unfortunately, despite some questions being easier for ruled surfaces with $g > 0$, this appears unlikely to be one of them.

7 Dimension and Chern classes of sheaves

In [15], a definition was given for a “non-commutative smooth proper $d$-fold”, and it was shown there that ruled surfaces (more precisely, quasi-ruled surfaces in which the two curves are isomorphic) satisfy their definition (with $d = 2$, of course). Our objective is to show that this continues to hold for iterated blowups of arbitrary quasi-ruled surfaces. In this section, our focus is on those of their conditions related to dimensions of sheaves, though in the process we will also be considering the Grothendieck groups in greater detail. This will give us the information required to finish our considerations of birational geometry; we will then prove the remaining Chan-Nyman axiom in Section 10 below.

Thus suppose $X = X_m$ is an $m$-fold blowup of a quasi-ruled surface $X_0$ (over an algebraically closed field), with intermediate blowups $X_1, \ldots, X_{m-1}$ and associated morphisms $\alpha_1, \ldots, \alpha_m$. We wish to show that $X$ satisfies the Chan-Nyman axioms. (Note that they implicitly include “strongly Noetherian” as an unnumbered axiom, but this of course follows as a special case of Theorem [6.7].)

The first two of their axioms are automatic: the Gorenstein condition simply states that there is a Serre functor such that $S[-2]$ is an autoequivalence, which follows from the above descriptions of the derived categories and $t$-structures; this in turn immediately implies that $\text{Ext}^p$ vanishes for $p \notin \{0, 1, 2\}$, giving their “smooth, proper of dimension 2” condition. Thus the first case that requires some work is the existence of a suitable dimension function (satisfying their axioms 3,4,6 as well as continuity and finite partitivity).

To define this, we recall that the description of the derived category immediately gives us a description of the Grothendieck group of $\text{coh} X$: it is the direct sum of $K_0(C_0)$, $K_0(C_1)$, and a copy
of $Z$ for each point being blown up. We define the rank of a class in the Grothendieck group to be the rank of the image in $K_0(C_0)$ minus the rank of the image in $K_0(C_1)$. This then immediately defines a rank for any coherent sheaf (or object in $D^b_{coh} X$) as the rank of its class in the Grothendieck group.

**Lemma 7.1.** If $m > 0$, then for any class $[N] \in K_0(X_{m-1})$, $\text{rank}(\alpha_m^*[N]) = \text{rank}([N])$, while for any $[M] \in K_0(X)$, $\text{rank}(\alpha_m *[M]) = \text{rank}([M])$.

**Proof.** The first claim is immediate from the definition, while the second claim follows from the first together with the fact that $\alpha_m^* \alpha_m * [M] - [M]$ is a multiple of the rank 0 class $[\mathcal{O}_{cm}(-1)]$. □

Applying the construction of Proposition 4.18 inductively gives an embedding of a commutative curve $Q$ as a divisor, with morphism $\iota : Q \to X$. Note that there is a natural map $L \iota^*$ from $D^b_{coh} X$ to the derived category $\text{perf}(Q)$ of perfect complexes on $Q$, and thus an induced map from $K_0(X)$ to $K^0_{\text{perf}}(Q)$. The latter of course also has a well-defined rank function, which is almost everywhere on $Q$ given by the alternating sums of the ranks of the cohomology sheaves. In particular, we may compute the rank by considering the restriction to $\hat{Q}$ (the scheme-theoretic union of component(s) of $Q$ which are not components of fibers).

**Lemma 7.2.** For any class $[M] \in K_0(X)$, $\text{rank}([M]) = \text{rank}(\iota^*[M])$.

**Proof.** It suffices to check this on each summand of $K_0(X)$. Each of the summands other than $K_0(C_0)$ and $K_0(C_1)$ is generated by a sheaf $\mathcal{O}_{c_1}(-1)$ of rank 0 that meets $\hat{Q}$ transversely, and thus has rank 0 restriction as required. Similarly, $K_0(C_0)$ and $K_0(C_1)$ are generated by line bundles, and in either case the restriction to $\hat{Q}$ is again a line bundle, so has rank 1 as required. □

**Corollary 7.3.** For any sheaf $M \in \text{coh} Q$, $\text{rank}(\iota_* M) = 0$.

**Proof.** We have $\text{rank}(\iota_* M) = \text{rank}(L \iota^* \iota_* M)$, and the cohomology sheaves of $L \iota^* \iota_* M$ are $M$ and the twist of $M$ by a suitable invertible sheaf, so almost everywhere have the same rank.

**Corollary 7.4.** For any class $[M] \in K_0(X)$, $\text{rank}(\theta[M]) = \text{rank}([M])$.

**Proof.** We have $[M] - \theta[M] = \iota^* \iota_* [M]$. □

**Proposition 7.5.** For any object $M \in \text{coh} X$, $\text{rank}(M) \geq 0$.

**Proof.** Since $\alpha_m^*$ preserves the rank, we may reduce to the case $m = 0$, so that $X = X_0$ is a quasi-ruled surface. Consider the function $r(l, [M]) := \text{rank} \rho_l^*[M]$ on $Z \times K_0(X_0)$. This is clearly linear in $[M]$ (since rank and the action of $\rho_l^*$ on the Grothendieck group are both linear), while in $l$ it satisfies (as an immediate consequence of Lemma 4.1)

$$r(l + 1, [M]) + r(l - 1, [M]) = 2r(l, [M]),$$

(7.1)

so that $r(l, [M]) - r(0, [M])$ is bilinear. Since

$$\text{rank}([M]) = r(0, [M]) - r(-1, [M]),$$

(7.2)

we find that $r(l, [M]) = r(0, [M]) + l \text{rank}([M])$. For $M$ a sheaf, $\rho_{0l} \theta^{-l} M$ is a sheaf for $l \gg 0$, and thus $\text{rank}(\rho_{0l} \theta^{-l} M) = r(2l, M) \geq 0$ for $l \gg 0$, implying $\text{rank}(M) \geq 0$ as required. (Here we use the fact that $R \rho_{0l} \theta^{-l} M$ differs from $R \rho_{2l}^* M$ via a twist by a line bundle.) □
The rank of course only depends on the algebraic class in $K_0(X)$, or in other words on the quotient $K_0^{\text{num}}(X)$ of $K_0(X)$ by the identity component $\text{Pic}^0(C_0) \oplus \text{Pic}^0(C_1)$ of $K_0(C_0) \oplus K_0(C_1)$. (The notation is justified by the fact that numeric and algebraic equivalence turn out to agree in this case, as we will see.) Let $[pt] \in K_0^{\text{num}}(X)$ denote the class of a point of $Q$; this is well-defined since the corresponding map $Q \to K_0(X)$ is a map from a connected scheme, so lies inside a single coset of the identity component. This can also be described in terms of the semiorthogonal decomposition: it is the class of a point in $K_0^{\text{num}}(C_0)$ minus the class of a point in $K_0^{\text{num}}(C_1)$, and is 0 in every other component. This is dual to the definition of rank, and indeed one finds that $\chi([M]) = \chi([M], [pt])$, where $\chi$ denotes the Mukai pairing (which on a pair of complexes is the alternating sum of Ext dimensions, and is bilinear on $K_0(X)$). We of course have $\text{rank}([pt]) = 0$, and thus we may use rank and $[pt]$ to define a filtration of the Grothendieck group, and in turn define the dimension of a coherent sheaf.

**Definition 7.1.** Given a nonzero sheaf $M \in \text{coh}(X)$, the dimension $\dim(M)$ of $M$ is defined to be 2 if $\text{rank}(M) > 0$, 0 if $[M] \propto [pt]$, and 1 otherwise. We say that $M$ is pure $d$-dimensional if $\dim(M) = d$ while any nonzero proper subsheaf of $M$ has dimension $< d$. A sheaf is torsion-free if it is either 0 or pure 2-dimensional.

To show that this is truly a dimension function, we need to show that a subsheaf or quotient of a $d$-dimensional sheaf has dimension at most $d$. (Chan and Nyman also ask for compatibility with the Serre functor, but this follows immediately from $\text{rank}(\theta[M]) = \text{rank}([M]).$) For $d = 2$ this is trivial, while for $d = 1$ it reduces to the fact that the rank is additive and nonnegative. For $d = 0$, this will require some additional ideas. We first note that the nonnegativity of the rank has an analogue for 0-dimensional sheaves.

**Proposition 7.6.** If $M \in \text{coh} X$ is a sheaf of numeric class $d[pt]$, then $d \geq 0$, with equality iff $M = 0$.

**Proof.** If $m > 0$, then $\alpha_m \theta^{-1}M$ is a sheaf for $l \gg 0$, and we readily verify that it also has class $d[pt]$. Thus by induction $d \geq 0$, and if $d = 0$, then $\alpha_m \theta^{-1}M = 0$ for $l \gg 0$; since $\alpha_m \alpha_m \theta^{-1}M \to \theta^{-1}M$ is surjective for $l \gg 0$, we conclude that $M = 0$ as required. Similarly, for $m = 0$, $\rho_{ts}M$ has class $d[pt]$ and is a sheaf for $l \gg 0$, so that we reduce to the corresponding claims in $C_0$ and $C_1$. 

**Corollary 7.7.** If $M, N$ are coherent sheaves with $[M] = [N]$ in $K_0^{\text{num}}(X)$, then any injective or surjective map $M \to N$ is an isomorphism.

**Proof.** The quotient resp. kernel would be a sheaf with trivial class in $K_0^{\text{num}}(X)$, and thus 0 by the Proposition.

**Definition 7.2.** The Néron-Severi lattice $\text{NS}(X)$ is the subquotient $\ker(\text{rank})/\mathbb{Z}[pt]$ of $K_0^{\text{num}}(X)$. Given two classes $D_1, D_2 \in \text{NS}(X)$, their intersection number $D_1 \cdot D_2$ is given by $-\chi(D_1, D_2)$. The canonical class $K_X \in \text{NS}(X)$ is the class $[\theta \mathcal{O}_X] - [\mathcal{O}_X]$

**Remark.** Since $\chi(D, [pt]) = \chi([pt], D) = 0$ iff $\text{rank}(D) = 0$, this pairing is indeed well-defined.

By mild abuse of notation, we will refer to the classes in $\text{NS}(X)$ as “divisor” classes. This might more properly be reserved for the extension of $\text{NS}(X)$ obtained as the quotient of the subgroup of 1-dimensional classes in $K_0(X)$ by the subgroup of 0-dimensional classes, but this quotient is badly behaved when $X$ is not a maximal order, since the subgroup of 0-dimensional classes need not be closed.

**Definition 7.3.** The (numeric first) Chern class $c_1 : K_0(X) \to \text{NS}(X)$ is defined by $c_1([M]) = [M] - \text{rank}([M])[\mathcal{O}_X]$. 

86
Proposition 7.8. The Picard lattice has rank $m+2$, and the intersection pairing is a nondegenerate symmetric bilinear form of signature $\langle +, - , \ldots , - \rangle$.

Proof. The semiorthogonal decomposition makes it straightforward to determine the Fourier-Mukai form on $K_0^{\text{num}}(X_m)$ from that of $K_0^{\text{num}}(X_{m-1})$, and we in particular find that the induced form on $\text{NS}(X_m)$ satisfies

$$ (\alpha_m^*D_1 + r_1e_m) \cdot (\alpha_m^*D_2 + r_2e_m) = (D_1 \cdot D_2) - r_1r_2, \quad (7.3) $$

so that we may reduce to the case $m = 0$. (Here we have defined $e_m$ to be the Chern class of the exceptional sheaf $O_{\text{et}}(-1)$.)

For $m = 0$, we have $K_0^{\text{num}}(C_i) \cong \mathbb{Z}^2$ (determined by rank and degree), and thus $K_0^{\text{num}}(X_0) \cong \mathbb{Z}^4$ and $\text{NS}(X_0) \cong \mathbb{Z}^2$. We may then define $f$ to be the (numeric) class of a point of $C_0$ (noting that the numeric class of a point in $C_1$ gives the same class in $\text{NS}(X)$, since they differ by $[\text{pt}]$), and let $s$ be any class which is rank 1 in both $C_0$ and $C_1$. We then readily compute that $s \cdot f = f \cdot s = 1$, giving the required symmetry. Moreover, we have $f^2 = 0$, making the signature $\langle +, - \rangle$ as required. \hfill \Box

We will often refer to the basis $s, f, e_1, \ldots, e_m$ of $\text{NS}(X)$ arising from this proof. The class $s$ is only defined modulo $f$, but since $(s + df)^2 = s^2 + 2d$, we can fix this by insisting that $s^2 \in \{-1, 0\}$ to obtain a canonical basis of $\text{NS}(X_m)$. We should caution that this basis is only canonical relative to the given representation of $X_m$ as an iterated blowup of a quasi-ruled surface; e.g., if $X_0$ is a sufficiently nondegenerate deformation of $\mathbb{P}^1 \times \mathbb{P}^1$, then it can be represented in two ways as a ruled surface, and the two resulting bases differ by interchanging $s$ and $f$.

Corollary 7.9. The radical of the Fourier-Mukai pairing is $\text{Pic}^0(C_0) \times \text{Pic}^0(C_1)$, and thus numerically equivalent classes in $K_0(X)$ are algebraically equivalent.

Proof. Since the Fourier-Mukai pairing is constant in flat families, the identity component of $K_0(X)$ is certainly contained in the radical, and we have just shown that the induced pairing on $[\text{pt}]^2/\{\text{pt}\}$ is nondegenerate, so that the radical of the induced pairing on $K_0^{\text{num}}(X)$ is contained in $\mathbb{Z}[\text{pt}]$. Since $\chi([O_X],[\text{pt}]) = 1$, it follows that the pairing on $K_0^{\text{num}}(X)$ is nondegenerate. \hfill \Box

We have the following by an easy induction, where we recall the notion of line bundle from Definition 5.11.

Corollary 7.10. For any divisor class $D$, there is a line bundle $L$ with $c_1(L) = D$, and any two line bundles with the same Chern class have the same class in $K_0^{\text{num}}(X)$.

Remark. The reader should bear in mind that line bundles do not form a group in any reasonable sense! Indeed, the map from the set of isomorphism classes of line bundles to $\text{NS}(X)$ (which, of course, is a group) may not even have constant fibers: half of the fibers are $\text{Pic}^0(C_0)$-torsors, and half are $\text{Pic}^0(C_1)$-torsors, depending on the parity of $D \cdot f$.

Since $O_X$ has Chern class 0, and $[\text{pt}]$ can be expressed as a linear combination of classes of line bundles, we conclude the following.

Corollary 7.11. $K_0^{\text{num}}(X)$ is generated by classes of line bundles.

For a split family of noncommutative surfaces, the above considerations imply that the family $K_0^{\text{num}}(X_s)$ of abelian groups is locally constant as $s$ varies, letting us make the following statement.

Corollary 7.12. If $X/S$ is a split family of noncommutative surfaces, then for any $M \in \text{perf}(X)$, the class of $M|_s^L$ in $K_0^{\text{num}}(X_s)$ is locally constant on $S$. 

87
Proof. The class in $K_0^{\text{num}}(X)$ of an object $M$ is uniquely determined by the linear functional $\chi(\_ , M)$ coming from the Fourier-Mukai pairing, and thus on the values $\chi(L, M)$. But $\chi(L|_s , M|_s^L)$ is locally constant since $R\text{Hom}(L, M)$ is perfect.

This implies the “no shrunken flat deformations” axiom of [13]: if $M$ and $N$ are distinct fibers of a flat family of coherent sheaves over a connected base, then any injective or surjective morphism between them is an isomorphism, since the cokernel or kernel is then a sheaf with trivial class in $K_0^{\text{num}}(X)$, and thus 0.

Corollary 7.13. A class in $K_0^{\text{num}}(X)$ is uniquely determined by its rank, Chern class and Euler characteristic $\chi(M) := \chi(O_X, M)$. The Fourier-Mukai pairing is given in these terms by

$$\chi(M, N) = - \text{rank}(M) \text{rank}(N) \chi(O_X) + \text{rank}(M) \chi(N) + \text{rank}(N) \chi(M) - c_1(M) \cdot (c_1(N) - \text{rank}(N)K_X).$$

(7.4)

Proof. We first observe that Serre duality implies

$$\chi([O_X], \theta[O_X]) = \chi([O_X], [O_X])$$

(7.5)

and

$$\chi(M, [O_X]) = \chi(M, [O_X] - \theta[O_X]) + \chi(M, \theta[O_X])$$

(7.6)

$$= \chi(M - \text{rank}(M)[O_X], [O_X] - \theta[O_X]) + \chi([O_X], M)$$

$$= - c_1(M) \cdot K_X + \chi(M),$$

while the definition of the intersection pairing gives

$$- c_1(M) \cdot c_1(N) = \chi(M - \text{rank}(M)[O_X], N - \text{rank}(N)[O_X]).$$

(7.7)

Expanding the right-hand side via bilinearity and simplifying gives the desired result.

In the above expression, $\chi(O_X)$ is easy to compute, as $O_X$ lives entirely inside the component $D^b_{\text{coh}}C_0$ of the semiorthogonal decomposition; we thus conclude that $\chi(O_X) = \chi(O_{C_0}) = 1 - g(C_0)$. More generally, if $L$ is a line bundle, one has $\chi(L, L) = 1 - g(C_{c_1(L), f})$, from which one can solve for $\chi(L)$:

$$\chi(L) = 1 - \frac{g(C_0) + g(C_{c_1(L), f})}{2} + \frac{c_1(L) \cdot (c_1(L) - K_X)}{2}. $$

(7.8)

This, of course, agrees with the standard Riemann-Roch formula for the Euler characteristic in the case of a ruled surface (as it must: $\chi(L)$ is locally constant as we vary the surface, so for ruled surfaces may be computed on the commutative fiber).

For $K_X$, the situation is slightly more complicated, but we have the following.

Proposition 7.14. In terms of the standard basis of $\text{NS}(X)$, we have

$$K_X = \begin{cases} 
-2s - (2 - g(C_0) - g(C_1))f + e_1 + \cdots + e_m, & s^2 = 0 \\
-2s - (3 - g(C_0) - g(C_1))f + e_1 + \cdots + e_m, & s^2 = -1 
\end{cases}.$$

(7.9)
Proof. We readily reduce to the case $m = 0$, where the description of the action of $\theta$ tells us that
\[ [\theta \mathcal{O}_X] + [\rho^*_0 \omega_{\mathcal{O}_0}] = \rho^*_1 V \quad (7.10) \]
for some rank 2 vector bundle $V$ on $C_1$. It follows that $K_X = -2s + df$ for some $d$, and since $K_X^2$ is linear in $d$, we reduce to showing $K_X^2 = 4(2-g(C_0) - g(C_1))$. Since $\chi(\rho^*_1 V, \rho^*_1 V) = \chi(\text{End}(V)) = 4(1-g(C_1))$ by Riemann-Roch, we find
\[ \chi([\theta \mathcal{O}_X] + [\rho^*_0 \omega_{\mathcal{O}_0}], [\theta \mathcal{O}_X] + [\rho^*_0 \omega_{\mathcal{O}_0}]) = 4 - 4g(C_1). \quad (7.11) \]
The left-hand side expands as a sum of 4 terms, three of which simplify via Serre duality to a calculation inside $D^b_{\text{coh}} C_0$ and the fourth of which can be simplified using the general expression for $\chi(M, N)$. We thus find
\[ 4 - 4g(C_1) = K_X^2 - c_1(\rho^*_0 \omega_{\mathcal{O}_0}) \cdot K_X. \quad (7.12) \]
Since $c_1(\rho^*_0 \omega_{\mathcal{O}_0}) = (2g(C_0) - 2)f$, this gives $K_X^2 = 4(2-g(C_0) - g(C_1))$ as required. \qed

Remark. We similarly find $[\mathcal{O}_Q] = -K_X + (g(Q) - 1)f$.

Corollary 7.15. The action of $\theta$ on $K_0^\text{num}(X)$ is given by
\[ \text{rank}(\theta M) = \text{rank}(M) \quad (7.13) \]
\[ c_1(\theta M) = c_1(M) + \text{rank}(M) K_X \quad (7.14) \]
\[ \chi(\theta M) = \chi(M) + c_1(M) \cdot K_X. \quad (7.15) \]

Proof. For each $M$, $\chi(M, N) = \chi(N, \theta M)$ by Serre duality. Both sides are linear functionals on $K_0^\text{num}(X)$, and comparing coefficients gives the desired expressions. \qed

The action of the duality $R\text{ad}$ is also straightforward to compute, since we know how it acts on line bundles.

Proposition 7.16. The action of $R\text{ad}$ on $K_0^\text{num}(X)$ is given by
\[ \text{rank}(R\text{ad} M) = \text{rank}(M) \quad (7.16) \]
\[ c_1(R\text{ad} M) = -c_1(M) + \text{rank}(M) K_X \quad (7.17) \]
\[ \chi(R\text{ad} M) = \chi(M). \quad (7.18) \]

Proof. Indeed, this is linear and acts correctly on line bundles. \qed

When $X$ is a maximal order, we are also interested in how the direct image and pullback functors relate the two Grothendieck groups. The nicest answer regards the Néron-Severi groups.

Proposition 7.17. Let $X$ be a rationally quasi-ruled surface, and suppose that $X \cong \text{Spec } A$ where $A$ is a maximal order of rank $r^2$ over the commutative surface $Z$, with associated morphism $\pi : X \to Z$. Then $X$ and $Z$ have the same parity, and in terms of the standard bases of $\text{NS}(X)$ and $\text{NS}(Z)$, the maps $\pi^*$ and $\pi_*$ are both multiplication by $r$.

Proof. Since $\pi^* \pi_* M \cong M \otimes_{\mathcal{O}_Z} A$ and $A$ is a vector bundle of rank $r^2$, we see that $c_1(\pi^* \pi_* M) = r^2 c_1(M)$. Adjunction then gives $\pi_* D_1 \cdot \pi_* D_2 = r^2 D_1 \cdot D_2$, and the same holds for $\pi^*$ since their product is multiplication by $r^2$.

We next address the question of parities, which is of course really about quasi-ruled surfaces. An elementary transformation flips both parities, and thus we may assume that we are in the
untwisted case with $\hat{Q} = \bar{Q}$. As we discussed when considering point sheaves, in this case there is a natural morphism $\rho_1^* \mathcal{O}_{C_1} \to \rho_0^* \mathcal{O}_{C_0}$ the cokernel of which is a sheaf of class in $s + \mathbb{Z}f$ disjoint from $Q$. The direct image of this sheaf is a vector bundle of rank $r$ on its support, a section of $Z$. Since we have shown that the direct is a similitude relative to the intersection form, we conclude that the classes in $s + \mathbb{Z}f$ on the respective surfaces have the same self-intersection, and thus the surfaces have the same parity, letting us identify their Néron-Severi lattices via the standard bases.

It remains to show that $\pi_!$ and $\pi^*$ are multiplication by $r$ relative to these bases. For $m \geq 1$, we note that $\pi_! \mathcal{O}_{e_m}(-1)$ is supported on the corresponding exceptional curve of $Z$, and thus has Chern class a multiple of $e_m$, which must be $re_m$ by the isometry property. Similarly, for any point $x \in C'$, we have $\pi^* \rho^* \mathcal{O}_x \cong \rho_0^* \phi^* \mathcal{O}_x$, where $\phi$ is the projection $C_0 \to C'$, and thus $\pi^*(f) = rf$. Finally, $\pi_* s$ is orthogonal to each $e_i$ and has intersection $r$ with $f$, so has the form $\pi_* s = rs + df$, with $d = 0$ then forced by $(\pi_* s)^2 = r^2$.

In fact, we can give the full map between the Grothendieck groups, though this is more complicated.

**Proposition 7.18.** If the rationally quasi-ruled surface $X$ is a maximal order over $Z$, then using the standard bases to identify their Néron-Severi lattices, one has

$$
\begin{align*}
\text{rank}(\pi_* M) &= r^2 \text{rank}(M) \\
c_1(\pi_* M) &= r c_1(M) + \text{rank}(M) \frac{r^2 K_Z - r K_X}{2} \\
\chi(\pi_* M) &= \chi(M)
\end{align*}
$$

and

$$
\begin{align*}
\text{rank}(\pi^* M) &= \text{rank}(M) \\
c_1(\pi^* M) &= rc_1(M) \\
\chi(\pi^* M) &= r^2 \chi(M) + \frac{c_1(M) \cdot (r^2 K_Z - r K_X)}{2} + \text{rank}(M)(\chi(\mathcal{O}_X) - r^2 \chi(\mathcal{O}_Z)).
\end{align*}
$$

**Proof.** Since $\pi^* \mathcal{O}_Z \cong \mathcal{O}_X$, we have $\chi(\pi_* M) = \chi(M)$, and since $\pi_* \mathcal{O}_X = \mathcal{A}$, $\text{rank}(\pi_* \mathcal{O}_X) = r^2$. Moreover, our Chern class computation tells us how $\pi_*$ acts on the Chern class of 1-dimensional sheaves. This almost determines how $\pi_*$ acts on a basis of $K_0^{\text{num}}(X)$, except that we still need to determine $c_1(\pi_* \mathcal{O}_X)$. Since $\pi_* \theta \mathcal{O}_X \cong \text{Hom}(\pi_* \mathcal{O}_X, \mathcal{O}_Z)$, we find that

$$c_1(\pi_* \theta \mathcal{O}_X) = r^2 K_Z - c_1(\pi_* \mathcal{O}_X)
$$

and thus

$$2c_1(\pi_* \mathcal{O}_X) = r^2 K_Z - r K_X.
$$

In the commutative setting, the notion of an effective divisor is of course quite crucial. In the commutative setting, a divisor on a smooth surface is effective if it can be represented by a curve; although curves themselves do not make sense in the noncommutative case (apart from components of $Q$), we are still led to the following definition.

**Definition 7.4.** A divisor class is **effective** if it is the Chern class of a 1-dimensional sheaf.
Remark. Note that the effective classes form a monoid, since we can always take the direct sum of the corresponding 1-dimensional sheaves.

Remark. In the commutative case, one often uses the equivalence between a divisor being effective and the corresponding line bundle having a global section. As stated, this does not hold in the noncommutative setting; there are cases (e.g., $e_1 - e_2$ when one blew up two points in the same orbit) of effective divisors such that no line bundle with the given Chern class has a global section. The situation is somewhat better if one allows both line bundles to vary, fixing the difference of Chern classes, but even then it is unclear whether the resulting classes form a monoid. (The monoid they generate is, however, correct, at least for rational or rationally ruled surfaces.)

If a 0-dimensional sheaf had a 1-dimensional subsheaf, then both the subsheaf and the quotient would have nonzero effective Chern classes, and thus to rule this out, we need to show that the monoid effective monoid intersects its antipode only in 0.

**Proposition 7.19.** If $D \in \text{NS}(X)$ is such that both $D$ and $-D$ are effective, then $D = 0$.

**Proof.** Let $M$ be a 1-dimensional sheaf with Chern class $D$, and let $N$ be a 1-dimensional sheaf with Chern class $-D$. If $m > 0$, then for $l \gg 0$, $\alpha_m \theta^{-l}M$ and $\alpha_m \theta^{-l}N$ are both sheaves, and their Chern classes add to 0. But then $[\alpha_m \theta^{-l}M]$ and $[\alpha_m \theta^{-l}N]$ are multiples of $[pt]$ for all $l$, with the coefficient depending linearly on $l$; since they must be nonnegative for $l \gg 0$, both linear terms must be nonnegative, implying that $d, -d \geq 0$ as required.

For $m = 0$, suppose $D = ds + df$ (relative to the standard basis discussed above). Then $\text{rank}(\rho_s M) = d = -\text{rank}(\rho_s N)$, and since both are sheaves for $l \gg 0$, we must have $d = 0$. But then $[\rho_s M]$ and $[\rho_s N]$ are proportional to the class of a point for all $l$, again depending linearly on $l$, with coefficients $\pm d'$, so that $d' = 0$ as well.

It follows immediately that our dimension function is *exact* in the sense of [15]: given an exact sequence

$$0 \to M' \to M \to M'' \to 0,$$

we have $\text{dim}(M) = \max(\text{dim}(M'), \text{dim}(M''))$. (We have also implicitly shown that the shifted Serre functor preserves dimension.)

The next two results essentially say that $X$ is irreducible.

**Lemma 7.20.** If $L_1$, $L_2$, $L_3$ are line bundles on $X_m$ and $\phi_1 \in \text{Hom}(L_1, L_2)$, $\phi_2 \in \text{Hom}(L_2, L_3)$ are morphisms such that $\phi_2 \circ \phi_1 = 0$, then $\phi_1 = 0$ or $\phi_2 = 0$.

**Proof.** For $m > 0$, we may write $L_i = \theta^{l_i} \alpha_m \theta^{-l_i} L'_i$ for line bundles on $X_m$, and we find that there are composition-respecting injections

$$\text{Hom}(L_1, L_2) \subset \text{Hom}(L'_1, L'_2) \quad \text{and} \quad \text{Hom}(L_2, L_3) \subset \text{Hom}(L'_2, L'_3).$$

(Indeed, by the construction of the blowup, $\text{Hom}(L_1, L_2)$ is essentially defined to be the subspace of $\text{Hom}(L'_1, L'_2)$ satisfying an appropriate condition of the form “vanishes to multiplicity $l_1 - l_2$.”)

We thus reduce by induction to the case $m = 0$, where it is simply the fact that the $\mathbb{Z}$-algebra $\overline{S}$ corresponding to a quasi-ruled surfaces is a domain.

**Proposition 7.21.** Any nonzero morphism between line bundles is injective.
**Proof.** Suppose otherwise, so that \( \phi_2 : L_2 \to L_3 \) is a morphism of line bundles with nonzero kernel. Then there is a line bundle \( L_1 \) such that \( L_1 \otimes \text{Hom}(L_1, \ker(\phi_2)) \to \ker(\phi_2) \) is surjective, and thus \( \text{Hom}(L_1, \ker(\phi_2)) \neq 0 \). A nonzero homomorphism \( L_1 \to \ker \phi_2 \) induces a nonzero homomorphism \( \phi_1 : L_1 \to L_2 \) such that \( \phi_2 \circ \phi_1 = 0 \), giving a contradiction. \( \square \)

**Corollary 7.22.** Line bundles are torsion-free.

**Proof.** If \( M \subset L \) is a rank 0 subsheaf of a line bundle \( L \), then as before, there exists a nonzero morphism \( L' \to M \) for some line bundle \( L' \) and thus the composition \( L' \to L \) has image a nonzero subsheaf of \( M \). But this composition is nonzero, so injective, and thus its image has rank 1, giving a contradiction. \( \square \)

Serre duality immediately gives the following.

**Corollary 7.23.** If \( L \) is a line bundle and \( M \) a \( 1 \)-dimensional sheaf, then \( \text{Ext}^2(L, M) = 0 \).

We would like more generally to know that the “cohomology” of a coherent sheaf \( M \) (i.e., \( R^q(M) := \text{RHom}(\mathcal{O}_X, M) \)) vanishes in degree \( > \dim(M) \). For \( 2 \)-dimensional sheaves, this follows trivially from the global bound on Ext groups, while for \( 1 \)-dimensional sheaves, this is a special case of the corollary. For \( 0 \)-dimensional sheaves, it will be handy to use the following dichotomy. We note that although the restriction map \( K_0(X) \to K_0^{\text{perf}}(Q) \) is not well-defined on \( K_0^{\text{perf}}(X) \), the rank is certainly well-defined, as is the class of the determinant in \( \text{Pic}(Q)/\text{Pic}^0(C_0) \times \text{Pic}^0(C_1) \).

In particular, there is a well-defined class \( q \) in the latter group obtained as the determinant of the restriction of \([pt]\). Note that if \( q' \not\sim \mathcal{O}_Q \), then any sheaf of class \( r[pt] \) has nontrivial restriction to \( Q \); in particular, if \( q \not\sim \mathcal{O}_Q \), then any sheaf of class \([pt]\) is a point of \( Q \).

**Proposition 7.24.** The class \( q \) is torsion iff \( X \) is a maximal order on a smooth commutative projective surface \( Z \).

**Proof.** If \( X \) is a maximal order in a central simple algebra of degree \( r \), then there are \( 0 \)-dimensional sheaves on \( X \) of class \( r[pt] \) which are disjoint from \( Q \), and thus the determinant of their restriction is trivial, implying \( rq \sim \mathcal{O}_Q \).

Now, suppose that \( q \) is torsion. The conclusion is inherited under blowing up, so we may assume \( m = 0 \), and since the conclusion is automatic for surfaces which are quasi-ruled but not ruled, we may assume \( X = X_0 \) is a ruled surface, and not of the hybrid type (since the conclusion also holds there) or commutative. In the differential case, we have \( \text{Pic}^0(Q)/\text{Pic}^0(C_0) \times \text{Pic}^0(C_1) \cong \mathbb{G}_a \) and find that \( q = 1 \), which is torsion only in finite characteristic, where the conclusion holds. In the difference cases, we can express \( q \) in terms of the action of \( s_0s_1 \), and find that the latter is torsion iff \( q \) is torsion. \( \square \)

**Remark.** The same calculation shows that for a rationally ruled surface, \( q \) is trivial iff \( X \) is commutative.

**Proposition 7.25.** If \( M \) is \( 0 \)-dimensional of class \( d[pt] \), then for any line bundle \( L \), \( \text{Ext}^p(L, M) = 0 \) for \( p > 0 \) and \( \dim \text{Hom}(L, M) = d \).

**Proof.** If \( X \) is a maximal order, then the claim follows immediately from the corresponding fact on \( Z \), so we suppose that \( q \) is not torsion.

Since \( \text{Ext}^2(L, M) = 0 \), we find that \( \dim \text{Hom}(L, M) - \dim \text{Ext}^1(L, M) = \chi(L, M) = d \), and thus any line bundle has a nonzero morphism to \( M \). The image and cokernel (if nonzero) of such a morphism will again be \( 0 \)-dimensional, and thus vanishing of \( \text{Ext}^1(L, M) \) will follow by induction.
in $d$. We may thus assume that $M$ has no proper sub- or quotient sheaf. Since $\det(M|_Q) \neq 0$, we conclude that $M|_Q \neq 0$, and thus that $M$ is actually supported on $Q$. In other words, we may write $M = \iota_*N$ for some 0-dimensional sheaf $N$ on $Q$, and find

$$R\text{Hom}(L, M) \cong R\text{Hom}(\iota^*L, N),$$

and vanishing follows since $\iota^*L$ is an invertible sheaf on $Q$. \hfill \Box

**Remark.** By Serre duality, it follows that $\text{Ext}^1(M, L) = 0$.

**Corollary 7.26.** If $M$ is $\leq d$-dimensional, then $R^p\text{ad }M = 0$ for $p > 2$ and $p < 2 - d$.

**Proof.** We have already shown that $\text{ad}$ is left exact of homological dimension 2. Since this is bounded, there is a line bundle $L$ on $X^{\text{ad}}$ such that each cohomology sheaf is acyclic and globally generated relative to $L$. On the other hand, we have

$$\text{Hom}(L, R^p\text{ad }M) \cong h^p(R\text{Hom}(L, R\text{ad }M)) \cong \text{Ext}^p(M, \text{ad }L) \cong \text{Ext}^{2-p}(\text{ad }L, \theta M)^*$$

and thus $R^p\text{ad }M$ vanishes if $2 - p > \dim(\theta M) = \dim(M)$. \hfill \Box

**Proposition 7.27.** For any coherent sheaf $M$, $\text{ad }M$ is torsion-free.

**Proof.** We have a surjection of the form $L^n \to M$ and thus by left exactness $\text{ad }M$ is a subsheaf of the torsion-free sheaf $\text{ad }L^n$.

Call a coherent sheaf $M$ “reflexive” if $R\text{ad }M$ is a sheaf.

**Corollary 7.28.** A coherent sheaf $M$ is reflexive iff there exists a sheaf $N$ such that $M \cong \text{ad }N$.

**Proof.** If $M$ is reflexive, then $M \cong R\text{ad }M = \text{ad}(\text{ad }M)$, so it remains to show that $\text{ad }N$ is always reflexive. But this follows from the spectral sequence $R^p\text{ad }R^q\text{ad }N \Rightarrow N$: if $R^p\text{ad }N \neq 0$ for $p \in \{1, 2\}$, then this would contribute to the positive cohomology of the limit of the spectral sequence. \hfill \Box

**Corollary 7.29.** For any coherent sheaf $M$, $R^p\text{ad }M$ has dimension $\leq 2 - p$.

**Proof.** We similarly conclude using the negative part of the spectral sequence that $R^p\text{ad }R^2\text{ad }M = 0$ for $p < 2$, and that for any line bundle $L$, $R^2\text{ad }R^2\text{ad }M$ is acyclic for $R\text{Hom}(L, \_\_)$.

It follows that $R^2\text{ad }R^2\text{ad }M$ is 0-dimensional, and thus (dualizing yet again) that $R^2\text{ad }M$ is 0-dimensional.

For $R^1\text{ad }M$, vanishing of the negative cohomology only directly tells us that $\text{ad }R^1\text{ad }M$ injects in $R^2\text{ad }R^2\text{ad }M$, but since $\text{ad }R^1\text{ad }M$ is torsion-free, its injection in a 0-dimensional sheaf forces it to vanish. But then

$$\text{rank}(R^1\text{ad }M) = \text{rank}(\text{ad }R^1\text{ad }M) = \text{rank}(R^2\text{ad }R^1\text{ad }M) - \text{rank}(R^1\text{ad }R^1\text{ad }M),$$

and since $R^2\text{ad }R^1\text{ad }M$ is 0-dimensional by the previous paragraph, we find that $\text{rank}(R^1\text{ad }M) + \text{rank}(R^1\text{ad }R^1\text{ad }M) = 0$. Since sheaves have nonnegative rank, it follows that $R^1\text{ad }M$ has rank 0, so is $\leq 1$-dimensional as required. \hfill \Box

**Corollary 7.30.** A nonzero $\leq 1$-dimensional sheaf $M$ is pure 1-dimensional iff $R^2\text{ad }M = 0$.  

93
Proof. For any 0-dimensional sheaf $N$, we have
\[
\text{Hom}(N, M) \cong h^0(R\text{Hom}(R\text{ad } M, R^2 \text{ad } N)) \cong \text{Hom}(R^2 \text{ad } M, R^2 \text{ad } N),
\]
(7.28)
and thus there is a nonzero morphism $N \to M$ if and only if there is a nonzero morphism $R^2 \text{ad } M \to R^2 \text{ad } N$. In other words, $N$ is a nonzero 0-dimensional subsheaf of $M$, then $R^2 \text{ad } N$ is a nonzero quotient of $R^2 \text{ad } M$, while if $N$ is a nonzero quotient of $R^2 \text{ad } M$, then $R^2 \text{ad } N$ is a nonzero 0-dimensional subsheaf of $M$.

Corollary 7.31. If $M$ is pure 1-dimensional, then $R^1 \text{ad } R^1 \text{ad } M \cong M$.

This gives an easy proof of the “finitely partitive” property considered in [15].

Proposition 7.32. Let $M = M_0 \supset M_1 \supset \cdots$ be a descending chain of coherent sheaves such that $M_i/M_{i+1}$ has dimension $d = \dim(M)$ for all $i \geq 0$. Then the chain must be finite.

Proof. If $d = 2$, then this follows from the fact that each subquotient has positive rank, so the chain terminates in at most $\chi(M)$ steps. For $d = 1$, we first replace each $M_i$, $i > 0$ by a slightly larger sheaf $\tilde{M}_i$ defined by letting $\tilde{M}_i/M_i$ be the maximal 0-dimensional subsheaf of $M_{i-1}/M_i$. This makes each subquotient a pure 1-dimensional sheaf without affecting the length of the chain. Furthermore, if $N$ is the maximal 0-dimensional subsheaf of $M$, then $N$ is contained in each $\tilde{M}_i$, and thus we may quotient the chain by $N$ without affecting the dimensions of the subquotients. We have thus reduced to the case that $M$ and every subquotient is pure 1-dimensional. But then applying $R^1 \text{ad}$ gives an ascending chain
\[
0 \subset R^1 \text{ad}(M_0/M_1) \subset R^1 \text{ad}(M_0/M_2) \subset \cdots \subset R^1 \text{ad } M_0
\]
which terminates since $\text{coh } X$ is Noetherian.

Remark. Of course, once we have an understanding (and have established the existence!) of ample divisors, we will be able to sharpen the 1-dimensional considerably; the length of the chain is bounded by $D_a \cdot c_1(M)$ for any ample divisor $D_a$.

The above results also hold with minor changes in the case of an iterated blowup of a noncommutative plane. The inductive steps are all the same, with the only difference being the base case. For a noncommutative plane, the semiorthogonal decomposition shows
\[
K^0(X) \cong \mathbb{Z}[\mathcal{O}_X] \oplus \mathbb{Z}[\mathcal{O}_X(-1)] \oplus \mathbb{Z}[\mathcal{O}_X(-2)],
\]
(7.30)
from which (together with constancy on flat deformations) it follows that $\chi([\mathcal{O}_X(-d)], [M])$ is a quadratic polynomial in $d$ and $[M]$ is uniquely determined by this polynomial. Moreover, this polynomial is nonnegative for $d \gg 0$ (since $\theta^{-1}$ is ample), with equality iff $M = 0$. The rank of $M$ is given by the coefficient of $d^2/2$ in this polynomial, while $[pt]$ is represented by the polynomial 1, and $\text{NS}(X) \cong \mathbb{Z}$ is generated by the class $h$ (with $h^2 = 1$) corresponding to the polynomials with leading term $d$, with $K = -3h$.

That morphisms between line bundles are injective can be readily established by choosing an integral component $C$ of $Q$ and observing that if a product of morphisms of line bundles vanishes, then so does the product of their restrictions to $C$, and thus one of the two morphisms vanishes on $C$; the result then follows by induction on the overall difference of Chern classes.

This is all we need for the proof of Theorem [8.6], which states that a one-point blowup of a noncommutative plane is a noncommutative Hirzebruch surface. (We need to know that $H^0$ of
a nonzero 0-dimensional sheaf is nonzero, but this follows from vanishing of \( H^2 \) and positivity of the Euler characteristic.) Given that, we can then reduce the remaining claims to statements on such surfaces. In particular, that a noncommutative plane is a maximal order iff \( q \) is torsion (and commutative iff \( q \) is trivial) follows by choosing points in distinct orbits, and observing that the maximal order property follows from the fact that both blowups are maximal orders.

8 Birational geometry

We can now finish the proof that the usual isomorphisms in the birational geometry of commutative surfaces carry over to the noncommutative setting. We recall that in each case we have constructed a derived equivalence and a pair of left exact functors related by the derived equivalence, and thus to show that the derived equivalence induces an abelian equivalence, it suffices to show that the functors \( f \) satisfy the property that for any nonzero sheaf \( M \), \( f_! \theta^l M \neq 0 \) for some \( l \in \mathbb{Z} \).

For elementary transformations, the functor is \( \rho_0 \alpha_* \), so suppose \( M \) is a nonzero sheaf such that \( \rho_0 \alpha_! \theta^l M = 0 \) for all \( l \in \mathbb{Z} \). Since

\[
- \operatorname{rank}(R^1(\rho_0 \alpha_!)\theta^l M) = \operatorname{rank}(R\rho_0 R\alpha_! \theta^l M) = \operatorname{rank}(R\rho_0 R\alpha_* M) - l \operatorname{rank}(M),
\]

we must have \( \operatorname{rank}(M) = 0 \), so that \( M \) is a (pure) 1-dimensional sheaf. (Here we have used the fact that \( \rho_0 \alpha_* \) has cohomological dimension 1.) We then have

\[
f \cdot c_1(M) = - \operatorname{rank}(R^1(\rho_0 \alpha_*)M). \tag{8.2}
\]

If this were not 0, then there would be line bundles on \( C_0 \) such that \( \operatorname{Ext}^2(\alpha^! \rho_0^* L, M) \neq 0 \), which is impossible for a 1-dimensional sheaf, and thus \( f \cdot c_1(M) = 0 \), so that \( c_1(M) \in \mathbb{Z} f + \mathbb{Z} e_1 \). Moreover, since now \( h^1(R\rho_0 R\alpha_! \theta^l M) = 0 \)-dimensional, we find that \( R\operatorname{Hom}(O_{C_0}, R\rho_0 R\alpha_* \theta^l M) \) is supported in degree 1, so its Euler characteristic is negative. It follows that \( c_1(M) \cdot K = 0 \), and thus \( c_1(M) = a(f - 2e_1) \) for some nonzero \( a \in \mathbb{Z} \).

Choose such an \( M \) that minimizes \( |a| \). We have \( \chi(M, M) = 4a^2 \geq 4 \), and thus \( \dim \operatorname{Hom}(M, M) + \dim \operatorname{Ext}^2(M, M) \geq 4 \). If \( \dim \operatorname{Hom}(M, M) > 1 \), then the endomorphism ring of \( M \) contains zero divisors, and thus there are nonzero endomorphisms with nontrivial kernel. The kernel and cokernel are both subsheaves of \( M \), so have nonzero Chern class proportional to \( f - 2e_1 \), which by minimality of \( |a| \) forces them to have opposite signs, contradicting Proposition 7.19. We thus conclude that \( \dim \operatorname{Hom}(M, M) = 1 \) and thus \( \dim \operatorname{Ext}^2(M, M) \geq 3 \). But this is equivalent to \( \dim \operatorname{Hom}(M, \theta M) = 3 \), and the same argument tells us that any such morphism must be injective. Since \( M \) and \( \theta M \) have the same class in the numeric Grothendieck group, such a morphism must be an isomorphism, and we get the desired contradiction. We have thus shown the following.

**Theorem 8.1.** Let \( X \) be a quasi-ruled surface and \( x \in Q \) a point. Then the blowup of \( X \) at \( x \) is a blowup of the quasi-ruled surface obtained by replacing the sheaf bimodule \( \mathcal{E} \) by the kernel of the point in \( \operatorname{Quot}(\mathcal{E}, 1) \) associated to \( x \).

**Remark.** The construction of the derived equivalence via the associated commutative ruled surface shows that this operation is an involution. The above description may appear to violate this (both steps make \( \mathcal{E} \) smaller!), but this is an illusion coming from the fact that \( \mathcal{E} \) is not uniquely determined by the quasi-ruled surface. Indeed, what one finds is that the sheaf bimodule resulting after two steps is isomorphic to the tensor product of \( \mathcal{E} \) with the line bundle \( \pi_* L(-\pi_1(x)) \), and thus determines the same quasi-scheme \((X, \mathcal{O}_X)\).

We also note the following useful fact we proved in the course of the above argument.
Proposition 8.2. If $D \in \text{NS}(X)$ is effective, then $D \cdot f \geq 0$.

Since $K \cdot f = -2$, we immediately conclude the following.

Corollary 8.3. The class $K$ is ineffective.

This has the following useful consequence.

Corollary 8.4. If $M$, $N$ are torsion-free sheaves of rank 1, then at least one of $\text{Hom}(M, N)$ and $\text{Ext}^2(M, N)$ vanishes.

Proof. A nonzero morphism $M \to N$ must be injective, since otherwise the image would be a $\leq 1$-dimensional subsheaf of $N$. The cokernel is thus a 1-dimensional sheaf of Chern class $c_1(N) - c_1(M)$, which must therefore be effective whenever $\text{Hom}(M, N) \neq 0$. Since $\text{Ext}^2(M, N) \cong \text{Hom}(N, \theta M)^*$, we similarly find that if $\text{Ext}^2(M, N) \neq 0$ then $c_1(M) - c_1(N) + K$ is effective. But these divisor classes cannot be simultaneously effective, since their sum $K$ is ineffective. □

For the remaining (rational) cases, the functor we consider is just the usual global sections functor $\Gamma(M) := \text{Hom}(\mathcal{O}_X, M)$. Here we have some additional complications coming from the fact that this functor has cohomological dimension 2. Luckily, this is only a possibility when $M$ is 2-dimensional, and we can rule that case out.

Lemma 8.5. Let $M$ be a sheaf on a noncommutative rational or rationally quasi-ruled surface $X$. Then $\text{Hom}(M, \theta^l \mathcal{O}_X) = 0$ for $l \gg 0$.

Proof. It suffices to show this when $M$ is a line bundle, since in general there is a surjection to $M$ from a power of a line bundle. On a noncommutative plane, the line bundles have the form $\mathcal{O}_X(d)$, and we have $\text{Hom}(\mathcal{O}_X(d), \theta^l \mathcal{O}_X) = 0$ for $l > -d/3$. Otherwise, if $\text{Hom}(L, \theta^l \mathcal{O}_X) \neq 0$, then $c_1(L) + lK_X$ is effective, but $(c_1(L) + lK_X) \cdot f = c_1(L) \cdot f - 2l$ is eventually negative. □

Remark. By Serre duality, this implies that $H^2(\theta^{-l}M) = 0$ for $l \gg 0$.

This implies that if $M$ is a sheaf on a noncommutative Hirzebruch surface or a one-point blowup of a noncommutative plane such that $H^0(\theta^l M) = 0$ for all $l$, then $M$ must be 1-dimensional. Indeed, if $\text{rank}(M) > 0$, then we have $\chi(\theta^{-l}M) = 4 \text{rank}(M)l^2 + O(l)$, and thus $\chi(\theta^{-l}M) > 0$ for $l \gg 0$, but this is impossible since $H^2(\theta^{-l}M) = 0$ for $l \gg 0$.

We then find as in the elementary transformation case that $c_1(M) \cdot K = 0$, which uniquely determines $c_1(M)$. For $F_1$ and the one-point blowup of $\mathbb{P}^2$, we have $\chi(M, M) \geq 8$, and obtain a contradiction as before.

Theorem 8.6. Let $X$ be a noncommutative Hirzebruch surface such that the corresponding commutative surface is $F_1$. Then $X$ is the one-point blowup of a noncommutative plane. Conversely, any one-point blowup of a noncommutative plane is the noncommutative Hirzebruch surface associated to a point of $\text{Pic}^3(Q)$ with $Q$ an anticanonical curve in $F_1$.

The $\mathbb{P}^1 \times \mathbb{P}^1$ case is somewhat more subtle, as the inequality we obtain is only that $\chi(M, M) \geq 2$, which is in fact possible. However, this does at least pin down that $c_1(M) = \pm (s - f)$, and $-s + f$ can be ruled out since $(-s + f) \cdot f < 0$. If $M$ is not transverse to $Q$ (i.e., if $M^{1}_{Q}$ is not a sheaf), then this gives a nonzero subsheaf of $\theta M$ supported on $Q$, which must have the same Chern class, and thus some component of $Q$ is a $-2$-curve on the corresponding commutative surface (and we may take $M = \mathcal{O}_{Q'}(-1)$ where $Q'$ is that component). Otherwise, since $c_1(M) \cdot Q = 0$, we must have $M^{1}_{Q} = 0$ and thus $\det(M^{1}_{Q}) \cong \mathcal{O}_Q$. In particular, the image of $s - f$ in $\text{Pic}^3(Q)$ must be a power of $q \in \text{Pic}^{0}(Q)$, and we conclude the following.
Theorem 8.7. Let $X$ be the noncommutative Hirzebruch surface associated to a triple $(\mathbb{P}^1 \times \mathbb{P}^1, Q, q)$ with $Q \subset \mathbb{P}^1 \times \mathbb{P}^1$ an anticanonical curve and $q \in \text{Pic}^0(Q)$. If the line bundle $\mathcal{O}_{\mathbb{P}^1 \times \mathbb{P}^1}(1, -1)|_Q$ is not a power of $q$, then swapping the two rulings gives an isomorphic noncommutative Hirzebruch surface.

Note that when the “not a power of $q$” hypothesis fails, then the commutative surface associated to some twist of $X$ will be $F_2$. There we have the following corollary of Proposition 4.27.

Proposition 8.8. Suppose that $X$ is the noncommutative Hirzebruch surface associated to a triple $(F_2, Q, q)$ with $Q \subset F_2$ an anticanonical curve disjoint from the $-2$-curve and $q \in \text{Pic}^0(Q)$ of order $r \in [1, \infty]$. Then there is an irreducible 1-dimensional sheaf $\mathcal{O}_{s-f}(-1)$ of Chern class $s - f$ and Euler characteristic 0, and if $0 \leq b - a \leq r$, there is a short exact sequence

$$0 \to \mathcal{O}_X(-bs - af) \to \mathcal{O}_X(-as - bf) \to \mathcal{O}_{s-f}(-1)^{b-a} \to 0. \quad (8.3)$$

Proof. Let $x \in \mathcal{Q}$ be any point. If we blow up $X$ in $x$, then an elementary transformation lets us interpret $\widetilde{X}$ as a blowup of a noncommutative $F_1$, and thus as a two-fold blowup of a noncommutative $\mathbb{P}^2$, in which the same point is blown up each time. The exceptional classes on the latter are $e'_1 = s - e_1$ and $e'_2 = f - e_1$, and thus there is a sheaf $\mathcal{O}_{e'_1 - e'_2}(-1)$, the direct image of which is the desired sheaf $\mathcal{O}_{s-f}(-1)$ on $X$. Moreover, there is a short exact sequence

$$0 \to \mathcal{O}_{\widetilde{X}}(-be'_1 - a'e_2) \to \mathcal{O}_{\widetilde{X}}(-ae'_1 - be'_2) \to \mathcal{O}_{e'_1 - e'_2}(-1)^{b-a} \to 0 \quad (8.4)$$

or equivalently

$$0 \to \mathcal{O}_{\widetilde{X}}(-bs - af + (a+b)e_1) \to \mathcal{O}_{\widetilde{X}}(-as - bf + (a+b)e_1) \to \mathcal{O}_{e'_1 - e'_2}(-1)^{b-a} \to 0 \quad (8.5)$$

The result follows by taking direct images down to $X$.

Remark. If $Q$ is not disjoint from the $-2$-curve, then it contains the $-2$-curve, so that one may define $\mathcal{O}_{s-f}(-1)$ as the appropriate line bundle on that component of $Q$, and one again obtains a short exact sequence for $0 \leq b - a \leq 1$.

The other thing we want to show vis-à-vis birational geometry is that “rationally quasi-ruled” and “birationally quasi-ruled” are essentially the same, or in other words the following.

Theorem 8.9. Suppose that $X$ is a noncommutative surface such that some iterated blowup of $X$ is an iterated blowup of a quasi-ruled surface with associated curves $(C_0, C_1)$. Then either $X$ is an iterated blowup of a quasi-ruled surface over the same pair of curves, or $C_0 \cong C_1 \cong \mathbb{P}^1$ and $X$ is a noncommutative plane.

By an easy induction, this reduces to showing that if a one-fold blowup of $X$ is an iterated blowup of a quasi-ruled surface or noncommutative plane, then the same is true for $X$, and thus to understanding when we can blow down a $-1$-curve on a rationally quasi-ruled surface.

Thus let $\alpha : \widetilde{X} \to X$ be a van den Bergh blowup with exceptional sheaf $\mathcal{O}_e(-1)$, such that $\widetilde{X}$ is rational or rationally quasi-ruled. We first need to deal with the technical issue that $X$ may not have a well-defined dimension function, and thus it is not immediately obvious that the exceptional sheaf is 1-dimensional. This is not too difficult to show: $X$ inherits a Serre functor from $\widetilde{X}$, and if

$$M_l := \alpha^*(\mathcal{O}_X(lC))(-l)$$

(where $C$ is the relevant curve on $X$), then we have short exact sequences

$$0 \to M_l \to M_{l+1} \to \mathcal{O}_e(-l-1) \to 0, \quad (8.6)$$

97
since $\mathcal{O}_X(lC)$ is a weak line bundle along $C$. An easy induction from $\theta^{-1}\mathcal{O}_e(-1) \cong \mathcal{O}_e$ shows that $\mathcal{O}_e(-l-1) \cong \theta^{-l}\mathcal{O}_e(-1)$ and thus has the same rank, implying that $\text{rank}(M_l) = \text{rank}(\mathcal{O}_e(-1))l + O(1)$. Since ranks of coherent sheaves are nonnegative, we conclude that $\text{rank}(\mathcal{O}_e(-1)) = 0$ as desired, making $e$ 1-dimensional.

Let $e$ denote the Chern class of $\mathcal{O}_e(-1)$. As one might expect, this behaves numerically like a $-1$-curve on a commutative surface. Since $\mathcal{O}_e(-1)$ is exceptional, $-e^2 = \chi(\mathcal{O}_e(-1), \mathcal{O}_e(-1)) = 1$. (In particular, $\tilde{X}$ cannot be a noncommutative plane, since $\text{NS}(\tilde{X}) \cong \text{NS}(\mathbb{P}^2)$ has no classes of self-intersection $-1$.) In addition, since

$$1 = \chi(\mathcal{O}_{\tau_p}) = \chi(\mathcal{O}_e) - \chi(\mathcal{O}_e(-1)) = \chi(\mathcal{O}_e) - \chi(\theta\mathcal{O}_e),$$

we have $e \cdot K = -1$. (Note that we can compute $\chi(\mathcal{O}_{\tau_p})$ inside $\text{coh}(\tilde{C})$.) Moreover, since $R\Gamma(\mathcal{O}_e(-1)) = 0$, $\mathcal{O}_e(-1)$ must be pure 1-dimensional.

Since $\text{rank}(\mathcal{O}_e(d)) = 0$, $\theta\mathcal{O}_e(d)$ and $\mathcal{O}_e(d)$ have the same Chern class, so that $c_1(\mathcal{O}_e(d)) = e$. It then follows that $\mathcal{O}_e/\mathcal{O}_e(-1)$ has numerical class $\chi(\mathcal{O}_e/\mathcal{O}_e(-1))[\text{pt}] = [\text{pt}]$. Thus this sheaf is a point, and the same holds (by algebraic equivalence) for any point $x \in \tilde{C}$. In particular, for any $x \in C$, $[\text{La}^*\mathcal{O}_e] = [\text{pt}]$.

Suppose $M$ is a quotient of $\mathcal{O}_e(-1)$ by a proper subsheaf $N$. Then the long exact sequence gives $R^1\alpha_*M = 0$ and $\alpha_*M \cong R^1\alpha_*N$, so that $\alpha_*M$ is an extension of point sheaves on $C$, thus $[\text{La}^*\alpha_*M] \cong [\text{pt}]$ and $[M]$ is in the span of $[\mathcal{O}_e(-1)]$ and $[\text{pt}]$. Since $c_1(M) + c_1(N) = e$ is a sum of effective divisors, the only possibilities are $c_1(M) = e$ or $c_1(M) = 0$, and the former case can be ruled out since $\mathcal{O}_e(-1)$ is pure 1-dimensional. We thus conclude that $\mathcal{O}_e(-1)$ is irreducible in a suitable sense: any proper quotient is 0-dimensional.

When $X_0$ (the surface of which $\tilde{X}$ is an iterated blowup) is strictly quasi-ruled, there is an additional constraint on $e$, namely that $e \cdot Q = 1$. (This constraint is equivalent to $e \cdot K = -1$ if $X_0$ is ruled, and is actually redundant unless $g(C_0) + g(C_1) = 1$!) Since $K + Q$ is a nonnegative multiple of $f$, Proposition 5.2 tells us that $e \cdot Q \geq e \cdot (-K) \geq 1$, so it suffices to show that if equality fails, then $e \cdot f = 0$. Suppose $e \cdot Q > 1$. Then $e$ meets $Q$ in at least 2 points (possibly by being a component of $Q$), and thus one finds that $\dim \text{Hom}(\mathcal{O}_e(-1), \mathcal{O}_e) > 1$. The kernel of any such homomorphism is a point sheaf, and thus there is an induced family of point sheaves parametrized by $\mathbb{P}^1$. Taking images to $X_0$ gives a family of point sheaves on $X_0$ and thus a morphism from $\mathbb{P}^1$ to $\text{Quot}(X_0, 1)$ (which is well-defined since $X_0$ is a maximal order). Since $X_0$ is strictly quasi-ruled, its curve of points is the union of an irreducible curve $Q$ of positive genus and a collection of fibers, and thus the morphism must map to a fiber, so that $e \cdot f = 0$ (which we can compute as an intersection in the center).

Thus in general, given an iterated blowup $X$ of a quasi-ruled surface, we need to classify the elements $e \in \text{NS}(X)$ such that $e^2 = e \cdot K = -e \cdot Q = -1$ and there exists an irreducible 1-dimensional sheaf $\mathcal{O}_e(-1)$ with Chern class $e$ and vanishing $R\Gamma$. Call such a class a “formal $-1$-curve” on $X$; our objective is to show that any such class can be blown down, and the result is as described in the Theorem.

Note first that if $m = 0$ with $s^2 = -1$ (if $s = 0$ any self-intersection is even), then the equations $e^2 = e \cdot K = -1$ imply $g(C_0) + g(C_1) \in \{0, 2\}$, as one must solve a quadratic equation with discriminant $9 - 4g(C_0) - 4g(C_1)$. If $g(C_0) + g(C_1) = 2$, the unique solution is $e = -s$, which is ineffective since then $e \cdot f < 0$, while if $g(C_0) = g(C_1) = 0$, then the unique solution is $e = s$, which can be blown down (to a noncommutative plane) precisely when there is an irreducible sheaf $\mathcal{O}_e(-1)$ (i.e., when the corresponding commutative surface is $F_1$). So we may reduce to the case $m > 0$.

A key observation is that we have shown that $X$ is not in general uniquely representable as an iterated blowup of a quasi-ruled surface. Changing the representation of course has no effect on
for some \( l > 0 \) and \( e \), and thus the reflection in \( g \) giving a contradiction. Since \( e \) \nexists Hirzebruch surface. Again, we can perform this reflection precisely when the corresponding class \( \lambda \) consists of integers greater than \( M \). It follows that \( e \) \nexists is negative forces \( \text{Hom}(\mathcal{O}_e(-1), \alpha_m^* \cdots \alpha_{i+2}^* M) \neq 0 \) or \( \text{Hom}(\theta^{-1} \alpha_m^* \cdots \alpha_{i+2}^* M, \mathcal{O}_e(-1)) \neq 0 \), neither of which can happen by irreducibility of \( \mathcal{O}_e(-1) \). (An easy induction shows that any irreducible constituent of the pullback of \( M \) has Chern class of the form \( e_j - \sum_{k \in S} e_k \) where \( j \geq i \) and \( |S| \) consists of integers greater than \( j \).) Similarly, if \( D \cdot e_1 \geq D \cdot f / 2 \), then we may perform an elementary transformation to subtract \( D \cdot e_1 \) from \( D \cdot f \).

Conjugation by an elementary transformation preserves the finite Weyl group \( W(D_m) \), and thus this process will eventually terminate in a basis such that \( e \cdot e_m \leq e \cdot e_{m-1} \cdots \leq e \cdot e_1 \leq (e \cdot f) / 2 \). If \( e \cdot e_m < 0 \), then irreducibility gives \( e = e_m \) and we are done, so we may assume \( e \cdot e_m \geq 0 \), and thus we have an expression

\[
e = ds + d' f - \lambda_1 e_1 - \cdots - \lambda_m e_m \tag{8.8}
\]

in which \( \lambda \) is an ordered partition with largest part at most \( d/2 \).

We now split into three cases, depending on the “genus” \( g := (g(C_0) + g(C_1)) / 2 \) appearing in the expression for \( K_X \). If \( g \geq 1 \), then we may write

\[
ds + d' f = -(d/2)K_{X_0} + ((2g - 2)d + n/2)f \tag{8.9}
\]

for some integer \( n \) (with parity depending on the parity of \( 2g \) and \( s^2 \)), in terms of which we have

\[
(ds + d' f)^2 = (2g - 2)d^2 + dn \quad \text{and} \quad (ds + d' f) \cdot K_{X_0} = -n. \tag{8.10}
\]

Since \( e \cdot K = -1 \), we find that \( \lambda \) is a partition of \( n - 1 \) into at most \( m \) parts all at most \( d/2 \) (and thus in particular \( n \geq 1 \)). It follows that

\[
\sum_{i} \lambda_i^2 \leq d(n - 1)/2, \tag{8.11}
\]

and thus

\[
e^2 = (2g - 2)d^2 + dn - \sum_{i} \lambda_i^2 \geq (2g - 2)d^2 + d(n + 1)/2 \geq 0, \tag{8.12}
\]

giving a contradiction.

If \( g = 1/2 \), then \( X_0 \) is strictly quasi-ruled, and not of the 4-isogeny type, so that \( Q = -K + lf \) for some \( l > 0 \). Since \( e \cdot (Q + K) = 0 \), we conclude that \( e \cdot f = 0 \), and thus \( d = 0 \), forcing \( \lambda = 0 \) and \( e^2 = 0 \).

In the \( g = 0 \) case (i.e., rational surfaces), we must consider an additional reflection, namely the reflection in \( s - f \) when \( X_0 \) is an even Hirzebruch surface or in \( s - e_1 \) when \( X_0 \) is an odd Hirzebruch surface. Again, we can perform this reflection precisely when the corresponding class
is not effective, and thus irreducibility of $O_e(-1)$ again ensures that we can perform the reflection whenever we would want to. Moreover, if we have already put $e$ into standard form relative to interchanges of blowups and elementary transformations, then the reflection in $s - f$ or $s - e_1$ will decrease $e \cdot f$, and since $e$ is effective (thus $e \cdot f \geq 0$), the resulting procedure (alternating between the two reductions) will necessarily terminate. (Note that it is no longer the case that there is a finite Coxeter group forcing termination!)

For convenience, we then perform an elementary transformation if needed to make $X_0$ an even Hirzebruch surface, so obtain an expression of the form

$$e = af + b(s + f) + c(s + f - e_1) + d(2s + 2f - e_1 - e_2) - \sum \lambda_i e_{i+2} \quad (8.13)$$

in which $a, b, c \geq 0$ and $\lambda$ is a partition with $\lambda_1 \leq d$. (Of course, if $m = 1$, we must have $\lambda = d = 0$ and find $e^2 \geq 0$) We have $|\lambda| = 2a + 4b + 3c + 6d - 1$ and thus

$$e^2 = 2ab + 2ac + 4ad + 2b^2 + 4bc + 8bd + c^2 + 6cd + 6d^2 - \sum \lambda_i^2$$

$$\geq 2ab + 2ac + 4ad + 2b^2 + 4bc + 8bd + c^2 + 6cd + 6d^2 - \lambda_1 |\lambda|$$

$$\geq 2ab + 2ac + 2ad + 2b^2 + 4bc + 4bd + c^2 + 3cd + d$$

$$\geq 0, \quad (8.14)$$

again giving a contradiction. \hfill \Box

**Remark.** It is worth noting that this only applies to the van den Bergh blowup; in the case of a maximal order, the underlying commutative surface $Z$ may very well have $-1$-curves that cannot be blown down via the above Proposition. The issue is that the local structure of the resulting order on the blown down surface at the base point may be “singular” in a suitable sense. One example of this comes from biquadratic extensions of $\mathbb{P}^1$. Any invertible sheaf on such an extension produces a quasi-ruled surface corresponding to a quaternion order on a Hirzebruch surface, and when the Euler characteristic of the invertible sheaf has the correct parity (depending on the various genera), the Hirzebruch surface is, at least generically, $F_1$. In characteristic 0, one can represent this as the Clifford algebra associated to a quadratic form, and find that the blown down algebra is the Clifford algebra associated to a quadratic form on a vector bundle on $\mathbb{P}^2$ such that the form vanishes identically at the base point of the blowup. In particular, the base change of the order to the complete local ring at that point is local but not of global dimension 2. Thus the blow down in this case more closely resembles the contraction of a $-2$-curve than the contraction of a $-1$-curve.

**Remark.** When $g > 0$ and thus the relevant group is finite, we may conclude that in the original basis for $\text{NS}(X)$, we have $e = e_i$ or $e = f - e_i$ for some $1 \leq i \leq m$. It is worth noting that these classes are always effective and satisfy all of the numerical conditions to be a formal $-1$-curve; the only condition they can violate is irreducibility, which happens iff $e_i - e_j$ or $f - e_i - e_j$ (respectively) is effective for some $j > i$.

If $X$ is a noncommutative rationally ruled surface, a “blowdown structure” on $X$ is an explicit isomorphism between $X$ and an iterated blowup of a quasi-ruled surface (which in the rational case should be expressed as a ruled surface; thus a noncommutative $\mathbb{P}^1 \times \mathbb{P}^1$ has two blowdown structures). The “parity” of a blowdown structure is the parity of the self-intersection of the resulting class $s$. The above discussion shows that a typical rationally quasi-ruled surface has many blowdown structures, but also gives us a fair amount of control. Specifying a blowdown structure is essentially equivalent to specifying a basis of $\text{NS}(X)$ in standard form, and thus any two blowdown
The atomic birational transformations all act in relatively simple ways on the basis; in particular, the commutation of blowups and the exchange of rulings on \( \mathbb{P}^1 \times \mathbb{P}^1 \) both act as reflections relative to the intersection pairing, with corresponding roots \( e_i - e_{i+1} \) and \( s - f \) respectively. Moreover, although an elementary transformation does not have such a description (since it changes the parity and thus the intersection matrix), the conjugate of the reflection in \( e_1 - e_2 \) by an elementary transformation is the reflection in \( f - e_1 - e_2 \). (Similarly, if \( X_0 \) is an odd Hirzebruch surface that blows down to \( \mathbb{P}^2 \), then reflection in \( s - e_1 \) acts as commutation on the two-point blowup of \( \mathbb{P}^2 \).)

In each case, the condition for the image under the reflection to still be a blowdown structure is precisely that the corresponding root is ineffective. With this in mind, we call the divisor classes \( f - e_1, e_1 - e_2, \ldots, e_{m-1} - e_m \) “simple roots”, along with \( s - f \) when \( X_0 \) is an even Hirzebruch surface and \( s - e_1 \) when \( X_0 \) is an odd Hirzebruch surface. Note that these are the simple roots of a Coxeter group of type \( D_m \) for \( g > 0 \) and \( E_{m+1} \) for \( g = 0 \). This, together with the reduction of Proposition 8.10, motivates the following definition.

**Proposition 8.11.** Let \( X \) be a noncommutative rationally quasi-ruled surface. Then any two blowdown structures on \( X \) with \( X_0 \) of the same parity are related by a sequence of reflections in ineffective simple roots.

**Proof.** Let \( s, f, e_1, \ldots, e_m \) and \( s', f', e'_1, \ldots, e'_m \) be the bases corresponding to the two blowdown structures. For \( m \geq 1 \), we have shown that there is a sequence of simple reflections and elementary transformations taking the second blowdown structure to one in which \( e'_m = e_m \). For \( m \geq 2 \), this is unchanged by an elementary transformation, and since the conjugate of a simple reflection by an elementary transformation is a simple reflection, we may arrange to eliminate all of the elementary transformations. We thus see that the second blowdown structure is related by a sequence of reflections in ineffective simple roots to one coming from a blowdown structure on \( X_{m-1} \) of the same parity, so that the claim follows by induction.

For \( m = 1 \), a formal \(-1\)-curve determines the parity of the blowdown structure, and the only case in which there is more than one of the correct parity is when \( X_0 \) is an odd Hirzebruch surface and both \( s \) and \( e_1 \) are formal \(-1\)-curves. But in that case \( s \) is a formal \(-1\)-curve iff \( s - e_1 \) is ineffective, and thus again they are related by a reflection. Similarly, for \( m = 0 \), the ruling is uniquely determined unless \( X_0 \) is an even Hirzebruch surface on which \( s - f \) is ineffective, in which case the corresponding reflection swaps the rulings.

**Proposition 8.12.** Let \( X \) be a noncommutative rationally quasi-ruled surface of genus \( g > 0 \). Then the functor \( R_\rho \circ R_\alpha_1 \circ \cdots \circ R_\alpha_m \) is independent of the choice of blowdown structure.

**Proof.** Reflection in \( e_i - e_{i+1} \) preserves the three factors

\[
R_\rho_0 R_\alpha_1 \cdots R_\alpha_{(i-1)} R_\alpha_i R_\alpha_{(i+1)} \cdots R_\alpha_m,
\]

so preserves the composition, while an elementary transformation preserves the two factors

\[
R_\rho_0 R_\alpha_{1*} R_\alpha_{2*} \cdots R_\alpha_{m*}.
\]

Since any two blowdown structures are related by a sequence of simple reflections and elementary transformations, the claim follows.

---

101
Remark. An alternate approach is to observe that $f$ is the unique effective class such that $f^2 = 0$, $f \cdot K = -2$, and that $C_0$ is the moduli space of irreducible 1-dimensional sheaves of Chern class $f$ and Euler characteristic 1, with the morphism to $C_0$ following as in [15].

9 Effective, nef, and ample divisors

Since the surfaces we are deforming are projective, not just proper, we would like to know that they have some analogue of ample divisors, and ideally be able to control the set of such divisors. It is unreasonable to hope that ample divisors will correspond to graded algebras (let alone quotients of noncommutative projective spaces), but we can still hope for some version of Serre vanishing and global generation. By Proposition 7.17, this is at least in principle easy when $X$ is a maximal order (though the lack of an anticanonical curve in the general quasi-ruled case makes it difficult to make everything explicit) as then we may identify the effective and nef cones of $X$ and its center, so that anything in the interior of the nef cone is ample.

We will thus restrict our attention to the ruled surface case. Note here that we are focused on noncommutative surfaces, and thus any commutative fiber will come with a choice of anticanonical curve. (It is also worth noting that our arguments do not actually work for the excluded case of a (characteristic 2) commutative ruled surface of genus 1 with integral anticanonical curve!)

In the commutative setting, the ample divisors on a surface are best understood as the integer interior points of the cone of nef divisors, for which we certainly have a well-behaved analogue in the noncommutative setting: a divisor class is nef iff it has nonnegative intersection with every effective divisor class.

Of course, to understand the nef cone, we will first need to fully understand the effective cone. To describe this cone, we will need one more set of effective classes.

Definition 9.1. A formal $-2$-curve is a $\theta$-invariant class of self-intersection $-2$ which is the Chern class of an irreducible sheaf.

Proposition 9.1. If $\alpha$ is a formal $-2$-curve, then there is a blowdown structure in which $\alpha$ is a simple root.

Proof. This is by the same argument as in Proposition 8.10 with only minor changes to the final inequalities. \qed

Theorem 9.2. Let $X$ be a rationally ruled surface with $m \geq 1$. Then the effective monoid of $X$ is generated by components of $Q$, formal $-1$-curves, and formal $-2$-curves.

Proof. Let $\mu$ denote the monoid so generated, which is clearly contained in the effective monoid. We will proceed in two steps: first showing that the effective monoid is generated by $\mu$ and its dual, then showing that $\mu$ contains its dual.

For the first claim, let $M$ be a pure 1-dimensional sheaf. If $c_1(M) \cdot Q < 0$ for some component $Q_i$ of $Q$, then $\chi(M_{|Q_i}) < 0$ and thus $h^{-1}(M_{|Q_i}) \neq 0$. Since this gives a subsheaf of $M(-Q_i)$, it must have positive rank, and thus there is a subsheaf of $M$ of Chern class $Q_i$. Similarly, if $D \cdot e < 0$ for some formal $-1$-curve $e$, then $\chi(O_e(-1), M) > 0$, so that either $\text{Hom}(O_e(-1), M) \neq 0$ or $\text{Hom}(M, \theta O_e(-1)) \neq 0$, giving either a subsheaf of class $e$ or a quotient sheaf of class $e$. Finally, if $\alpha$ is a formal $-2$-curve with $D \cdot \alpha < 0$, then $\chi(M_\alpha, M) > 0$ for any irreducible sheaf $M_\alpha$ of the appropriate Chern class, and thus again there is a sub- or quotient sheaf of Chern class $\alpha$.

We may thus obtain a descending sequence of subquotients of $M$ by repeatedly choosing sub- or quotient sheaves of Chern class a component of $Q$ or a formal $-1$- or $-2$-curve. The corresponding
pair of chains of subsheaves of $M$, one ascending, one descending, both terminate, and thus this process terminates. The only way it can terminate is with a subquotient of $M$ having nonnegative intersection with all generators of $\mu$, giving an expression for $c_1(M)$ as the sum of an element of $\mu$ and an element of the dual monoid as required.

To proceed further, we note first that any effective simple root (for any blowdown structure!) is either a formal $-2$-curve or a sum of components of $Q$ (with negative self-intersection) and formal $-1$-curves, so is in $\mu$. Moreover, if $e$ is in the $W(D_m)$ or $W(E_{m+1})$-orbit of $e_m$, then when applying the procedure of Proposition [8.10] to move $e$ back to $e_m$, each reflection in an effective simple root subtracts a positive multiple of that root, and thus $e$ is a sum of effective roots and a formal $-1$-curve, so again in $\mu$. In particular, both $e_1$ and $f - e_1$ are in $\mu$, so that $f$ is $\mu$. Furthermore, the pullback of a class in $\mu(X_{m-1})$ is in $\mu(X_m)$.

Thus if $D$ is in the dual of $\mu$ and $\alpha$ is a simple root such that $D \cdot \alpha < 0$, then $\alpha$ is ineffective and we may reflect in $\alpha$, and iterating this process will eventually terminate since there can be only a bounded number of steps in a row which do not decrease $D \cdot f$ and $D \cdot f$ cannot become negative. We may thus assume that $D$ is in the fundamental chamber.

If $g = 0$, we conclude that the dual of the monoid is contained in the simplicial monoid generated by (relative to an even blowdown structure)

$$f, s + f, s + f - e_1, 2s + 2f - e_1 - e_2, \ldots, 2s + 2f - e_1 - \cdots - e_m.$$  \hfill (9.1)

(This is just the dual of the monoid generated by simple roots and $e_m$.) For each $i \geq 2$, the class $2s + 2f - e_1 - \cdots - e_i$ is certainly a sum of components of $Q$ on $X_i$, and thus (being a pullback) is in $\mu$. We have already shown that $f$ is in $\mu$, and since $s - e_1$ is in the orbit of $f - e_1$, it is also in $\mu$, so that $(s - e_1) + (f - e_1) + (e_1)$ and $(s - e_1) + (f - e_1) + 2(e_1)$ are in $\mu$. It follows that any element of the dual monoid is in $\mu$ as required.

If $g > 0$, we note that $X_0$ (which we again take to be even) has at least one component of $Q$ of class $s - df$ for $d \geq 0$, which is again in $\mu$ (as a pullback). We thus conclude that $D \cdot (s - df) \geq 0$, telling us that $D$ is an element of the simplicial monoid with generators

$$f, s + df, s + df - e_1, 2s + df - e_1 - e_2, \ldots, 2s + df - e_1 - \cdots - e_m.$$  \hfill (9.2)

It is again easy to see that each of these classes is in $\mu$, using

$$Q = -K_X = 2s + (2 - 2g)f - e_1 - \cdots - e_m$$  \hfill (9.3)

for all but the first three generators and the expressions

$$f = (f - e_1) + (e_1)$$  \hfill (9.4)

$$s + df = (s - df) + d(f - e_1) + d(e_1)$$  \hfill (9.5)

$$s + df - e_1 = (s - df) + d(f - e_1) + (d - 1)(e_1).$$  \hfill (9.6)

If $d = 0$, this last case fails, but then $Q$ on $X_0$ has no vertical components, and thus the point being blown up must lie on one of the at most two components of class $s$, so that $s - e_1$ is in $\mu$. \hfill \Box

Remark. This fails if $m = 0$, but is easy enough to work around since a class on $X_0$ is effective iff its pullback is effective. We find that the effective monoid of $X_0$ is generated by $s'$ and $f$ where $s'$ is the effective class of minimal self-intersection such that $s' \cdot f = 1$, and the only case in which $s'$ is not a formal $-1$- or $-2$-curve or a component of $Q$ is when $X_0$ is noncommutative $\mathbb{P}^1 \times \mathbb{P}^1$ and $s' = s$. Similarly, the effective monoid of a noncommutative plane is the same as the nef monoid, and is generated by the class $h := c_1(\mathcal{O}_X(1))$. 

103
Remark. It is worth noting that effectiveness is a numerical condition; there will be some 1-dimensional sheaf with the given Chern class, but we cannot expect to have any particular control over the continuous part of its class in $K_0(X)$. Thus, for instance, if $g > 1$, then $f$ is effective, but not every line bundle of Chern class $f$ has a global section. (This can also be an issue for effective simple roots in general.)

**Corollary 9.3.** Any nef divisor class is effective.

**Proof.** In the course of the above proof, we showed that the dual of the effective monoid is contained in the effective monoid. □

It is important to note that some of these generators are redundant.

**Proposition 9.4.** For $m \geq 1$, the effective monoid is generated by formal $-1$- and $-2$-curves and those components $Q_i$ of $Q$ such that $Q_i \cdot Q \leq 0$, unless $g = 0$, $m = 7$, and $Q$ is integral.

**Proof.** We need to show that if $Q_i$ is a component of $Q$ such that $Q_i \cdot Q > 0$, then $Q_i$ is in the stated span. If $Q_i$ is a vertical component with positive intersection with $Q$, then it is either exceptional or the strict transform of a fiber, and thus is either $f$ or a $-1$-curve, and is redundant in either case.

If $g > 1$ or in the differential case for $g = 1$, any horizontal component has negative intersection with $Q$. In the remaining (elliptic difference) case with $g = 1$, there are two disjoint components, $s - df - \sum_{i \in I} e_i$ and $s + df - \sum_{i \in I} e_i$, and only the latter can have positive intersection with $Q$. We moreover must have $|I| < 2d$. The difference of the two components may then be written as

$$(2d - |I|)(f) + \sum_{i \in I} (f - e_i) + \sum_{i \not\in I} (e_i),$$

(9.7)
each term of which is a sum of formal $-1$- and $-2$-curves.

We are thus left with the rational case. When $Q$ is integral, we have $Q^2 = 8 - m$, and thus need only establish that $Q$ is redundant for $1 \leq m \leq 6$. For $m = 1$, this is easy: $2s + 2f - e_1 = 2(f - e_1) + 2(s - e_1) + e_1$, while for $2 \leq m \leq 6$, there is a commutative rational surface with anticanonical curve an $8 - m$-gon of $-1$-curves, again giving an expression of $-K_X$ as a sum of elements in the orbit of $e_m$.

When $Q$ is not integral, then its components are rational, and $Q_i \cdot Q > 0$ implies $Q_i^2 \geq -1$. If $Q_i^2 = -1$, then it is a formal $-1$-curve, so we may assume $Q_i^2 \geq 0$. As in the proof of Proposition 8.10, we may assume that $Q_i$ is in the fundamental chamber. We then find (by the analogous inequality) that $Q_i \cdot Q - 2 = Q_i^2 \geq Q_i \cdot Q$ unless $Q_i \cdot e_2 = 0$, so that we reduce to the case $m = 1$. The generators of the relevant monoid are contained in the monoid generated by $e_1$, $f - e_1$, $s - e_1$, so the claim follows. □

**Remark.** As in the commutative case, when $g = 0$, $m = 7$ and $Q$ is irreducible, the generator $Q$ is nearly redundant, since $2Q$ can be expressed as a sum of $-1$-curves on a suitable commutative surface.

Our understanding of the effective monoid also gives us the following stronger version of the finitely partitive property.

**Corollary 9.5.** For any divisor class $D$, there are only finitely many $D'$ such that both $D'$ and $D - D'$ are effective.
Proof. Since any formal \(-1\)- or \(-2\)-curve can be expressed as a nonnegative linear combination of simple roots and \(e_m\), we find that the effective monoid is contained in a finitely generated monoid (generated by components of \(Q\), simple roots, and \(e_m\)). Moreover, all of the generators are lexicographically positive (relative to the ordering \(s, f, e_1, \ldots, e_m\) of the standard basis), and thus any linear dependence between the generators has two coefficients of opposite sign. It follows that the dual cone has dimension \(m + 2\), and thus its interior contains integer elements. An element of the interior induces a grading on the larger monoid with respect to which it is finite and thus there are only finitely many elements of the monoid of degree strictly smaller than \(D\).

\[\square\]

Remark. It is worth noting that this result continues to hold even if we allow the surface to vary over a Noetherian base, and simply ask for \(D'\) and \(D - D'\) to be effective on some surface in the family. Indeed, there are still only finitely many possible divisor classes of components of \(Q\) (this reduces to a statement about families of commutative surfaces), giving a finitely generated monoid containing the effective monoid of any fiber and having dual of full dimension.

As for commutative rational surfaces, we can adapt the above arguments to give an essentially combinatorial algorithm for determining whether a class is effective (resp. nef). Indeed, if we start by reducing to the fundamental chamber, each step either just changes the blowdown structure (and possibly reduces \(D \cdot f\)) or exhibits a formal \(-2\)-curve or component of \(Q\) having negative intersection with \(D\), which we may subtract without changing whether \(D\) is effective. Thus after a finite number of steps, we will either have put \(D\) into the fundamental chamber or made \(D \cdot f\) negative (in which case it was not effective). If the result has nonnegative intersection with every component of \(Q\), then it is effective, and otherwise, we may subtract the offending component and rereduce to the fundamental chamber as necessary. Each such step subtracts a nontrivial effective divisor from \(D\), and thus again we can only do this finitely many times before eventually reaching a divisor having negative intersection with some element of the interior of the dual of the cone generated by simple roots, \(e_m\) and components of \(Q\).

To determine if \(D\) is nef, the algorithm is even simpler: any time we would have wanted to subtract an effective divisor class from \(D\), we simply terminate saying that \(D\) was not nef.

Having mostly settled the question of what the effective and nef divisor classes look like, we now turn to understanding ample divisors. Since our divisor classes are only numerical, the two things we would like an ample divisor \(D_a\) to satisfy are (a) that for any sheaf \(M\), there is an integer \(B\) such that for any line bundle \(L\) of Chern class \(-BD_a\) with \(b \geq B\), \(\text{Ext}^p(L, M) = 0\) for \(p > 0\), and (b) that there is a similar bound guaranteeing that \(L \otimes \text{Hom}(L, M) \to M\) is surjective. (If both hold, we say that \(M\) is acyclically globally generated by \(L\).) We will not entirely characterize the divisor classes satisfying these conditions (there are some technical issues coming from the fact that there can be 1-dimensional sheaves disjoint from \(Q\) without proper subsheaves), but will show that anything in the interior of the nef cone will do. (It is also easy to see that (a) and (b) fail for divisors which are not nef, so the only issues arise on the boundary.)

A key observation is that global generation for general sheaves follows if we can establish global generation for line bundles; there is also a more subtle reduction to line bundles for acyclic global generation (see below). Since the only thing we know about \(D_a\) is certain numerical inequalities, we are led to look for a statement along the following lines: if \(L\) and \(L'\) are line bundles such that \(c_1(L) - c_1(L')\) satisfies certain inequalities, then \(L\) is acyclically globally generated by \(L'\). The presence of an anticanonical curve turns out to be extremely helpful in this regard; the condition will essentially be that \(c_1(L) - c_1(L')\) is nef and that the ratio of their restrictions to \(Q\) is acyclic and globally generated. The latter condition is somewhat different depending on whether \(X\) is rational or has genus \(\geq 1\). Note that in either case \(Q\) may be embedded as an anticanonical curve.

105
Lemma 9.6. Let $Q$ be an anticanonical curve on a (commutative) rational surface and let $L$ be a line bundle having nonnegative degree on every component of $Q$. Then $L$ is acyclic if $\deg(L) \geq 1$ and globally generated if $\deg(L) \geq 2$.

Proof. When the ambient surface is $\mathbb{P}^2$ or $\mathbb{P}^1 \times \mathbb{P}^1$, this was shown in [6] §7. In fact, the only way in which the ambient surface was used in those proofs was in showing two numerical connectivity properties of $Q$: first, that if $Q = A + B$ with $A, B$ nonzero effective divisors on the ambient surface, then $A \cdot B > 0$, and second that if $Q = A + B + C$ with $A, B$ nonzero effective and $C$ a smooth irreducible component of $Q$, then $A \cdot B > 0$. The first was shown for any anticanonical curve on a rational surface in [11] Lem. 5.13, which further showed that $A \cdot B$ is even. Thus in the latter situation, we find that $A \cdot (B + C)$ and $B \cdot (A + C)$ are both positive even integers, and thus their sum

$$2(A \cdot B) + (A + B) \cdot C \geq 4.$$  \hspace{1cm} (9.8)

Since $C$ is a smooth rational curve, $(A + B) \cdot C = 2$, and thus $A \cdot B \geq 1$ as required. \hfill \square

Proposition 9.7. Let $X$ be a noncommutative rational surface, and let $L, L'$ be line bundles on $X$ such that $D = c_1(L) - c_1(L')$ is nef. If $D \cdot Q \geq 1$, then $\text{Ext}^p(L', L) = 0$ for $p > 0$, and if $D \cdot Q \geq 2$, then $\text{Hom}(L', L) \otimes L' \to L$ is surjective.

Proof. Since the nef cone is invariant under twisting $X$ by a line bundle, we may as well assume that $L' \cong O_X$, so that we need to show that for any nef divisor $D$ and line bundle $L$ of class $D, L$ is acyclic if $D \cdot Q \geq 1$ and globally generated if $D \cdot Q \geq 2$. If $m \geq 1$, choose a blowdown structure on $X$ such that $D$ is in the fundamental chamber. In particular, $D$ is in the monoid generated by

$$f, s + f, s + f - e_1, 2s + 2f - e_1 - e_2, \ldots, 2s + 2f - e_1 - \cdots - e_m.$$ \hspace{1cm} (9.9)

Acyclicity and global generation are inherited by pullbacks, so if $D$ is a pullback (i.e., if $D \cdot e_m = 0$) then we may reduce to $X_{m-1}$ and induct. This also applies when $m = 1$, except that now the reduction applies if either $D \cdot e_1$ or $D \cdot (f - e_1)$ is 0, and we may need to perform an elementary transformation before blowing down. Similarly, for the odd $m = 0$ case, if $D \cdot s = 0$, then $s$ must be a $-1$-curve and we can reduce to $m = -1$.

Thus suppose that $m \geq 1$ and $D \cdot e_m > 0$ (with $D \cdot (f - e_1) > 0$ if $m = 1$). To show that $L$ is acyclic (resp. and globally generated), it will suffice to show that $L(-Q)$ and $L_Q$ are acyclic (resp. and globally generated). The latter holds since $L_Q$ has nonnegative degree on every component (since $L$ is nef) and has total degree $D \cdot Q$. For the former, we need to show that $D - Q$ is nef and either vanishes or satisfies the same inequality. The result is certainly still in the fundamental chamber, so that for nefness we need only show that it has nonnegative intersection with the components of $Q$ having nonnegative intersection with $Q$. If $Q$ is reducible and $Q_i$ is such a component, then $(D - Q) \cdot Q_i = D \cdot Q_i - (Q \cdot Q_i) \geq D \cdot Q_i$ as required. It thus remains only to consider when $(D - Q) \cdot Q \geq 1$ (or 2, as appropriate). If $Q^2 = 8 - m \leq 0$, there is again no difficulty, while if $m < 7$, then any generator of the standard monoid has intersection $\geq 2$ with $Q$, and $O_X$ is certainly acyclic and globally generated.

The only case in which $D - Q$ fails to satisfy the requisite inequality is when $m = 7$ and $D = 2Q$. In that case, we still have acyclicity, and need only establish global generation. One global section of $O_X(2Q)$ is easy to understand: simply take the composition of the maps $O_X \to O_X(Q)$ and $O_X(Q) \to O_X(2Q)$ coming from the anticanonical natural transformation. The cokernel of this global section is an extension

$$0 \to O_X(Q) \to O_X(2Q)/O_X \to O_X(2Q)|_Q \to 0.$$ \hspace{1cm} (9.10)
Since $O_X$ is acyclic and globally generated, $O_X(2Q)$ is globally generated iff $O_X(2Q)/O_X$ is globally generated, and since this is an extension of sheaves on $Q$ with acyclic kernel, it is globally generated iff its restriction to $Q$ is globally generated. But $O_X(2Q)|_Q$ is globally generated by degree considerations.

It remains only to consider the base cases $m = 0$ and $m = -1$. Here, the relevant inequalities force $D = 0$ or $D \cdot Q \geq 2$, so we always want acyclic global generation. For $m = -1$, any effective line bundle is acyclically globally generated, essentially by construction. For $m = 0$, the effective monoid is generated by $f$ and either $s$ or the most negative horizontal component of $Q$, so if $D \cdot f \geq 2$, then $D - Q$ will again be nef and either be 0 or have sufficiently large degree on $Q$. For $D \cdot f = 1$, acyclicity and global generation reduce to the corresponding properties for $\mathcal{E}$, so again we may reduce to what happens on $Q$, while for $D \cdot f = 0$, so $D \propto f$, we find that $O_X(D)$ is the pullback of an acyclic and globally generated sheaf on $\mathbb{P}^1$.

The argument for higher genus surfaces is analogous, the main difference being in the specific numeric condition along $Q$.

**Lemma 9.8.** Let $Q$ be an anticanonical curve on a commutative rationally ruled surface of genus $g \geq 1$ (with $Q$ not integral), and let $L$ be a line bundle having nonnegative degree on every component of $Q$. Then $L$ is acyclic if it has degree at least $2g - 1$ on the horizontal component(s) of $Q$ and globally generated if it has degree at least $2g$ on the horizontal component(s).

**Proof.** Since 0-dimensional sheaves are acyclic and globally generated and both “acyclic” and “acyclic and globally generated” are closed under extensions, we may feel free to replace $L$ by any line bundle it contains that still satisfies the numerical conditions. In particular, we may as well assume that $L$ has degree 0 on every vertical component of $Q$. But then we may as well contract that component before checking the desired conditions, and we may achieve this effect by blowing down to a ruled surface and performing a suitable sequence of elementary transformations. We may thus reduce to the case that $Q$ has only horizontal components. If $Q$ is reduced, then $g = 1$, $Q$ is smooth, and $L$ is clearly acyclic (resp. globally generated) on each component. If $Q$ is nonreduced, then we have a short exact sequence

$$0 \to L' \to L \to L|_{Q\text{red}} \to 0$$

(9.11)

where $L'$ is a line bundle on $Q^\text{red} \cong C$. That $L|_{Q\text{red}}$ is acyclic (resp. acyclic and globally generated) follows by standard facts about line bundles on smooth curves, and $L'$ has degree at least that of $L|_{Q\text{red}}$, so is also acyclic.

**Remark.** Since a component of $Q$ is vertical iff $Q_i \cdot f = 0$ and horizontal iff $Q_i \cdot f = 1$, we may rephrase the numerical condition for $O_X(D)|_Q$ as saying that $D - (2g - 1)f$ (resp. $D - 2gf$) has nonnegative intersection with every component of $Q$. Since any formal $-1$- or $-2$-curve on a higher genus rationally ruled surface is orthogonal to $f$, we may in fact rewrite this as saying that $D - (2g - 1)f$ (resp. $D - 2gf$) is nef.

**Proposition 9.9.** Let $X$ be a noncommutative rationally ruled surface of genus $g \geq 1$, and let $L$, $L'$ be line bundles on $X$. If $c_1(L) - c_1(L') - (2g - 1)f$ is nef, then $\text{Ext}^p(L', L) = 0$ for $p > 0$, and if $c_1(L) - c_1(L') - 2gf$ is nef, then $L$ is acyclically globally generated by $L'$.

**Proof.** We may again assume that $L' = O_X$ and choose a blowdown structure such that $D = c_1(L) - (2g - 1)f$ (resp. $c_1(L) - 2gf$) is in the fundamental chamber with $D \cdot e_m \geq 1$ if $m \geq 1$ (and $D \cdot (f - e_1) \geq 1$ if $m = 1$). For $m \geq 1$, there is no difficulty since if $D$ is nef with $D \cdot e_m > 0$, then
$D - Q$ is again nef, and thus we readily reduce to $m = 0$. In that case, we again find that $D - Q$ remains nef as long as $D \cdot f \geq 2$, and thus reduce to the cases $D \cdot f = 1$ and $D \cdot f = 0$. The latter is immediate (since then $L$ is the pullback of an acyclic or acyclic and globally generated line bundle on $C$), while the former reduces to the corresponding claim for $E$ and thus for $Q$. \hfill \Box

**Theorem 9.10.** Let $X$ be a noncommutative rational or rationally ruled surface, and let $D_a$ be an integral element of the interior of the nef cone. Then for any sheaf $M$ on $X$, there is an integer $B$ such that for any line bundle $L$ of Chern class $-bD_a$ with $b \geq B$, $M$ is acyclically globally generated by $L$.

**Proof.** There is certainly some line bundle $L_0$ that acyclically globally generates $M$, and a line bundle $L_1$ that acyclically globally generates the kernel, etc., giving us a resolution

\[ \cdots \to L_1^{\alpha_1} \to L_0^{\alpha_0} \to M. \]  

(9.12)

For any other line bundle $L$, we may use this resolution to compute $R\text{Hom}(L, M)$, and find that the only possible contributions to $\text{Ext}^p(L, M)$ for $p \geq 0$ come from $\text{Ext}^2(L, L_1)$ and $\text{Ext}^3(L, L_0)$ for $p \in \{1, 2\}$. Thus if $c_1(L_1) - c_1(L)$ and $c_1(L_0) - c_1(L)$ are nef divisors satisfying the appropriate additional inequality, then $\text{Ext}^p(L, M) = 0$ for $p > 0$. Similarly, if $L_0$ is globally generated by $L$, then so is $M$. Since $D_a$ is in the interior of the nef cone, it has positive intersection with every effective class, and thus there is some $B$ such that for $b \geq B$, $bD_a + c_1(L_0)$ and $bD_a + c_1(L_1)$ are both nef and have intersection at least 2 with $Q$ or $2g$ with the horizontal components of $Q$ as appropriate. \hfill \Box

**Remark.** Since we have shown that the nef cone contains a subcone of full dimension, there are indeed ample divisors.

**Corollary 9.11.** If we choose for each $b \in \mathbb{Z}$ a line bundle of Chern class $bD_a$, then $X$ may be recovered as the Proj of the corresponding full subcategory of $X$, viewed as a $\mathbb{Z}$-algebra.

Now, suppose that $X/S$ is a family of noncommutative surfaces over some Noetherian base $S$. Let $Y/S$ be the corresponding family of commutative surfaces, and let $D$ be an ample divisor on that family. Since $D^2 > 0$, it follows that $(D, Q)^\perp$ is negative definite, and thus that it meets the root system $E_{m+1}$ or $D_m$ (as appropriate) in a finite subsystem. If we first base change so that $Y$ has a blowdown structure, then change the blowdown structure so that $D$ is in the fundamental chamber, then $(D, Q)^\perp$ meets the ambient root system in a finite parabolic subsystem, and it follows that the set of such blowdown structures is a torsor over the corresponding finite Coxeter group. (None of these roots can be effective on $Y$, since $D$ is ample.) It follows that there is a finite étale (and Galois) cover of $S$ over which $Y$ has a blowdown structure. Over this larger family, we may choose a new divisor $D'$ which is not only ample on every fiber but in the interior of the fundamental chamber. Although this divisor class itself will typically not descend to $X$, we note that since the $t$-structure is invariant under the action of monodromy, the monodromy preserves the ample cone. Thus the trace (in the obvious sense) of $D'$ will still be ample, and now descends to a class in $\text{NS}(X)$ over $S$. Moreover, any blowdown structure on $Y$ that puts $\text{Tr}(D')$ into the fundamental chamber will give rise to the same $t$-structure on $X$. The significance of this is that $\text{Tr}(D')$ makes sense even without first assuming that $\text{perf}(X)$ has a rational $t$-structure, and thus we may use it to define such a $t$-structure whenever it exists.

In fact, we may use such a divisor to construct a model of $X$ as the Proj of a sheaf of $\mathbb{Z}$-algebras on $S$. Let $D_a \in \text{NS}(X)$ be a divisor which is ample on every fiber. The main difficulty is that we need to choose a line bundle of each Chern class which is a multiple of $D_a$, and there may not be
any such line bundle over $S$. The main issues are that the corresponding $\text{Pic}^0_{C/S}$-torsor could fail to have points over $S$, and that a point over $S$ need not correspond to an actual line bundle. For the first issue, we note that the $\text{Pic}^0_{C/S}$-torsor lies in an appropriate component of $\text{Pic}_{Q/S}$, and is in the image of the natural map

$$\Gamma(S; \text{Pic}_{Q/S} / \text{Pic}^0_{C/S}) \rightarrow H^1(S; \text{Pic}^0_{C/S}). \quad (9.13)$$

The element in $\Gamma(S; \text{Pic}_{Q/S} / \text{Pic}^0_{C/S})$ can be computed as the image under the determinant-of-restriction map $K^0_{\text{num}}(X) \rightarrow \text{Pic}_{Q/S} / \text{Pic}^0_{C/S}$ of the numeric class of a line bundle of Chern class $bD_a$. Since the class of such a line bundle depends quadratically on $b$, we obtain a quadratic map $\mathbb{Z} \rightarrow \Gamma(S; \text{Pic}_{Q/S} / \text{Pic}^0_{C/S})$ and thus a quadratic map $\mathbb{Z} \rightarrow H^1(S; \text{Pic}^0_{C/S})$. Moreover, since each component of $\text{Pic}_{Q/S}$ is quasi-projective, so is each $\text{Pic}^0_{C/S}$-torsor, and thus the $\text{Pic}^0_{C/S}$-torsors are projective. This implies that the resulting classes in $H^1(S; \text{Pic}^0_{C/S})$ are torsion, and thus that we can make the map to $H^1(S; \text{Pic}^0_{C/S})$ trivial by replacing $D_a$ by a sufficiently divisible positive multiple. Moreover, we find that not only does the map $\mathbb{Z} \rightarrow \Gamma(S; \text{Pic}_{Q/S} / \text{Pic}^0_{C/S})$ map to the image of $\text{Pic}_{Q/S}(S)$, but we may choose a lifting of the map which is still quadratic. (Indeed, we may simply choose arbitrary preimages for the images of $\pm 1$, and take the image of 0 to be trivial.) The obstruction to being able to lift this map from $\text{Pic}_{Q/S}(S)$ to $\text{Pic}(Q)$ is a quadratic map $\mathbb{Z} \rightarrow H^2(S; \mathcal{O}_m)$, and again the image is torsion since $Q$ is projective. So multiplying $D_a$ by another sufficiently divisible positive integer makes the Brauer obstruction vanish and allows us to lift. We thus obtain a system of line bundles $L_b$, $b \in \mathbb{Z}$ satisfying $L_b \cong \mathcal{L}_1^{h(b+1)/2} \otimes \mathcal{L}_1^{h(b-1)/2}$ and such that for each $b \in \mathbb{Z}$, there is a line bundle $L_b$ on a suitable base change of $X$ which has Chern class $bD_a$ and satisfies $L_b|_Q \cong L_b$. Moreover, by including this isomorphism, we rigidify $L_b$ and guarantee that it descends to $S$. (Indeed, $L_b$ is unique up to automorphisms, and its automorphisms are scalars, so change the isomorphism to $L_b$.) The full subcategory of qcoh $X$ with objects $L_b$, $b \in \mathbb{Z}$ is a sheaf of $\mathbb{Z}$-algebras on $S$ and every fiber of $X$ agrees with the Proj of the corresponding fiber of this sheaf of $\mathbb{Z}$-algebras.

By mild (but very suggestive) abuse of notation, we will denote the line bundles $L_b$ so constructed by $\mathcal{O}_X(bD_a)$. The reader should be cautioned that these sheaves do not descend to the moduli stack of noncommutative surfaces, as their construction required some additional choices.

In the commutative case, one normally says that a line bundle is effective if it has a global section. This does not quite agree as stated with our definition above, but leads one to ask not only when a line bundle has global sections, but how many global sections it has. Although it is unclear how to answer this question for general ruled surfaces, we can give a complete answer in the rational case, and in fact (just as in the case of a smooth anticanonical curve [42]) can give an essentially combinatorial algorithm to compute the dimensions of Ext groups between any two line bundles.

Let $D_1, D_2 \in \text{Pic}^{\text{num}}(X)$ be a pair of divisor classes, and suppose that we wish to compute $\dim \text{Ext}^i(\mathcal{O}_X(D_1), \mathcal{O}_X(D_2))$ for $i \in \{0, 1, 2\}$. We know the alternating sum of these dimensions, and thus it suffices to compute $\dim \text{Hom}(\mathcal{O}_X(D_1), \mathcal{O}_X(D_2))$ and $\dim \text{Ext}^2(\mathcal{O}_X(D_1), \mathcal{O}_X(D_2)) = \dim \text{Hom}(\mathcal{O}_X(D_2), \mathcal{O}_X(D_1)).$ If $D_2 - D_1$ is not effective, then $\dim \text{Hom}(\mathcal{O}_X(D_1), \mathcal{O}_X(D_2)) = 0$ while if $K_X + D_1 - D_2$ is not effective, then $\dim \text{Ext}^2(\mathcal{O}_X(D_1), \mathcal{O}_X(D_2)) = 0$; since $K_X$ is ineffective, at least one of these must be the case. We thus reduce to the question of computing $\dim \text{Hom}(\mathcal{O}_X(D_1), \mathcal{O}_X(D_2))$ when $D_2 - D_1$ is effective. This in turn reduces to computing $\dim \Gamma(\mathcal{O}_X(D_2 - D_1))$ where $X'$ is a suitable twist of $X$, so that we may as well take $D_1 = 0$, $D_2 = D$. 

109
As in the algorithms above, a key step is to reduce to the case that $D$ is nef and in the fundamental chamber. If there is a component $Q_1$ of $Q$ such that $D \cdot Q_1 < 0$, then $\mathcal{O}_{Q_1}(D)$ has no global sections, and thus

$$\Gamma(\mathcal{O}_X(D - Q_1)) \cong \Gamma(\mathcal{O}_X(D)), \quad (9.14)$$

allowing us to replace $D$ by $D - Q_1$. We may then iterate this until $D$ has nonnegative inner product with every component of $Q$. (Since $D$ is assumed effective, this process terminates just as in the algorithm for testing whether $D$ is effective.)

The same argument lets us subtract $e_m$ from $D$ whenever $D \cdot e_m < 0$, and thus it remains to consider the case that $D$ has negative intersection with a simple root. If the simple root is ineffective, then we may apply the corresponding reflection, but this of course fails when the simple root is effective. Suppose that the simple root is $e_i - e_{i+1}$. We have already disposed of the possibility that $e_i - e_{i+1}$ is an anticanonical component on $X_{i+1}$, and thus the only way it can be effective is when the two points being blown up are smooth points of the anticanonical curve in the same orbit. We may then for simplicity twist by $e_{i+1}$ to ensure that the points are the same, at the cost of changing the required computation to $\dim \text{Hom}(\mathcal{O}_X(le_{i+1}), \mathcal{O}_X(D + le_{i+1}))$ for some $l$. If $q$ is non-torsion, then there is a unique such $l$, while if $q$ is torsion of order $r$, we choose $l$ so that $-r \leq (D + le_{i+1}) \cdot (e_i - e_{i+1}) < 0$.

If $(D + le_{i+1}) \cdot (e_i - e_{i+1}) \geq 0$, so that $q$ is non-torsion and $l = (le_{i+1}) \cdot (e_i - e_{i+1}) > 0$, then we may apply Proposition 4.27 to compute the opposite spherical twists and again conclude that

$$0 \to \mathcal{O}_X(le_{i+1}) \to \mathcal{O}_X(le_i) \to \mathcal{O}_{e_i-e_{i+1}}(-1)^l \to 0 \quad (9.15)$$

and

$$0 \to \mathcal{O}_X(D + le_{i+1}) \to \mathcal{O}_X(s_i(D) + le_i) \to \mathcal{O}_{e_i-e_{i+1}}(-1)^{(D+le_{i+1})\cdot(e_i-e_{i+1})} \to 0, \quad (9.16)$$

where $s_i(D)$ is the image of $D$ under the reflection. We may thus compute the spherical twists of $\mathcal{O}_X(le_{i+1})$ and $\mathcal{O}_X(D + le_{i+1})$, allowing us to conclude that

$$\text{Hom}(\mathcal{O}_X(le_{i+1}), \mathcal{O}_X(D + le_{i+1})) \cong \text{Hom}(\mathcal{O}_X(le_i), \mathcal{O}_X(s_i(D) + le_i)), \quad (9.17)$$

so that $\mathcal{O}_{X'}(D)$ and $\mathcal{O}_{s_i(X')}(s_i(D))$ have isomorphic spaces of global sections, where $X'$ is the appropriate twist of $X$. Similarly, if $l \leq 0$, then either $q$ is non-torsion or $-r < l \leq 0$, so that we may use Proposition 4.27 to compute the opposite spherical twists and again conclude that

$$\text{Hom}(\mathcal{O}_X(le_{i+1}), \mathcal{O}_X(D + le_{i+1})) \cong \text{Hom}(\mathcal{O}_X(le_i), \mathcal{O}_X(s_i(D) + le_i)). \quad (9.18)$$

The remaining case is that $l > 0$ but $(D + le_{i+1}) \cdot (e_i - e_{i+1}) < 0$. In that case, we still have a short exact sequence

$$0 \to \mathcal{O}_X(s_i(D) + le_i) \to \mathcal{O}_X(D + le_{i+1}) \to \mathcal{O}_{e_i-e_{i+1}}(-1)^{(D+le_{i+1})\cdot(e_i-e_{i+1})} \to 0, \quad (9.19)$$

but now have

$$\text{Hom}(\mathcal{O}_X(le_{i+1}), \mathcal{O}_{e_i-e_{i+1}}(-1)) = 0, \quad (9.20)$$

so that

$$\text{Hom}(\mathcal{O}_X(le_{i+1}), \mathcal{O}_X(s_i(D) + le_i)) \cong \text{Hom}(\mathcal{O}_X(le_{i+1}), \mathcal{O}_X(D + le_{i+1})). \quad (9.21)$$

Setting $D' = s_i(D) + le_i - le_{i+1}$, we find that $D - D'$ is a positive multiple of $e_i - e_{i+1}$, so that this reduces $-D \cdot (e_i - e_{i+1})$.  

110
We thus find that in each case such that $D \cdot (e_i - e_{i+1}) < 0$ with $e_i - e_{i+1}$ effective, we have an isomorphism $\Gamma(O_X(D)) \cong \Gamma(O_X(D'))$ where $D - D'$ is a positive multiple of $e_i - e_{i+1}$. Similar calculations also hold for the simple roots $f - e_1 - e_2$ (related to $e_1 - e_2$ by an elementary transformation) and $s - f$. Thus in general if $D$ has negative intersection with a simple root, we may reduce the problem to the corresponding calculation on a related surface with smaller (relative to the effective cone) $D$, sandwiched between the original $D$ and its image under the reflection. In particular, we can perform only finitely many such reductions before ending up in the fundamental chamber.

It remains to determine what happens when $D$ is nef and in the fundamental chamber; we may also assume that $D \cdot e_m > 0$ as otherwise we may reduce to the blown down surface. If $D = 0$ or $D \cdot Q > 0$, then $O_X(D)$ is acyclic, and thus we have $\dim \Gamma(O_X(D)) = \chi(O_X(D)) = 1 + (D \cdot (D + Q))/2$. It remains only to consider what happens when $D \neq 0$ with $D \cdot Q = 0$. We again have a short exact sequence

$$0 \to O_X(D - Q) \to O_X(D) \to O_X(D)|_Q \to 0. \quad (9.22)$$

If $O_X(D)|_Q$ is nontrivial (so has no global sections) or $O_X(D - Q)$ is acyclic, then this induces a short exact sequence

$$0 \to \Gamma(O_X(D - Q)) \to \Gamma(O_X(D)) \to \Gamma(O_X(D)|_Q) \to 0, \quad (9.23)$$

again allowing us to reduce the dimension calculation.

At this point, the only way $D$ can avoid all of our reductions is to have $m = 8$, $Q^2 = 0$ and $D \propto Q$, such that any rational component of $Q$ has self-intersection $-2$. We thus need to compute $\Gamma(O_X(lQ))$ for $l > 0$, where $Q$ is of this form and $O_Q(lQ) \cong O_Q$. If $l$ is minimal with this property, then $O_X((l - 1)Q)$ is acyclic, so that we may compute

$$\dim \Gamma(O_X(lQ)) = \chi(O_X((l - 1)Q)) + 1 = 2. \quad (9.24)$$

Since these global sections are generically nonzero on $Q$, but there is a 1-dimensional subspace vanishing on $Q$, they are algebraically independent, and thus we conclude that

$$\dim \Gamma(O_X(alQ)) \geq a + 1 \quad (9.25)$$

for any integer $a \geq 0$. The long exact sequence tells us that

$$\dim \Gamma(O_X((a + 1)lQ)) \leq 1 + \dim \Gamma(O_X(((a + 1)(l - 1)Q)) = 1 + \dim \Gamma(O_X(alQ)), \quad (9.26)$$

from which it follows that $\dim \Gamma(O_X(alQ)) = a + 1$, finishing off our calculation of dimensions of global sections.

Although the construction of $X$ via the $\mathbb{Z}$-algebra associated to an ample divisor is in principle explicit, it is still not the nicest model one might hope for. In the ideal situation, we could represent $X$ as the Proj of an actual graded algebra. This is too much to hope for in complete generality, as it requires us coh $X$ to have an ample autoequivalence, and this is not the case in general. There is one case in which can guarantee such an autoequivalence, namely when $X$ is Fano, i.e., when $Q$ is ample. More generally, as long as $Q$ is nef with $Q^2 \geq 1$, we can hope to obtain a graded algebra deforming the anticanonical coordinate ring of a degenerate del Pezzo surface. (Such rings may be of particular interest as models of noncommutative surfaces with rational singular points.)

This leads us to the question of what form the presentation of the anticanonical graded algebra $\bigoplus_i \Gamma(\theta^{-i}O_X)$ takes. A key observation is that there is a central element of degree 1 corresponding
to the anticanonical natural transformation, and the quotient by the corresponding principal ideal is the graded algebra
\[ \bigoplus_i \Gamma(\theta^{-i}O_X|Q), \tag{9.27} \]
which is essentially a twisted homogeneous coordinate ring of \( Q \), except that if \( Q \) has components of self-intersection \(-2\), its Proj will contract those components. Indeed, for any \( i \), \( \theta^{-i}O_X|Q \) has degree 0 on any such component, and thus we may as well work over the contracted curve. Moreover, we may think of the anticanonical ring itself as a filtered deformation of this twisted homogeneous coordinate ring (i.e., a filtered ring with that associated graded); in particular, apart from the additional generator of degree 1 and the relations that it be central, the structure of the presentation is the same.

The case of degree 1 del Pezzo surfaces is particularly nice, as in that case the contracted curve is just the Weierstrass model of \( Q \). In general, let \( L_i \) be the line bundle on \( Q \) given by \( \theta^{-i}O_X|Q \).

**Lemma 9.12.** If \( Q \) is nef with \( Q^2 = 1 \) and \( q \) is nontrivial, then the anticanonical ring is a filtered deformation of a ring generated by elements of degree 1 and 2, with relations of degree 4, 5, and 6.

**Proof.** This is really just a statement about the twisted homogeneous coordinate ring of a Weierstrass curve relative to a degree 1 line bundle and a translation \( q \). We first observe that there is an exact sequence
\[ 0 \to L_{-6} \to L_{-5} \oplus L_4 \to L_{-2} \oplus L_{-1} \to O_Q \to 0 \tag{9.28} \]
of sheaves on \( Q \), which may be obtained as the Yoneda product of
\[ 0 \to L_{-6} \to L_{-5} \oplus L_4 \to L_{-2} \oplus L_{-1} \to 0 \tag{9.29} \]
and
\[ 0 \to L_{-2} \otimes L_{-1} \to L_{-2} \oplus L_{-1} \to O_Q \to 0 \tag{9.30} \]
Here the maps \( L_{-1} \to O_Q \) and \( L_{-6} \to L_{-5} \) come from the degree 1 generator \( v_1 \) (which is unique modulo scalars) and similarly for the maps \( L_{-2} \to O_Q \) and \( L_{-6} \to L_{-4} \), and the identification of \( L_{-2} \otimes L_{-1} \) is via determinant considerations. It follows in particular that the algebra is generated by the elements of degree 1 and 2 coming from this exact sequence.

The correspondence between sheaves and graded modules over the twisted homogeneous coordinate ring is by applying \( \theta^{-i} \) and taking global sections. The only degrees in which the corresponding sequence of graded modules is not exact are those for which some terms have nontrivial \( H^1 \) (and some terms have global sections), and thus only \( 0 \leq i \leq 6 \) need be considered. For \( 0 < i \), surjectivity at \( O_Q \) is straightforward (given \( q \) nontrivial), and implies exactness for \( i \in \{1, 2, 3\} \). We dually have exactness for \( i \in \{3, 4, 5\} \), so that only \( i = 0 \) and \( i = 6 \) remain. For \( i = 0 \), we clearly have cohomology \( 0, 0, 0, k \), while for \( i = 6 \) the fact that the spectral sequence converges to 0 lets us read off the cohomology of global sections from the cohomology of \( H^1 \), and thus we obtain \( 0, 0, k, 0 \). But this implies that the relations are generated by the relations of degree 4 and 5 coming from the complex, except that there is one missing relation of degree 6.

**Remark.** In the commutative case, we need an additional generator and relation of degree 3, and the only relation which is not a commutator is the relation of degree 6.

For degree 2 del Pezzo surfaces, the situation is slightly more complicated since the contracted curve may be reducible. It is always a double cover of \( \mathbb{P}^1 \), however, and this makes things tractable.

**Lemma 9.13.** If \( Q \) is nef with \( Q^2 = 1 \) and \( q \) nontrivial, then the anticanonical ring is a filtered deformation of a ring generated by two elements of degree 1 with relations of degree 3, 3, and 4.
Proof. Analogous, except that now the relevant exact sequence has the form

$$0 \to L_{-4} \to L_{-3}^2 \to L_{-1}^2 \to \mathcal{O}_Q \to 0,$$

(9.31)

again obtained as a Yoneda product. □

Remark. Again, we need an additional generator and relation of degree 2 in the commutative case, with the only nontrivial relation that of degree 4.

For $Q^2 \geq 3$, the algebra is generated in degree 1; this follows from the general fact that if $\mathcal{L}_1$, $\mathcal{L}_2$ are invertible sheaves on $Q$ with nonnegative degree on every component and total degree at least 3, then $\Gamma(\mathcal{L}_1) \otimes \Gamma(\mathcal{L}_2) \to \Gamma(\mathcal{L}_1 \otimes \mathcal{L}_2)$ is surjective. (The proof of [42, Lem. 2.3] extends easily from the smooth case.)

Lemma 9.14. If $Q$ is nef with $Q^2 = 3$ and $q$ nontrivial, then the anticanonical ring is a filtered deformation of a ring generated by three elements of degree 1 with three quadratic relations and one cubic relation.

Proof. Similar but now with

$$0 \to L_{-3} \to L_{-2}^3 \to L_{-1}^3 \to \mathcal{O}_Q \to 0,$$

(9.32)

which can be obtained by observing that $Q$ embeds in a noncommutative $\mathbb{P}^2$ in a way that respects the automorphism. □

Something similar should hold in higher degrees, and one expects the algebra to be quadratic for $Q^2 \geq 4$.

In special cases, one expects additional graded algebras; indeed, if $Q$ is reducible, then we get a graded algebra corresponding to a singular form of the surface from any linear combination of components of $Q$ which is nef and has positive self-intersection. There are also cases where the autoequivalence is less canonical; e.g., for a noncommutative $\mathbb{P}^2$, twisting by $\mathcal{O}_X(1)$ is not an autoequivalence in general, but does act trivially on the open substack of the moduli stack where the anticanonical curve is integral and not an additive curve of characteristic 3. The corresponding scheme of isomorphisms is the $\text{Pic}^0(Q)[3]$-torsor corresponding to $q \in \text{Pic}^0(Q)/\text{Pic}^0(Q)^3$, giving a $\text{Pic}^0(Q)[3]$-torsor of graded algebra representations. (This, of course, gives rise to the classical construction of noncommutative planes via graded algebras [6].) In general, for rational surfaces, a divisor class gives rise to an autoequivalence of $X$ whenever there is an isomorphism of the corresponding commutative surfaces that identify the two embeddings of $q$ as sheaves on the respective anticanonical curves as well as the images of the nef cone of $X$. (The first condition gives a derived autoequivalence, and the second ensures that it preserves the $t$-structure. The latter can be weakened to simply asking that the chosen divisor lie in the intersection of the images of the nef cone of $X$ under the action of the group generated by the autoequivalence on $\text{Pic}(X)$.)

10 Quot and Hilbert schemes

There remains one of Chan and Nyman’s axioms we have yet to show: the “halal Hilbert scheme” condition, which states that for any coherent sheaf $M$, the functor $\text{Quot}(M)$ is representable by a separated scheme, locally of finite type, which is a countable union of projective schemes. Since $\text{Quot}(M)$ classifies families of sheaves, this suggests that we should ask for this condition to hold when $M$ itself is a family of sheaves, or better yet a sheaf on a family of surfaces. Furthermore,
the commutative and maximal order cases strongly suggest that there should be a better version of the Quot scheme condition: if $M$ is a $S$-flat family of sheaves on $X/S$ (with $S$ Noetherian), then the subfunctor of Quot classifying quotients of Hilbert polynomial $P$ (relative to some fixed ample divisor class) should be (and, as we will show, is) projective.

In order to carry out the usual commutative construction of the Quot functor, we need some boundedness results, as well as an analogue of the flattening stratification. A key issue is that we need to be able to force not just the original family, but various base changes, to be acyclically generated by line bundles $O_{X}(-bD_a)$ for uniformly bounded $b$. In particular, our previous results give this over a field, but we both need to control how the bound varies with the fiber and need to deal with the fact that acyclicity and global generation are not a priori inherited from fibers when the sheaf is not flat over the base.

Luckily, this last fact turns out not to be an issue. We will need to start by showing this for curves.

**Lemma 10.1.** Let $C/S$ be a smooth proper curve over a Noetherian base $S$. Then a sheaf $E \in \text{coh}(C)$ is acyclic iff every fiber is acyclic.

**Proof.** For any point $s$, the complex $R\Gamma(E) \otimes^L k(s) \cong R\Gamma(E \otimes^L k(s))$ has vanishing cohomology in all degrees $> 1$, and thus $H^1(E) \otimes k(s) \cong H^1(E \otimes k(s))$. $\square$

For global generation, a globally generated sheaf has globally generated fibers, but the converse need not hold. Luckily, if we also ask for acyclicity, this problem goes away. The key idea is the following. In the proofs of the next several results, we abbreviate “acyclic and globally generated” by “a.g.g.”.

**Lemma 10.2.** Let $C/S$ be a smooth proper curve over a Noetherian base $S$, and let $\Delta \subset C \times_S C$ be the diagonal, with projections $\pi_1$, $\pi_2$. Then a sheaf $M \in \text{coh}(C)$ is acyclic and globally generated iff $\pi_2^* M(-\Delta)$ is $\pi_1^*$-acyclic.

**Proof.** We first note that $M$ is globally generated iff

$$\pi_1^* \pi_2^* M \to \pi_1^* (\pi_2^* M|_\Delta)$$

(10.1)

is surjective, as this is nothing other than the map $\Gamma(M) \otimes_S O_C \to M$. Let $N$ be the kernel of the (surjective) natural map $\pi_2^* M \to \pi_2^* M|_\Delta$. Then we have an exact sequence

$$0 \to \pi_1^* N \to \pi_1^* \pi_2^* M \to \pi_1^* (\pi_2^* M|_\Delta) \to R^1 \pi_1^* N \to R^1 \pi_1^* \pi_2^* M \to 0,$$

(10.2)

from which it follows immediately that $M$ is a.g.g. iff $R^1 \pi_1^* N = 0$. We then note the short exact sequence

$$0 \to \text{Tor}_1(\pi_2^* M, O_\Delta) \to \pi_2^* M(-\Delta) \to N \to 0.$$ 

(10.3)

Since the kernel is supported on $\Delta$, it is $\pi_1^*$-acyclic, and thus $N$ is $\pi_1^*$-acyclic iff $\pi_2^* M(-\Delta)$ is $\pi_1^*$-acyclic. $\square$

**Corollary 10.3.** The set of points $s \in S$ such that $M_s$ is acyclic and globally generated is open in $S$.

**Proof.** Indeed, it is the complement of the image of the support of $R^1 \pi_1^* \pi_2^* M(-\Delta)$. $\square$

**Corollary 10.4.** $M$ is acyclic and globally generated iff every fiber of $M$ is acyclic and globally generated, and then every Noetherian base change of $M$ is acyclic and globally generated.
Proof. We may interpret $R^1\pi_1^*\pi_2^*M(-\Delta)$ as the relative $H^1$ of a sheaf on the base change of $C$ to $C$. Thus $R^1\pi_1^*\pi_2^*M(-\Delta) = 0$ iff for every point $x \in C$, $H^1(M(-x)) = 0$. This is equivalent to asking that $H^1(M_s(-x)) = 0$ for every point $s \in S$ and $x \in C_s$, which is in turn equivalent to asking that every fiber be a.g.g. Acyclic global generation on fibers is clearly inherited by base changes, so the remaining claim follows.

Proof. Acyclic generation descends along étale morphisms, so we may assume $X$ split. We can then use twist functors to reduce to the case $L = O_X$. If $m > 0$, then $M$ is a.g.g. iff it is a.g.g. relative to $\alpha_m$ and $\alpha_m^*M$ is a.g.g. But the argument of Proposition 1.22 carries over to an arbitrary family and shows that $M$ is a.g.g. relative to $\alpha_m$ iff $\text{Ext}^2(O_{\alpha_m}, M) = 0$. The same argument as in the curve case (since this is the highest possible degree of a nonvanishing cohomology sheaf) shows that this is equivalent to the same condition on fibers, and thus the result holds by induction.

If $X$ is a ruled surface, we similarly find that $M$ is a.g.g. iff it is a.g.g. relative to $\rho_0$ and $\rho_0^*M$ is a.g.g. We can again use the semiorthogonal decomposition to find that $M$ is a.g.g. relative to $\rho_0$ iff $R^1\rho_{-1,*}M = 0$. Since $\rho_{-1,*}$ has cohomological dimension 1, we once more find that this is equivalent to the condition on fibers, and thus the result reduces to the curve case.

It remains to consider the case that $X$ is a noncommutative plane. Take the (fppf) base change of $X$ to $Q$, and let $X$ be the blowup of this family in the tautological section of $Q$. The sheaf $\alpha^*M$ is a.g.g. iff $\alpha_\ast\alpha^*M$ is a.g.g. and $R^1\alpha_\ast\alpha^*M = 0$. The spectral sequence associated to $R\alpha_\ast L\alpha^*M \cong M$ tells us that $R^1\alpha_\ast\alpha^*M$ always vanishes, and that there is a short exact sequence

$0 \to R^1\alpha_\ast L_1\alpha^*M \to M \to \alpha_\ast\alpha^*M \to 0.$

The kernel is an extension of sheaves on $Q$ with support finite over $S$, and thus is a.g.g.; it follows that $M$ is a.g.g. iff $\alpha_\ast\alpha^*M$ is a.g.g.

Thus $M$ is a.g.g. iff $\alpha^*M$ is a.g.g. iff $(\alpha^*M)_q$ is a.g.g. for all $q \in Q$ iff $(\alpha^*M)_s$ is a.g.g. for all $s \in S$. Since $\alpha^*$ is right exact, $(\alpha^*M)_s \cong (\alpha^*M_s)$ and thus this is a.g.g. iff $M_s$ is a.g.g.  

Here and below, we assume that $D_a$ is not only ample, but $D_a \cdot Q \geq 2$ or $D - 2gf$ is nef as appropriate. (This can always be arranged by replacing $D_a$ by a sufficiently large multiple of $D_a$, without changing the validity of the final result. E.g., in the following result, we need simply combine the bounds for finitely many twists of $M$ by multiples of the original ample divisor.)

Corollary 10.6. Let $X/S$ be a family of noncommutative surfaces over a Noetherian base. Then for any $M \in \text{coh}(X)$, there is an integer $b_0$ such that for $b \geq b_0$, every Noetherian base change of $M$ is acyclically generated by $O_X(-bD_a)$.

Proof. It suffices to find a bound that works for $M$ itself. For each $b$, let $M_b$ be the image of the natural map

$O_X(-bD_a) \otimes_{O_S} \text{Hom}(O_X(-bD_a), M) \to M.$

Since $O_X(-bD_a)$ is acyclically generated by $O_X(-(b+1)D_a)$, this gives an ascending chain of subsheaves of $M$, which therefore terminates and gives a surjection

$O_X(-b_1D_a) \otimes_{O_S} N_1 \to M.$
for some $N_1 \in \text{coh}(S)$. The kernel is again a coherent sheaf, so we can extend this to a resolution

$$
\mathcal{O}_X(-b_0D_a) \otimes_{\mathcal{O}_S} N_0 \to \mathcal{O}_X(-b_1D_a) \otimes_{\mathcal{O}_S} N_1 \to M \to 0
$$

(10.7)

with $b_0 \geq b_1$. Thus $M$ is generated by $\mathcal{O}_X(-bD_a)$ as long as $b \geq b_1$, and is acyclic for $\mathcal{O}_X(-bD_a)$ as long as $b \geq b_0$. But then the same statement holds on an arbitrary Noetherian base change. □

**Remark.** One consequence is that the support of $M$ over $S$ is closed (and can be given a natural closed subscheme structure), as it may be identified with the support of the coherent $\mathcal{O}_S$-module $\text{Hom}(\mathcal{O}_X(-bD_a), M)$. This, together with the fact that the cohomology sheaves of perfect complexes are coherent (since $X/S$ is Noetherian), implies that a perfect complex being a sheaf is an open condition (the complement of the unions of the supports of the other cohomology sheaves, only finitely many of which can be nonzero).

In particular, this lets us prove the following criterion for flatness.

**Lemma 10.7.** Let $X/S$ be a family of noncommutative surfaces over a Noetherian base. A coherent sheaf $M \in \text{coh}(X)$ is $S$-flat iff for all $b \gg 0$, $R\text{Hom}(\mathcal{O}_X(-bD_a), M)$ is an $S$-flat sheaf.

**Proof.** Let $b_0$ be such that $M$ is acyclically generated by $\mathcal{O}_X(-bD_a)$ for all $b \geq b_0$. Then the complex $R\text{Hom}(\mathcal{O}_X(-bD_a), M)$ is certainly a sheaf, and is clearly flat whenever $M$ is flat. Thus suppose that $R\text{Hom}(\mathcal{O}_X(-bD_a), M)$ is a flat sheaf on $S$ for all $b \geq b_0$. For any closed point $s \in S$, we can find $b' \geq b_0$ such that both $\text{Tor}_1(M, k(s))$ and $\text{Tor}_2(M, k(s))$ are acyclically generated by $\mathcal{O}_X(-b'D_a)$. But then we find that

$$
0 = \dim(h^{-1}R\text{Hom}(\mathcal{O}_X(-b'D_a), M) \otimes^L k(s))
$$

$$
= \dim(h^{-1}R\text{Hom}(\mathcal{O}_X(-b'D_a), M \otimes^L k(s)))
$$

$$
\geq \dim\text{Hom}(\mathcal{O}_X(-b'D_a, \text{Tor}_1(M, k(s))))
$$

(10.8)

so that $\text{Tor}_1(M, k(s)) = 0$. □

We define the Hilbert polynomial of a coherent sheaf over a field in the obvious way, namely as the polynomial $P_M(b) = \chi(\mathcal{O}_X(-bD_a), M)$. This is clearly locally constant in flat families (since it respects field extensions and on a geometric fiber depends only on the class of $M$ in $K^\text{num}_0(X)$). The usual argument then gives the following.

**Corollary 10.8.** If $S$ is integral and Noetherian, then a coherent sheaf $M \in \text{coh} X$ is $S$-flat iff all of its fibers have the same Hilbert polynomial.

**Proof.** For $b \gg 0$, so that every fiber of $M$ is acyclically generated by $\mathcal{O}_X(-bD_a)$, we have $\dim\text{Hom}(\mathcal{O}_X(-bD_a), M_s) = \chi(\mathcal{O}_X(-bD_a), M_s)$, and thus by semicontinuity, $\text{Hom}(\mathcal{O}_X(-bD_a), M)$ is flat.

This lets us construct a weak form of flattening stratification. For any sheaf $M \in \text{coh}(X)$, suppose that $M$ is acyclically generated by $\mathcal{O}_X(-bD_a)$ for all $b \geq b_0$. Then for each such $b$, the sheaf $\text{Hom}(\mathcal{O}_X(-bD_a), M)$ has a universal flattening stratification, and taking the fiber product over $b \geq b_0$ gives a covering of $S$ by a countable union of localizations of closed subschemes. (This fiber product exists and is affine since each factor is affine.) This satisfies the universal property that any $f : T \to S$ such that $f^*M$ is $S$-flat (a "flattening morphism for $M$") factors through this fiber product. Say that $M$ has "finite flattening stratification" if the fiber product is a finite union of locally closed subschemes.
Lemma 10.9. Let $X/S$ be a family of noncommutative surfaces over a Noetherian base $S$, and $M \in \text{coh}(X)$. Suppose that for any integral closed subscheme $S' \subset S$, there is an open neighborhood of $k(S')$ in $S'$ on which $M$ is flat. Then $M$ has finite flattening stratification.

Proof. Let $s$ be the generic point of some component of $S$. Then by hypothesis, there is an open neighborhood of $k(s)$ in its reduced closure on which $M$ is flat, and thus in particular the Hilbert polynomial of $M$ is constant. It follows by Noetherian induction that $S$ is the disjoint union of finitely many locally closed subsets on which the Hilbert polynomial of $M$ is constant. The corresponding disjoint union of reduced subschemes is a flattening morphism, so factors through the universal flattening morphism. Each set in the partition maps to at most one component of the flattening morphism, which therefore has only finitely many components, each of which must therefore be locally closed.

This is somewhat difficult to prove in general, but a large family of special cases where generic flatness holds was given in [8] (a categorical version of the main result of [4]), implying the following.

Corollary 10.10. [8, Thm. C5.1] If $S$ is of finite type, then any sheaf on $X$ has finite flattening stratification.

Remark. In fact, it follows from the reference that this holds whenever $S$ is “admissible”, as defined in [4], but the finite type case turns out to be enough to let us bootstrap to a general Noetherian base, see Corollary 10.25 below.

We now turn to the Quot scheme. Given a family $X/S$ of noncommutative surfaces over a Noetherian base and a sheaf $M \in \text{coh}(X)$, we define a functor $\text{Quot}_{X/S}(M, P)$ on the category of schemes over $S$ by taking $\text{Quot}_{X/S}(M, P)(T)$ to be the set of isomorphism classes of short exact sequences

$$0 \to I \to M_T \to N \to 0 \quad (10.9)$$

such that $N$ is a $T$-flat coherent sheaf all fibers of which have Hilbert polynomial $P$. (Recall that a “$T$-flat coherent sheaf” is a $T$-flat element of $\text{perf}(X_T) \cap \text{qcoh}(X_T)$, so makes sense even when $T$ is not Noetherian, and the usual argument tells us that $\text{Quot}$ respects base change.) This is of course a contravariant functor of $T$, and also satisfies a partial functoriality in $M$. Indeed, given any surjection $M' \to M$, we obtain a morphism $\text{Quot}_{X/S}(M, P) \to \text{Quot}_{X/S}(M', P)$ by pullback of short exact sequences (in particular keeping the same quotient sheaf). This is a closed embedding, and thus to show that $\text{Quot}_{X/S}(M, P)$ is projective, it suffices to show this for some sheaf surjecting on $M$. We may thus reduce to considering $\text{Quot}(O_X(-bD_a) \otimes_S M, P)$ for $M \in \text{coh}(S)$, and then by twisting to the case $b = 0$. (Note that although we have only defined twisting functors for split families, the twist functor descends as long as $L$ is defined over $S$.)

In order to carry out the standard commutative argument, we need to show that we can make a global choice of $b$ such that for any $T$ and any short exact sequence in $\text{Quot}_{X/S}(O_X \otimes_S M, P)(T)$, $O_X(-bD_a)$ acyclically generates $I$. Since this reduces to a question about fibers (modulo some technical issues coming from the fact that $T$ is not Noetherian), a bound that works when $T$ is a geometric point of $S$ will work in general. In particular, if we can give a bound that works for a surface over an algebraically closed field and depends only on the combinatorics of the surface, this will produce a bound for $S$.

Thus let $X$ be a surface over an algebraically closed field $k$, and consider a quotient of $O_X \otimes V$. A complete flag in $V$ induces a filtration of $O_X \otimes V$, and thus a filtration of the short exact sequence. This suggests that we should be able to reduce this problem to the case $V = k$. 

117
Thus suppose consider a short exact sequence
\[ 0 \to I \to \mathcal{O}_X \to M \to 0 \]  
(10.10)
over a geometric point of \( S \). Since \( \mathcal{O}_X \) is torsion-free of rank 1, \( I \) either vanishes or is itself torsion-free of rank 1.

**Lemma 10.11.** Any nonzero homomorphism between torsion-free sheaves of rank 1 is injective.

**Proof.** The image is a nonzero subsheaf of a torsion-free sheaf, so must have positive rank, and thus the kernel is a rank 0 subsheaf of a torsion-free sheaf, so is 0. \( \square \)

**Corollary 10.12.** If \( I, I' \) are torsion-free sheaves of rank 1, then \( \text{Hom}(I, I') = 0 \) unless \( c_1(I') - c_1(I) \) is effective.

We will want to understand the moduli space of such sheaves below, so one natural question is the dimension of that space.

**Proposition 10.13.** Suppose that \( I \) is a torsion-free sheaf of rank 1 on a noncommutative rational surface. Then
\[ \chi(I, I) \leq 1, \]  
(10.11)
with equality iff \( I \) is a line bundle.

**Proof.** Since \( \chi(I, I) \) is invariant under twisting, we may as well assume that \( c_1(I) = 0 \). Since \( c_1(\theta I) - c_1(I) = K \) is ineffective, we find that \( \text{Ext}^2(I, I) = \text{Hom}(I, \theta I) = 0 \), and since any endomorphism of \( I \) is injective, we must have \( \dim \text{Hom}(I, I) = 1 \). The inequality follows immediately. If equality holds, then Riemann-Roch gives \( \chi(I) = 1 \), and thus \( I \) is numerically equivalent to \( \mathcal{O}_X \) and \( \text{Hom}(\mathcal{O}_X, I) \neq 0 \), forcing \( I \sim \mathcal{O}_X \). \( \square \)

In particular, the line bundles on a noncommutative rational surface are precisely the torsion-free sheaves of rank 1 with \( \chi(I, I) = 1 \), and thus the notion is independent of the blowdown structure. As this is of independent interest, we include quasi-ruled surfaces in the next result.

**Proposition 10.14.** Suppose that \( I \) is a torsion-free sheaf of rank 1 on a noncommutative rationally quasi-ruled surface over curves of genus \( g_0 \) and \( g_1 \). Then
\[ \chi(I, I) \leq 1 - g c_1(t) \cdot f, \]  
(10.12)
with equality iff \( I \) is a line bundle.

**Proof.** Again, we may as well assume that \( c_1(I) = 0 \), and may use Riemann-Roch to restate the inequality as \( \chi(I) \leq 1 - g_0 \). Let \( \rho \) denote the composition \( \rho_0 \circ \alpha_1 \circ \cdots \circ \alpha_m \), and note that \( \rho_* \) has cohomological dimension 1. A homomorphism from \( I \) to a line bundle must be injective, and thus if \( \text{Hom}(I, L) \neq 0 \), then \( c_1(L) \) is effective. It follows that for any line bundle \( \mathcal{L} \) on \( C_0 \), we have
\[ \text{Ext}^2(\rho^* \mathcal{L}, I) \cong \text{Hom}(I, \theta \rho^* \mathcal{L})^* = 0, \]  
(10.13)
since \( (K + df) \cdot f = -2 < 0 \) for any \( d \). It follows that
\[ \text{Ext}^2(\mathcal{L}, R\rho_* I) = 0 \]  
(10.14)
for any \( \mathcal{L} \) and thus that \( \text{rank}(R^1 \rho_* I) = 0 \). We then compute \( \text{rank}(\rho_* I) = \text{rank}(I) = 1 \) and
\[ \chi(I) = \chi(\rho_* I) - \chi(R^1 \rho_* I) \leq \chi(\rho_* I). \]  
(10.15)
In particular, if \( \chi(I) \geq 1 - g_0 \), then \( \chi(\rho_*I) \geq 1 - g_0 \), and thus there is a degree 0 line bundle \( \mathcal{L} \) on \( C_0 \) such that \( \text{Hom}(\mathcal{L}, \rho_*I) \neq 0 \), making \( \text{Hom}(\rho^*\mathcal{L}, I) \neq 0 \). Since \( \rho^*\mathcal{L} \) is again torsion-free of rank 1, we again find that such a morphism must be injective. Since the quotient has trivial Chern class, it must be 0-dimensional, and since \( \text{Ext}^1 \) from a 0-dimensional sheaf to a line bundle always vanishes, the corresponding short exact sequence splits. Since \( I \) is torsion-free, the quotient must be 0 and thus \( I = \rho^*\mathcal{L} \).

**Remark.** In the rational or rationally ruled case, we may use Riemann-Roch to restate the bound as

\[
\chi(I) \leq 1 - g + c_1(I) \cdot (c_1(I) - K_X)/2,
\]

again with equality iff \( I \) is a line bundle. An analogous formula of course exists in the quasi-ruled case, but is significantly messier.

**Corollary 10.15.** Let \( X \) be a noncommutative rational or rationally quasi-ruled surface and suppose that \( L \) is a line bundle with respect to some blowdown structure on \( X \). Then \( L \) is a line bundle with respect to every blowdown structure on \( X \).

**Proof.** Certainly, \( L \) is a torsion-free sheaf of rank 1 and saturates the relevant bound. In the rational or rationally ruled case, the bound is manifestly independent of the blowdown structure, so the result is immediate. For a strictly quasi-ruled surface, we need merely observe that the class \( f \) is the same in any blowdown structure, so the bound remains invariant.

We now return to considering only rational and rationally ruled surfaces. It turns out that our bound on the Euler characteristic of torsion-free sheaves of rank 1 also gives a bound on certain globally generated sheaves.

**Corollary 10.16.** If \( M \) is a quotient of \( \mathcal{O}_X \), then either \( M \cong \mathcal{O}_X \) or \( \text{rank}(M) = 0 \), \( c_1(M) \) is effective, and

\[
\chi(M) \geq c_1(M) \cdot (c_1(M) + K_X)/2.
\]

**Proof.** Let \( I \) be the kernel of the map \( \mathcal{O}_X \to M \), and observe that either \( I = 0 \) or \( I \) is torsion-free of rank 1, with \( c_1(I) = -c_1(M) \) and \( \chi(I) = \chi(\mathcal{O}_X) - \chi(M) = 1 - g - \chi(M) \).

**Corollary 10.17.** If \( M \) is globally generated, then \( c_1(M) \) is effective.

**Proof.** If \( \mathcal{O}_X \otimes \text{Hom}(\mathcal{O}_X, M) \to M \) is surjective, then each subquotient of the filtration induced by a complete flag in \( \text{Hom}(\mathcal{O}_X, M) \) has effective Chern class, since it is either \( \mathcal{O}_X \) or 1-dimensional.

**Corollary 10.18.** For any integer \( n \) and quadratic polynomial \( P \), there is a finite subset of \( K_{\text{num}}^n(X) \), depending only on \( D_a \) and the combinatorics of \( Q \), that contains the class of any quotient of \( \mathcal{O}_X^n \) with Hilbert polynomial \( P \).

**Proof.** The Hilbert polynomial determines the rank, the Euler characteristic, and \( c_1(M) \cdot D_a \). Since \( c_1(M) \) is effective, we reduce to showing that there are finitely many classes that are effective on some surface with the given combinatorics and have given intersection with \( D_a \). The effective monoid of \( X \) is generated by components of \( Q \) and formal \(-1\) and \(-2\)-curves on \( X \), so it will suffice to find a finitely generated monoid containing the latter such that every generator has positive intersection with \( D_a \). We assume \( m \geq 1 \) (the cases \( m \leq 0 \) are straightforward) so that we may choose a blowdown structure such that \( D_a \) is in the fundamental chamber.

Let \( W(D_a) \) be the Weyl group generated by the reflections in the simple roots orthogonal to \( D_a \). Since \( D_a^2 > 0 \) so \( D_a^\perp \) is negative definite, this is a finite Weyl group. We then claim that any
formal $-1$- or $-2$-curve is contained in the monoid generated by the $W(D_a)$-orbits of the simple roots not orthogonal to $D_a$ along with the $W(D_a)$-orbit of $e_m$ (and $f - e_1$ for $m = 1$). But this follows by the usual argument, once we observe that since $D_a$ is ample, a simple root orthogonal to $D_a$ cannot be effective.

Since $D_a$ is $W(D_a)$-invariant, has positive intersection with $e_m$ (and $f - e_1$ if needed), and nonnegative intersection with any simple root, it follows that this finitely generated monoid is indeed finitely graded by the intersection with $D_a$, as is the monoid obtained by throwing in the components of $Q$.

Returning to a split family $X$ over a Noetherian base, let $\text{Hilb}^{n,+}(X)$ denote the functor such that $\text{Hilb}^{n,+}(X)(T)$ is the set of $T$-flat coherent sheaves such that every geometric fiber is torsion free, with $\text{rank}(I) = 1$, $c_1(I) = 0$ and $\chi(I) = 1 - g - n$. (We will eventually show (Theorem 10.26) that this is represented by a smooth projective scheme over $S$.) Note that these conditions on a sheaf are independent of the blowdown structure, and thus this functor can be defined for a non-split family.

We need to show that this functor is covered by a Noetherian scheme; i.e., that there exists a family of sheaves $I$ over some base change of $X$ such that every geometric point of $\text{Hilb}^{n,+}(X)$ is a fiber of $I$.

**Proposition 10.19.** Let $X$ be a split family over a Noetherian base. Then $\text{Hilb}^{n,+}(X)$ is empty for $n < 0$, while for $n > 0$, it is covered by a Noetherian scheme.

**Proof.** For noncommutative planes, an explicit construction was given in [30] showing that the functor $\text{Hilb}^{n,+}(X_{-1})$ is not only representable but projective.

For $m > 0$, the proof of [12, Lem. 11.43] applies mutatis mutandis to the case of general rationally ruled surfaces, and thus tells us that if $I \in \text{Hilb}^{n,+}(X_m)$, then $\alpha_m I(-ne_m) \in \text{Hilb}^{n(n+3)/2,+}(X_{m-1})$ and one can recover $I$ from $\alpha_m I(-ne_m)$. It follows that $\text{Hilb}^{n,+}(X_m)$ is a closed subfunctor of $\text{Hilb}^{n(n+3)/2,+}(X_{m-1})$.

For $m = 0$, the semiorthogonal decomposition gives a five-term exact sequence

$$0 \to \rho_1^*M_1 \to \rho_0^*M_0 \to I \to \rho_1^*N_1 \to \rho_0^*N_0 \to 0 \quad (10.18)$$

for sheaves $M_i$, $N_i$ on $C$. Chern class considerations tell us that $\text{Ext}^2(\rho_*\mathcal{L}, I) = \text{Ext}^2(\rho_*\mathcal{L}, I) = 0$ for any line bundle $\mathcal{L}$ on $C$, and thus that $\text{rank}(N_0) = \text{rank}(N_1) = 0$, so that $\text{rank}(M_1) = 0$ and $\text{rank}(M_0) = 1$. If $M_0$ had a nonzero $0$-dimensional subsheaf, then the corresponding image in $I$ would have nontrivial class in $K_0^{\text{num}}(X)$ and rank $0$, which is impossible since $I$ is torsion-free. We thus conclude that $M_0$ is a line bundle and $M_1 = 0$. Moreover, $\chi(M_0) - \chi(N_0)$ and $\chi(N_1)$ are determined by $[I]$, and $\deg(M_0)$ is bounded between $-n$ and $-1$. Thus for each $n$, the moduli stack of potential triples $(M_0, N_1, N_0)$ is Noetherian, and remains so when we include the map $\rho_1^*N_1 \to \rho_0^*N_0$ (on which we impose the open condition of surjectivity) and then the $\text{Ext}^1$ from the kernel to $M_0$ and the torsion-free condition on the extension. The result is a Noetherian family of sheaves surjecting on $\text{Hilb}^{n,+}(X_0)$ as required.

**Corollary 10.20.** For any quadratic polynomial $P(t)$, the functor $\text{Quot}_{X/S}(\mathcal{O}_X, P)$ is covered by a Noetherian scheme.

**Proof.** The kernel in any corresponding short exact sequence is a torsion-free sheaf of rank $1$, and thus up to a twist is just a point in $\text{Hilb}^{n,+}(X)$ for suitable $n$. There are only finitely many possible choices for the associated Chern class, and the short exact sequence is determined by a choice of injective map from the torsion-free sheaf to $\mathcal{O}_X$. 

120
Proposition 10.21. For any coherent sheaf \( M \in \text{coh}(S) \) and any quadratic polynomial \( P(t) \), the functor \( \text{Quot}_{X/S}(O_X \otimes_S M, P) \) is covered by a Noetherian scheme.

Proof. Since \( S \) is Noetherian, it suffices to prove this on each piece of an affine covering of \( S \), and on each such covering we can cover \( M \) by a free module, so that it suffices to consider the case that \( M \cong O_S^a \).

Consider a subsheaf of \( O_X^a \) with fixed class \([I_n]\) \( \in K^\text{num}(X) \) having the given Hilbert polynomial. (By Corollary 10.18, there are only finitely many possible values of \([I_n]\).) The filtration associated to a complete flag gives subquotients each of which is either 0 or torsion-free of rank 1. If we ignore the Euler characteristics for the moment, then there are only finitely many possibilities for the rank and Chern class of the last subquotient, since the last subquotient is either 0 or has Chern class \(-D\) such that both \( D \) and \(-c_1([I]) - D\) are effective. We thus find by induction that there are only finitely many choices for the entire sequence of ranks and Chern classes of subquotients. For each such choice, every subquotient has an upper bound on its Euler characteristic, and since the total Euler characteristic is fixed, there are only finitely many possible choices for the sequence of Euler characteristics. In particular, we conclude that there are indeed only finitely many possible choices for the numerical invariants of the last subquotient, and thus only finitely many possible choices for its Hilbert polynomial.

Fix such a choice \( P_n \), and consider the morphism \( \text{Quot}_{X/S}(O_X^n, P) \to \text{Quot}_{X/S}(O_X^{n-1}, P - P_n) \times \text{Quot}_{X/S}(O_X, P_n) \). The fiber over a point corresponding to subsheaves \( I_{n-1} \subset O_X^{n-1} \) and \( I \subset O_X \) is represented by the affine space \( \text{Hom}(I, O_X^{n-1}/I_{n-1}) \). Since this is Noetherian and \( \text{Quot}_{X/S}(O_X, P - P_n) \), \( \text{Quot}_{X/S}(O_X, P_n) \) are covered by Noetherian schemes, the claim follows.

Applying Corollary 10.16 to this covering family gives the following.

Corollary 10.22. Let \( X/S \) be a family of noncommutative surfaces over a Noetherian base, and let \( M \) be a coherent sheaf on \( S \). Then for any quadratic polynomial \( P \), there is a bound \( b_0 \) such that for all \( T/S \) and \( I \in \text{Quot}_{X/S}(O_X \otimes_O M, P)(T) \), \( I \) is acyclically generated by \( O_X(-bD_a) \) for all \( b \geq b_0 \).

Proof. Since \( T \) need not be Noetherian, our previous arguments do not suffice to show that \( I \) inherits acyclic generation from its fibers. Acyclicity is not a difficulty, since we can represent \( I \) by the complex

\[
O_X \otimes_O M \otimes_O T \to N \tag{10.19}
\]

with \( N \) flat coherent (thus certainly inheriting acyclicity from fibers) and \( M \) coherent, and thus

\[
\Ext^1(O_X(-bD_a), I) \otimes k(t) \cong \Ext^1(O_X(-bD_a), I \otimes k(t)) = 0 \tag{10.20}
\]

for all points \( t \in T \), implying \( \Ext^1(O_X(-bD_a), I) = 0 \), since \( \Ext^1(O_X(-bD_a), I) \) is a quotient of the (flat) coherent sheaf \( \text{Hom}(O_X(-bD_a), N) \).

For global generation, it suffices to show that for each \( b \geq b_0 \), there is some \( b_1 \) such that

\[
\text{Hom}(O_X(-b'D_a), O_X(-bD_a)) \otimes \text{Hom}(O_X(-bD_a), I) \to \text{Hom}(O_X(-b'D_a), I) \tag{10.21}
\]

is surjective for all \( b' \geq b_1 \). By the snake lemma, the cokernel is a quotient of the locally free coherent sheaf

\[
\ker(\text{Hom}(O_X(-b'D_a), O_X(-bD_a)) \otimes \text{Hom}(O_X(-bD_a), N) \to \text{Hom}(O_X(-b'D_a), N)) \tag{10.22}
\]

so that again it suffices to check vanishing on fibers. The existence of a global \( b_1 \) that works for every fiber follows using the Noetherian covering family.
As is common in these constructions, the direct approach will only give quasiprojectivity, so we need to check the valuative condition.

**Lemma 10.23.** The functor $\text{Quot}_{X/S}$ is proper.

*Proof.* Let $X/R$ be a family of noncommutative surfaces, where $R$ is a discrete (since the base scheme is Noetherian) valuation ring with quotient field $K$ and field of fractions $k$. For $M \in \text{coh}(X)$, consider an exact sequence

$$0 \to I \to M_K \to N \to 0 \quad (10.23)$$

in $\text{coh}(X_K)$. We need to show that there is a unique short exact sequence

$$0 \to I' \to M \to N' \to 0 \quad (10.24)$$

such that $I'_K = I$ and $N'$ is $R$-flat, or equivalently $N'$ is $R$-torsion-free (since a module over a dvr is flat iff it is torsion-free). Let $I'$ be the maximal submodule of $M$ such that $I'_K = I$. Then $M/I'$ cannot have torsion, since we could move any torsion to the subsheaf without changing the generic fiber, while any proper subsheaf $I'' \subsetneq I'$ has $I'/I''$ torsion since they have the same generic fiber, and thus makes $N''$ fail to be torsion-free. It follows that $I'$ gives rise to the desired unique extension. \qed

**Theorem 10.24.** Let $X/S$ be a family of noncommutative surfaces over a Noetherian base. Then for any $M \in \text{coh}(X)$, $\text{Quot}_{X/S}(M, P)$ is a projective scheme over $S$.

*Proof.* As already discussed, it suffices to prove this for $\text{Quot}_{X/S}(\mathcal{O}_X \otimes_{\mathcal{O}_S} M, P)$ with $M \in \text{coh}(S)$. We thus find in general that there is a constant $b_0$ such that for any $T$-point of $Q := \text{Quot}_{X/S}(\mathcal{O}_X \otimes_{\mathcal{O}_S} M, P)$, the kernel in the corresponding short exact sequence is acyclically generated by $\mathcal{O}_X(-b_0D_a)$. We thus obtain a resolution

$$\mathcal{O}_X(-b_0D_a) \otimes_{\mathcal{O}_T} \text{Hom}(\mathcal{O}_X(-b_0D_a), I) \to \mathcal{O}_X \otimes_{\mathcal{O}_T} M_T \to N_T \to 0, \quad (10.25)$$

giving a $T$-point of the Grassmannian

$$G := \text{Grass}(\text{Hom}(\mathcal{O}_X(-b_0D_a), \mathcal{O}_X) \otimes_{\mathcal{O}_S} M, P(b_0)) \quad (10.26)$$

classifying rank $P(b_0) = \text{rank}(\text{Hom}(\mathcal{O}_X(-b_0D_a), N_T))$ quotients of $\text{Hom}(\mathcal{O}_X(-b_0D_a), \mathcal{O}_X) \otimes_{\mathcal{O}_S} M$.

In the other direction, any point of the Grassmannian determines a quotient sheaf of $\mathcal{O}_X \otimes_{\mathcal{O}_T} M_T$, which gives a point of $Q$ iff it has the correct Hilbert polynomial. It follows that $Q$ is a component of the universal flattening stratification of the universal quotient sheaf over the Grassmannian. If we knew that sheaf had finite flattening stratification, we could then conclude that $Q$ was locally closed in $G$. Since $Q$ is proper and $G$ is projective, this would imply $Q$ projective as required. In particular, this implies that the theorem holds whenever $S$ (and thus $G$) is of finite type.

For more general base rings, it clearly suffices to show that $Q$ is closed in $G$. In particular, if we can show that $Q$ is fppf locally projective, then it follows that the map $Q \to G$ is fppf locally closed, so closed, and thus $Q$ must be projective. As the question is now fppf local, we may still make some simplifying assumptions: since $X$ is étale locally split, we may assume that $X$ is split, and since $M$ is Zariski locally a quotient of a free sheaf, we may assume this is so. Since the corresponding map of Quot functors is closed, we may assume $M \cong \mathcal{O}_X^n$.

Let $\mathcal{M}$ denote the moduli stack of split surfaces, and note that $X/S$ induces a map $S \to \mathcal{M}$. Since $S$ is Noetherian and $\mathcal{M}$ is locally of finite type, there is a morphism $U \to \mathcal{M}$ with $U$ of finite
type such that the fiber product is smooth and surjective over $S$. Let $T$ be that fiber product, and observe that one has

$$\text{Quot}_{X/S}(O_X^n, P) \times_S T \cong \text{Quot}_{X_T/T}(O_X^n, P) \cong \text{Quot}_{X_U/U}(O_X^n, P) \times_U T. \quad (10.27)$$

Since $U$ is of finite type, the corresponding Quot scheme is projective, and thus $\text{Quot}_{X/S}(O_X^n, P)$ is fppf locally projective as required.

**Remark.** Of course, in the last part of the argument, what we are really proving is that the functor $\text{Quot}_{X/M}(O_X^n, P)$, appropriately defined, is fppf locally projective.

Although much of the above proof involved working around the potential lack of finite flattening, this is in some sense unnecessary, as finite flattening always holds. Unfortunately, the only proof we have of this fact uses projectivity of the Quot scheme!

**Corollary 10.25.** Let $X/S$ be a family of noncommutative surfaces over a Noetherian base. Then any sheaf $M \in \text{coh}(X)$ has finite flattening stratification.

**Proof.** It suffices to show that when $S$ is integral, there is an open neighborhood of $k(S)$ on which $M$ is flat, or equivalently on which the Hilbert polynomial is constant. Let $p$ be the Hilbert polynomial of $M_{k(S)}$, and consider the Quot scheme $Q = \text{Quot}_{X/S}(M, P)$, with associated short exact sequence

$$0 \to I \to M_Q \to N \to 0. \quad (10.28)$$

We first note that the fiber over $k(S)$ consists of the single short exact sequence

$$0 \to 0 \to M_{k(S)} \to M_{k(S)} \to 0, \quad (10.29)$$

as the Hilbert polynomial constraint forces the map $M \to N$ to become an isomorphism. In particular, since the image of $\pi : Q \to S$ contains $k(S)$, the morphism is surjective. Since $N$ is flat, the restriction of the short exact sequence to any point $q \in Q$ will still be a short exact sequence, and thus we find that $I_q \neq 0$ precisely when the Hilbert polynomial of $M_{\pi(q)}$ is different from $p$. In other words, the closed subset $\pi(\text{supp}(I))$ of $S$ agrees with the set of points where the Hilbert polynomial jumps. It follows that the set of points with the same Hilbert polynomial as the generic point is open as required. 

**Remark.** This argument in fact shows that the class in the Grothendieck group is upper semicontinuous: it is constant on locally closed subsets, and the value at a point on the boundary of such a set differs by the class of a sheaf over that point.

We now turn to a closer analysis of the functors $\text{Hilb}^{n,+}(X/S)$ for families over a Noetherian base. Note that since any torsion-free sheaf of rank 1 is stable, we automatically find (via the standard argument of Langton) that the functor is proper, with smoothness following by deformation theory, since $\text{Ext}^2(I, I) = 0$. We then find that the dimension is everywhere $1 - \chi(I, I) = 2n + g$.

**Theorem 10.26.** For all $n \geq 0$, the functor $\text{Hilb}^{n,+}(X/S)$ is represented by a smooth projective scheme of dimension $2n + g$ over $S$ with geometrically integral fibers.

**Proof.** Since $\text{Hilb}^{n,+}(X/S)$ is covered by a Noetherian family, there is a line bundle $L = O_X(-bD_a)$ such that any point $I \in \text{Hilb}^{n,+}(X)$ is acyclically generated by $L$. As above, a complete flag in $\text{Hom}(L, I)$ determines a filtration of $I$ and there are only finitely many possibilities for the sequence of subquotients; it follows that there are only finitely many possibilities for the class in $\text{Pic}^{\text{num}}(X)$.
of a subsheaf of \( I \) which is generated by \( L \). It follows as in [12, Thm. 11.47] (following the usual commutative arguments) that we can represent \( \text{Hilb}^{n,+}(X/S) \) as a subscheme of a GIT quotient of \( \text{Quot}(L^{(L/I)}_n)[I] \), making it quasi-projective. Since it is proper, it is projective as required.

For irreducibility, it suffices to consider the moduli problem over a smooth covering of the moduli stack of surfaces; in particular, we may assume that the family contains commutative fibers. When \( X \) is commutative, the numerical conditions on \( I \) force it to be the tensor product of a line bundle in \( \text{Pic}^0(X) \) by the ideal sheaf of an \( n \)-point subscheme, and thus that fiber is connected, and thus (following [30, Prop. 8.6]) every fiber is connected. Since the fibers are smooth, they are geometrically integral as required.

In the rational case, this is a family of deformations of the Hilbert scheme of the corresponding commutative surface (except when \( n = 1 \), when it is the corresponding commutative surface, just as in [42]). To recover something closer to the usual Hilbert scheme in higher genus, we observe that there is a natural morphism \( \text{Hilb}^{n,+}(X) \to \text{Pic}(Q) \) given by \( I \mapsto \det(I^L) \). Since the numerical class of \( I \) is fixed, the image is contained in a particular coset of \( \text{Pic}^0(C) \). Any line bundle in \( \text{Pic}^0(C) \) induces an autoequivalence of \( \text{coh} X \), and we find that this autoequivalence simply twists the determinant of the restriction to \( Q \) by that same line bundle. We thus find that the fibers of the determinant-of-restriction map are all isomorphic, and we thus have an isomorphism of the form \( \text{Hilb}^{n,+}(X) \cong \text{Hilb}^n(X) \times \text{Pic}^0(C) \) where \( \text{Hilb}^n(X) \) is any fiber of the determinant-of-restriction map. (One caveat is that this presumes the image of the determinant-of-restriction map has a point!) We conclude that \( \text{Hilb}^n(X) \) is smooth, irreducible, and projective of dimension \( 2n \). When \( X \) is commutative, the relevant coset of \( \text{Pic}^0(C) \) is the trivial coset, and thus there is a canonical choice of fiber, and we find that the result agrees with the usual Hilbert scheme of \( n \) points.

In the commutative case, there is also a map from the Hilbert scheme of \( n \) points to \( \text{Sym}^n(C) \). This too has an analogue in the noncommutative setting. We saw in the case of a ruled surface that \( I \) always satisfies \( \rho_{-1} I = 0 \) and \( R^1 \rho_{-1} I \) is 0-dimensional of degree \( n \), inducing a map \( \text{Hilb}^{n,+}(X) \to \text{Sym}^n(C) \) which is preserved by the action of \( \text{Pic}^0(C) \), and thus factors through \( \text{Hilb}^n(X) \). In general, one finds that for \( I \in \text{Hilb}^{n,+}(X_m) \), there is an integer \( 0 \leq d \leq n \) such that \( \alpha_{m} \cdot I \in \text{Hilb}^{d,+}(X_{m-1}) \) and \( R^1 \alpha_m I \) is a 0-dimensional sheaf of degree \( n - d \). It follows by induction that

\[
\begin{equation}
\text{h}^1(R\rho_{-1} R\alpha_{1} \cdots R\alpha_m I)
\end{equation}
\]

is again a 0-dimensional sheaf of degree \( n \), so the map to \( \text{Sym}^n(C) \) survives.

### 11 Moduli of sheaves and complexes

Now that we have established that our surfaces behave reasonably, the most natural next object of study is the corresponding moduli spaces of sheaves. The construction via the derived category suggests that a more natural first problem would be to study moduli spaces in \( \text{perf}(X) \). The most general result along those lines is the following (specializing a result of [49] for fairly general dg-categories).

**Proposition 11.1.** [49] For any family \( X/S \) of noncommutative surfaces, there is a derived stack \( \mathcal{M}_{X/S} \) such that for all derived schemes \( T/S \), \( \mathcal{M}_{X/S}(T) \) is the set of quasi-isomorphism classes of objects in \( \text{perf}(X_T) \). This stack is locally geometric and locally of finite presentation, and the tangent complex to \( \mathcal{M}_{X/S} \) at a geometric point \( M \) is \( R\mathcal{E}nd(M)[1] \).

**Proof.** Per the reference, this holds if \( \text{perf}(X) \) is saturated, i.e., if it is locally perfect, has a compact generator, is triangulated, and is smooth. The first three properties follow immediately from the
description via a dg-algebra in \( \text{perf}(S) \). Smoothness follows from the fact that gluing preserves smoothness \([28]\), along with the fact that \( \text{perf}(S) \) and \( \text{perf}(C) \) are smooth over \( S \).

**Remark.** Of course, the most natural object to study here is the derived stack classifying objects of the universal \( \text{perf}(X) \) over the moduli stack of surfaces. Since the moduli stack of surfaces is singular, this suggests that one should really define a derived moduli stack of surfaces, and then obtain a moduli stack of objects on the universal derived noncommutative surface over that derived moduli stack.

This, of course, is quite far from a stack in the usual sense, and even the truncation is only a higher Artin stack. However, we can use this to obtain algebraic stacks in the usual sense. After \([27]\), call an object in a geometric fiber “gluable” if \( \text{Ext}^i(M,M) = 0 \) for \( i < 0 \). By semicontinuity, this is an open condition. (More precisely, it is open for each \( i \), and \( R\text{End}(M) \) is perfect, so locally bounded in cohomological degree.) Thus we may define a functor \( \mathcal{M}^u_{X/S} \) such that (for \( T/S \) an ordinary scheme) \( \mathcal{M}^u_{X/S}(T) \) is the set of quasi-isomorphism classes of objects in \( \text{perf}(X_T) \) such that every geometric fiber is gluable, and this functor will be an open substack of the truncation of \( \mathcal{M}_{X/S} \).

**Corollary 11.2.** The functor \( \mathcal{M}^u_{X/S} \) can be represented by an algebraic stack locally of finite presentation.

**Remark.** Note that the substack of \( \mathcal{M}_{X/S} \) classifying flat families of coherent sheaves is contained in the derived stack of which \( \mathcal{M}^u_{X/S} \) is a truncation, since any coherent sheaf on \( X/k \) is gluable. We thus find that coherent sheaves on \( X \) are classified by an algebraic stack locally of finite presentation. In fact, this is true for any family of \( t \)-structures on \( D_{\text{qcoh}}(X) \).

Similarly, one calls an object over a geometric fiber “simple” if the natural map

\[
k \to \tau_{\leq 0} R\text{End}(M)
\]

is an isomorphism. Again, this condition is open, so defines an open substack \( \mathcal{M}^s_{X/S} \). Here there is a further reduction one can make: since the family of automorphism groups of any family with simple fibers is just \( \mathbb{G}_m \) (so flat and locally of finite presentation), \( \mathcal{M}^s_{X/S} \) is a gerbe over an algebraic space \( \text{Sp}^l_{X/S} \). The corresponding functor is easy enough to define: an element of \( \text{Sp}^l_{X/S}(T) \) is an equivalence class of simple objects in \( \text{perf}(X_U) \) with \( U/T \) étale, such that the two base changes to \( U \times_T U \) are quasi-isomorphic (but not necessarily canonically so). Objects \( M \) and \( M' \) are equivalent if their base changes to the fiber product étale cover are quasi-isomorphic.

**Corollary 11.3.** The functor \( \text{Sp}^l_{X/S} \) is represented by an algebraic space locally of finite presentation.

**Remark.** Note that a stable sheaf (relative to any stability condition) is automatically simple.

In the commutative setting (\([12, 19, 39]\); also for the noncommutative rational surfaces considered in \([42]\)), the moduli space of simple sheaves has an important additional structure, namely a Poisson structure (defined for algebraic spaces as a consistent family of Poisson brackets on an étale covering by affine schemes). Such a Poisson structure is in particular a biderivation, and the construction of the biderivation (going back to \([50]\) in the commutative setting) carries over to \( \text{Sp}^l_{X/S} \). To wit, the cotangent sheaf on \( \text{Sp}^l_{X/S} \) is given by \( \text{Ext}^1(M, \theta M) \) where \( M \) is the universal family (the cotangent complex on the corresponding derived stack is \( R\text{Hom}(M, \theta M)[1] \), and the \( \text{Ext}^2(M, \theta M) \) term is killed by the structure morphism of the gerbe), and one has a bivector defined by

\[
\text{Ext}^1(M, \theta M) \otimes \text{Ext}^1(M, \theta M) \to \text{Ext}^1(M, M) \otimes \text{Ext}^1(M, \theta M) \to \text{Ext}^2(M, \theta M) \to \mathcal{O}_{\text{Sp}^l_{X/S}},
\]

(11.2)
where the map $\theta M \to M$ comes from a choice of isomorphism $\theta M \cong M(-Q)$. (In other words, the map $\theta M \to M$ is a Poisson structure on $X$ that vanishes on $Q$. This is unique modulo scalars, so such Poisson structures on noncommutative surfaces form a line bundle over the moduli stack of noncommutative surfaces. The associated biderivation scales linearly with the choice of Poisson structure on the surface, so is associated to the same line bundle.) In order to define a Poisson structure, this bivector needs to be alternating and satisfy the Jacobi identity. Since it is defined via the Yoneda product, it is easy to see that it is antisymmetric, so (apart from characteristic 2), only the Jacobi identity remains. This is unfortunately tricky to deal with, though see below for the case of simple sheaves.

One important part of the known special cases is the identification of the symplectic leaves of the Poisson structure. This can be stated without using the Jacobi identity (or alternation in characteristic 2). Indeed, for manifolds, any bivector induces a foliation by manifolds with nondegenerate 2-forms, which are closed if the bivector is Poisson. (In fact, the converse is true, though in the algebraic setting this only holds for bivectors on reduced schemes.) This was key to the argument of [39] for vector bundles (extending the result of [12] to finite characteristic). In the algebraic setting, such a foliation need not exist, but the tangent space at $M$ to the foliation is always defined, and given by the image of the cotangent space in the tangent space under the bivector. In our case, this is the image of

$$\Ext^1(M, M) \to \Ext^1(M, M),$$

or equivalently, the kernel of the natural map to $\Ext^1(M, M|_Q) \cong \Ext^1(S^1M|_Q, M|_Q)$. This suggests that the symplectic leaves should be the fibers of $|_Q$, and indeed this is the case for simple sheaves on commutative rationally ruled surfaces [39].

In general, each simple object $M \in \mathcal{S}pl_{X/k}$ defines a subspace of simple objects with quasi-isomorphic derived restriction to $Q$, which we (somewhat abusively) call the symplectic leaf of $M$. (Note, however, that contrary to the usual analytic notion of symplectic leaf, these symplectic leaves need not be connected.) The bivector on $\mathcal{S}pl_{X/k}$ induces a perfect pairing on the cotangent spaces of the symplectic leaf, and thus (if the leaf is smooth!) defines an isomorphism between the tangent and cotangent spaces, thus a nondegenerate 2-form. (We of course conjecture that this form is closed, as this would follow if the bivector satisfied the Jacobi identity.)

We thus wish to know that the symplectic leaves are smooth (which in characteristic 2 implies the pairing is alternating, as the self-pairing gives the obstruction to extending a first-order deformation). This is especially the case in finite characteristic, where Poisson structures themselves are not nearly as useful, but the symplectic leaves are still natural moduli spaces to consider. The first hope would be that the corresponding obstructions might vanish. We can compute this using the derived moduli stack $\mathcal{M}_{X/k}$. Indeed, the symplectic leaves (rather, certain gerbes over the symplectic leaves) are truncations of open substacks of fibers of the obvious map $\mathcal{M}_{X/k} \to \mathcal{M}_{Q/k}$. We can thus compute the tangent complex $T_M$ to the derived symplectic leaf containing $M$ as the cone:

$$T_M \to R\Hom(M, M)[1] \to \tau_{\geq 1} R\Hom_Q(M|_Q^1, M|_Q)[1] \to .$$

(Indeed, $R\Hom(M, M)[1]$ is the tangent complex in $\mathcal{M}_{X/k}$, and the other term is the normal complex of the given point, viewed as a higher Artin stack.) This makes it easy to compute the homology of $T_M$:

$$h^p(T_M) = \begin{cases} 
\Ext^{p+1}(M, M) & p < 0 \\
\text{im}(\Ext^1(M, \theta M) \to \Ext^1(M, M)) & p = 0 \\
\Ext^{p+1}(M, \theta M) & p > 0
\end{cases}$$

(11.5)
Indeed (unsurprisingly), the tangent complex of the symplectic leaf is self-dual. Since $M$ is simple, $T_M$ has amplitude $[-1, 1]$, but we have $h^{-1}T_M \cong k$ and thus by duality $h^1T_M \cong k$, giving an obstruction.

The dimension of the tangent space at $M$ of its symplectic leaf is $\dim(h^1(T_M)) = \chi(T_M) + 2$, and the description of $T_M$ as a cone tells us that

$$-\chi(T_M) = \chi(M, M) - \chi(T \Hom_{Q}(M|_Q^L, M|_Q^R)).$$

(Compare the “index of rigidity” of [39].) The second term is clearly constant on the symplectic leaf, while the first term depends only on $[M] \in K_0^{\num}(X)$, and is thus at least locally constant. In other words, the tangent spaces to symplectic leaves have locally constant dimension, and thus each component of a symplectic leaf is either smooth or nowhere reduced. (The latter can actually happen for the commutative Poisson surfaces of characteristic 2 that are not fibers of the moduli stack of noncommutative rational or rationally ruled surfaces.)

Luckily, there are two cases in which we can prove smoothness, which together are large enough that we have been unable to construct an object to which neither case applies.

**Proposition 11.4.** Let $X/k$ be a noncommutative rational or rationally ruled surface over an algebraically closed field, and let $N \in \perf(Q)$ be any nonzero object. Then the fiber over $N$ in $\Spl_{X/k}$ is smooth.

**Proof.** We need to show that for any local Artin algebra $A$ with residue field $k$, any small extension $A^+$ of $A$, and any $M \in \perf(X_A)$ with $M|_Q^L \cong N \otimes_k A$, there is an extension $M^+$ of $M$ to $A^+$ with $M^+|_Q^L \cong N \otimes_k A^+$.

We first consider the problem of extending $M$, ignoring for the moment the constraint on its restriction to $Q$. The obstruction to extending $M$ is given by a class in $\Ext^2(M_k, M_k)$, and the image of this class in $\Ext^2_Q(N, N)$ is the obstruction to extending $M|_Q^L$. Since $M|_Q^L$ is a trivial deformation, there is no such obstruction, and thus the obstruction to extending $M$ is in the image of $\Ext^2(M_k, \theta M_k)$. The map $\Ext^2(M_k, \theta M_k) \to \Ext^2(M_k, M_k)$ vanishes, since it is dual to $\Hom(M_k, \theta M_k) \to \Hom(M_k, M_k)$, which vanishes since $\Hom(M_k, M_k) \to \Hom_Q(N, N)$ is injective. It follows that the obstruction to extending $M$ is trivial, and thus it has extensions, classified by a torsor $T$ over $\Ext^1(M_k, M_k)$.

It remains to show that at least one of those extensions restricts to $N \otimes_k A^+$. The map taking an extension of $M$ to its restriction, viewed as a deformation of $N$, is a torsor map $T \to \Ext^1_Q(N, N)$ compatible with the homomorphism $\Ext^1(M_k, M_k) \to \Ext^1_Q(N, N)$, and thus its image is a coset of the image of $\Ext^1(M_k, M_k)$. We thus find that the image of $T$ contains $0$ iff the composition

$$T \to \Ext^1_Q(N, N) \to \Ext^2(M_k, \theta M_k)$$

is $0$. The composition

$$\Ext^1_Q(N, N) \to \Ext^2(M_k, \theta M_k) \cong k$$

is dual to the morphism

$$k \to \Hom_Q(N, N)$$

taking $1$ to $id$, and thus has the alternate expression

$$\Ext^1_Q(N, N) \overset{\text{tr}}{\longrightarrow} \Ext^1_Q(O_Q, O_Q) \to \Ext^2(O_X, \theta O_X) \cong k.$$  

The trace of a deformation of complexes on a commutative scheme is the deformation of its determinant, so that we finally reduce to showing that $\det(M|_Q^L) \otimes \det(N \otimes_k A^+)^{-1}$ is in the image of $\Pic^0(C)(A^+)$ for any $M^+$. But this follows from the fact that determinant-of-restriction gives a well-defined map from $K_0^{\num}(X)$ to $\Pic(Q)/\Pic^0(C)$. 

\[\square\]
Remark. Much the same argument was used for vector bundles on commutative surfaces in \cite{39}; the main new complication is that $\text{Ext}^2(M, M)$ is no longer guaranteed to vanish. Of course, since it does not actually contribute to the obstructions of the symplectic leaf, it is unsurprising that we can show that we never see nontrivial classes in $\text{Ext}^2(M, M)$.

When $M|_Q^L = 0$, we have $\text{Ext}^2(M, \theta M) \cong \text{Ext}^2(M, M)$, and thus we can no longer get started in the above argument. The key idea for dealing with (nearly all of) these remaining cases is that in any deformation theory problem, the moduli space of formal deformations is a quotient of the completion at the origin of the affine space of infinitesimal deformations, and the obstruction space gives a bound on the number of elements required to generate the ideal. In particular, since our obstruction space is 1-dimensional, the ideal must be principal (hopefully 0). Directly showing that the ideal is 0 can be difficult (as it is unexpected behavior), but when the ideal is nonzero, controlling the ideal reduces to showing that certain deformations do not extend, giving us an alternate angle of attack.

Of course, since our objective is to prove the ideal is 0, this may not seem particularly helpful. However, because we are now asking for $M|_Q^L$ to be 0, we can embed the symplectic leaf in a family of moduli problems by allowing the surface to vary. The argument for $M|_Q^L \neq 0$ suggests that we should look at $\det M|_Q^L$, or rather its image in $\text{Pic}^0(Q)/\text{Pic}^0(C)$. This can be computed in two ways. On the one hand, it is $\det(0) = \mathcal{O}_Q \text{Pic}^0(C)$ by our assumption on the restriction of $M$. On the other hand, we can also compute $\det(M)$ via its class in $K_0^{\text{num}}(X)$. Thus if we allow $X$ to vary in such a way that $\det([M])$ varies, then the resulting moduli problem will be visibly obstructed, but the obstruction will necessarily be in the direction of the deformation of surfaces.

Lemma 11.5. Let $X/k$ be a noncommutative surface over an algebraically closed field, and let $[M] \in K_0^{\text{num}}(X)$ be a nonzero class such that $[M]|_Q$ is numerically trivial. Then there is a dvr $R$ with residue field $k$ (and field of fractions $K$) and an extension $X'/R$ (as a split family) of $X_t$ to $R$ such that $\det([M]|_Q)_K \notin \text{Pic}^0(C_K)$.

Proof. Of course, if $\det([M]|_Q) \notin \text{Pic}^0(C)$, then we may simply take the trivial extension. Otherwise, we may consider the (smooth!) locally closed substack of the moduli stack of surfaces determined by the combinatorial type of $Q$ (and, in the rational case, whether $\text{Pic}^0(Q)$ is elliptic, multiplicative, or additive). It suffices to show that $\det([M]|_Q) \in \text{Pic}^0(C)$ cuts out a nontrivial divisor in this substack, since then any point of the divisor can be extended to a dvr not contained in the divisor. In particular, we may restrict our attention to the corresponding stack in characteristic 0.

If $c_1([M]) \cdot e_m \neq 0$, then $e_m$ cannot be a component of $Q$, so that $x_m$ is a smooth point of the anticanonical curve of $X_{m-1}$, and varying $x_m$ varies the determinant. If $c_1([M]) \cdot e_m = 0$, then we may reduce to the blowdown, and thus reduce to ruled surfaces and planes. If $c_1([M]) \neq 0$, then $X$ must be a ruled surface, and then $c_1([M])$ is fixed by the condition $c_1([M]) \cdot Q = 0$. We must also have $\hat{Q} = \overline{Q}$, and by varying the invertible sheaf (again possibly including a lift to characteristic 0) on $\hat{Q}$, we may again vary the determinant. Finally, if $c_1([M]) = 0$, then the only way $\det([M]|_Q)$ can be 0 is if $X$ has center of order dividing $\chi([M]) \neq 0$, which is cut out by a nontrivial codimension 1 condition on $q$. \hfill \Box

One useful observation is that $M|_Q^L = 0$ is an open condition on any Noetherian substack of $\text{Spl}_{X/k}$ (the complement of the supports of the cohomology sheaves, only finitely many of which can be nonzero on the substack).

Proposition 11.6. Let $X/k$ be a noncommutative surface over an algebraically closed field. The fiber of $\text{Spl}_{X/k}$ over 0 is smooth, except possibly on those components with trivial class in the Grothendieck group.
Proof. Choose $M \in \mathcal{S}pI_{X/k}$ with $[M] \neq 0$ and $M_{|Q}^L = 0$, let $X'/R$ be the extension of $X$ given by the Lemma, and consider the localization $\mathcal{S}$ of $\mathcal{S}pI_{X'/R}$ at $M$. Then by standard deformation theory, one has

$$\dim(S) \geq 1 + \dim \text{Ext}^1(M, M) - \dim \text{Ext}^2(M, M) = \dim \text{Ext}^1(M, M). \quad (11.11)$$

Since $\det([M]|_Q)$ is nontrivial over $K$ and $M_{|Q}^L = 0$ on $\mathcal{S}$, we conclude that $\mathcal{S}(K) = 0$, and thus that $\mathcal{S}$ is annihilated by some power of the maximal ideal of $R$. It follows that $\dim(S) = \dim(S_K)$, and thus $\dim(S_K) \geq \dim(\text{Ext}^1(M, M))$. Since $\text{Ext}^1(M, M)$ is the tangent space at $M$, $S_K$ is smooth at $M$ as required.

Remark. It is not clear if it is even possible for a simple object to have trivial class in the Grothendieck group (let alone also have trivial restriction to $Q$). Note in particular that such an object satisfies $\chi(M, M) = \chi(0,0) = 0$, and thus any such connected component of $\mathcal{S}pI_{X/k}$ is either a smooth surface or a nowhere reduced curve. Note that to show smoothness in finite characteristic, it would suffice to show smoothness in characteristic 0: if $M$ lifts to characteristic 0, then semicontinuity of fiber dimension forces its component to be smooth, and if it does not lift, the deformation theory argument shows that its component is smooth!

For simple sheaves, the proof of the Jacobi identity in [42] can be carried out for more general rational noncommutative surfaces (in fact, a density argument lets one deduce the general rational case from the elliptic case), but the argument depends quite strongly on the existence of the $O_X$ semiorthogonal decomposition, and thus fails for higher genus ruled surfaces. There is a general approach (via shifted Poisson structures, see below) for arbitrary simple objects that should work for general surfaces, but in the case of sheaves, we can hope for a more elementary approach. (The resulting argument is actually somewhat simpler even in the rational case!)

As long as we restrict ourselves to sheaves, we can apply the reduction of [19], which as observed in [42] applies in the noncommutative setting. This has the effect of replacing $M$ by the cokernel of a map $\text{Hom}(L, M) \otimes L \to M$ for a suitable line bundle $L$, and gives a locally closed embedding of a neighborhood of $M$ in $\mathcal{S}pI_{X/S}$ in a neighborhood of the kernel, respecting the pairings on the cotangent bundles (up to a sign). Now, since $\text{ad}$ has homological dimension 2, and $\text{coh} X$ is generated by $\text{ad}$-acyclic (i.e., reflexive) sheaves (namely the line bundles), performing this reduction twice gives a locally closed bivector-preserving embedding of the neighborhood of $M$ in the moduli space $\text{Refl}_{X/S}$ classifying reflexive sheaves. (Note that being reflexive is an open condition, as a family fails to be reflexive precisely on the union of the supports of $R^1 \text{ad} M$ and $R^2 \text{ad} M$.) Thus if we can show that the bivector on $\text{Refl}_{X/S}$ is Poisson, then it will follow for the moduli space of simple sheaves. The Jacobi identity is a closed condition (it corresponds to the vanishing of a certain trivector), and thus it suffices (at least when $S$ is reduced) to prove this for a dense subset of the universal moduli stack $\text{Refl}$ (classifying pairs $(X, M)$ with $M$ reflexive).

**Lemma 11.7.** The points of $\text{Refl}$ over finite fields are dense, and this remains true if we exclude finitely many characteristics.

**Proof.** We first note that the characteristic 0 points of $\text{Refl}$ are dense; given any point $(X, M)$ over a field of characteristic $p$, we can lift a finite separable base change of $X$ to a surface over a mixed characteristic dvr, and then by smoothness can lift $M$ over an étale extension of the dvr. Since being reflexive is an open condition, the lifted sheaf will still be reflexive, and thus gives a characteristic 0 point having $(X, M)$ in its closure.

Now, suppose $(X, M)$ is defined over a field of characteristic 0. Since the moduli stack of noncommutative surfaces is locally of finite type, we may write $X$ as the base change of a surface
over a field \( l \) of finite transcendence degree over \( \mathbb{Q} \), and then similarly for \( M \). If \( l \) is not a number field, then we may choose a subfield \( k \subset l \) which is algebraically closed in \( l \) and such that \( l/k \) has transcendence degree 1. Then we may view \( l \) as the function field of a smooth projective curve \( C_l/k \), and find that \( X \) extends to a surface over an open subset of \( C_l \), and any extension of \( M \) will be reflexive over an open subset of that open subset. Since the closed points of that open subset are dense in \( C_l \), we see that \((X, M) \) is in the closure of a set of points defined over fields of lower transcendence degree. We thus reduce to the case that \( l \) is a number field, where the same argument applies with an arbitrary open subset of \( \text{Spec}(O_l) \) in place of \( C_l \), allowing us to exclude finitely many characteristics. 

Since noncommutative surfaces over finite fields are maximal orders, we conclude the following.

**Corollary 11.8.** The points of \( \text{Refl} \) such that the surface is a maximal order are dense, and this remains true if we exclude finitely many characteristics.

**Remark.** This fails in general if we ask for the maximal order to be characteristic 0, for the simple reason that a surface with \( g \geq 2 \) is a maximal order iff it has finite characteristic. In particular, even if one only wishes to know that the characteristic 0 moduli spaces are Poisson, the argument below will require working in finite characteristic. (In contrast, for \( g = 0 \) or \( g = 1 \), one can show that characteristic 0 elliptic difference cases with \( q \) torsion are dense.)

**Remark.** The same argument shows that the characteristic 0 localization of \( \text{Spl}_{X/S} \) is contained in the closure of the maximal orders with characteristic avoiding any finite set. Showing that the characteristic 0 points are dense is more difficult, since \( \text{Spl}_{X/S} \) is no longer smooth, though in most cases this could be avoided by lifting along the symplectic leaf (which requires a careful choice of the lift of \( X \) when \( M|_Q = 0 \) and may fail if \( M|_Q = 0 \) and \([M] = 0\)).

Thus to show that the sheaf locus in \( \text{Spl}_{X/S} \) (\( S \) reduced) is Poisson, it will suffice to prove that \( \text{Refl}_{X/k} \) is Poisson whenever \( X \) is a maximal order of characteristic prime to 6. (Here we avoid characteristic 3 for convenience and characteristic 2 by necessity.) Thus suppose that our surface \( X/k \) is \( \text{Spec}(\mathcal{A}) \) for a maximal order \( \mathcal{A} \) on the smooth surface \( Z \).

**Proposition 11.9.** A module \( M \in \text{coh} X \) is reflexive iff it is locally free as an \( \mathcal{A} \)-module.

**Proof.** For any point \( z \in Z \), \( \mathcal{A}_z = \mathcal{A} \otimes \mathcal{O}_{Z,z} \) has finite global dimension, and thus (applying \( \text{ad} \) to a sufficiently long resolution of \( \text{ad} M \) in powers of line bundles pulled back from \( Z \)) a reflexive sheaf is locally projective. Since \( \mathcal{A}_z \) is semilocal, \( M \) is free of rank \( n \) over \( \mathcal{A}_z \) iff for any simple \( \mathcal{A}_z \)-module \( N \), \( \dim_{k(z)} \text{Hom}(M, N) = \dim_{k(z)} \text{Hom}(\mathcal{O}_{X}^n, N) \). Now, \( N \) is a 0-dimensional sheaf defined over \( k(z) \), and thus for \( p > 0 \),

\[
\text{Ext}^p(M, N) = \text{Ext}^{p+2}(\text{ad}^2 M, \text{ad} M) = 0, \tag{11.12}
\]

so that

\[
\dim_{k(z)} \text{Hom}(M, N) = \chi(M, N) = \text{rank}(M)\chi(N) = \chi(\mathcal{O}_{X}^n, N) = \dim_{k(z)} \text{Hom}(\mathcal{O}_{X}^n, N), \tag{11.13}
\]

and thus \( M \) is free (of rank \( \text{rank}(M) \)) over \( \mathcal{A}_z \).

Since a sheaf is reflexive iff it is locally reflexive (localize at a prime associated to the support of \( R^2 \text{ad} M \) or \( R^1 \text{ad} M \)) and \( \mathcal{O}_{X}^n \) is reflexive, it follows that a locally free sheaf is reflexive.  

**Remark.** Note that “locally free of rank 1” is not a synonym for “line bundle” as we have defined the latter. Indeed, for \( M \in \text{Hilb}^{n,+}(X) \), the map \( M \to \text{ad} M \) is injective with 0-dimensional cokernel of Euler characteristic at most \( n \), so that if \( n < \text{ord}(q) \), then \( M \) is reflexive iff its restriction to \( Q \) is a line bundle.
We may thus represent a reflexive sheaf $M$ of rank $n$ via a 1-cocycle in $\Omega^1_{\mathcal{O}(A)}$, with the symplectic leaf condition that $M|_Q$ be constant corresponding to the requirement that the image of the cocycle in $H^1_{\text{ét}}(\text{GL}_n(\mathcal{O}_Q))$ be constant. (To be precise, this condition is that the image in $H^1_{\text{ét}}(\text{GL}_n(\mathcal{O}_Q))$ be constant, but any gauge transformation in $\text{GL}_n(\mathcal{O}_Q)$ making the cocycle constant can be lifted to $\text{GL}_n(A)$.) We thus obtain a family of cocycles taking values in the corresponding cosets of $\text{GL}_n(A,\mathcal{I}_Q)$, where $\mathcal{I}_Q$ is the ideal sheaf of $Q$ and $\text{GL}_n(A,I)$ denotes the kernel of $\text{GL}_n(A) \rightarrow \text{GL}_n(A/I)$.

To proceed further, we need to understand the isomorphism $\mathcal{I}_Q \cong \omega_X$. As an $A$-module, $\omega_X$ is represented by $\text{Hom}_{\mathcal{O}_Z}(A,\omega_Z)$, and the bimodule map

$$\alpha : \mathcal{I}_Q \cong \text{Hom}_{\mathcal{O}_Z}(A,\omega_Z)$$

may be expressed as a map $\tau : \mathcal{I}_Q \rightarrow \omega_Z$ such that $\tau(ab) = \tau(ba)$ for $a$ a local section of $A$ and $b$ a local section of $\mathcal{I}_Q$, and such that the induced bilinear form $(a,b) \mapsto \tau(ab)$ is a perfect pairing. Since the generic fiber of the central simple algebra, the condition $\tau(ab) = \tau(ba)$ implies $\tau$ has the form $\tau(b) = \text{Tr}(b)\omega$ where $\text{Tr}$ is the reduced trace and $\omega$ is some meromorphic 2-form on $Z$. Now, since $\mathcal{I}_Q' = A \otimes \mathcal{O}_Z(-Q')$, any element of $\mathcal{I}_Q$ is nilpotent on $\mathcal{O}_Q'$, and thus $\text{Tr} \mathcal{I}_Q \subset \mathcal{O}_Z(-Q')$. But multiplication by $\omega$ must be an isomorphism from $\text{Tr} \mathcal{I}_Q \rightarrow \omega_Z$, and thus $\text{Tr} \mathcal{I}_Q = \mathcal{O}_Z(-Q')$ and $\tau(b) = \alpha' \text{Tr}(b)$ where $\alpha' : \mathcal{O}_Z(-Q') \cong \omega_Z$ is a Poisson structure on $Z$ vanishing along $Q'$.

At this point, the proof of [39][§3.1] extends mutatis mutandis (the main change being to replace the trace on $\text{Mat}_n(\mathcal{O}_X)$ by the reduced trace on $\text{Mat}_n(A)$) to show that the corresponding 2-form is closed, and thus we have finished proving the following.

**Theorem 11.10.** Let $X/S$ be a noncommutative rational or rationally ruled surface over a reduced locally Noetherian base. Then the subspace of $\text{Spl}_X/S$ classifying simple sheaves has a natural Poisson structure, and if $S$ is a field, the fibers of derived restriction to $Q$ are a foliation by smooth symplectic leaves.

**Remark.** Since the moduli stacks of noncommutative rational surfaces and noncommutative rationally ruled surfaces of genus 1 are both reduced, the Theorem continues to hold in those cases even when the base scheme is nonreduced.

The ease with which the proof of the Jacobi identity extended suggests that it should be possible to generalize things further. With this in mind, let $X/k$ be a smooth projective surface over a field of characteristic not 2 and let $G/X$ be a smooth group scheme. (The construction actually works over more general base schemes on which 2 is invertible, as long as the global sections of $Z(G)$ are flat over the base.) Then the moduli stack $\mathcal{T}_{\text{Tors}_G}$ classifying étale-locally trivial $G$-torsors on $X$ (i.e., splittings of the map $[X/G] \rightarrow X$) has an open substack corresponding to “simple” torsors, those with automorphism group $\Gamma(Z(G))$. In particular, the isotropy substack is flat and locally of finite presentation, and thus this substack is a gerbe over an algebraic space $\text{Spl}_G$.

Now, suppose $H$ is a smooth normal subgroup of $G$ having the same generic fiber, and let $\tau$ be a $G$-invariant perfect pairing

$$\tau : \mathfrak{g} \otimes \mathfrak{h} \rightarrow \omega_X$$

which is symmetric on $\mathfrak{h}$. Then for any $G$-torsor $V$, $\tau$ induces a perfect pairing

$$H^1(\mathfrak{g}(V)) \otimes H^1(\mathfrak{h}(V)) \rightarrow H^2(\omega_X),$$

so that the cotangent sheaf at $V$ may be identified with $H^1(\mathfrak{h}(V))$ and we obtain a bivector as the composition

$$H^1(\mathfrak{h}(V)) \otimes H^1(\mathfrak{h}(V)) \rightarrow H^1(\mathfrak{g}(V)) \otimes H^1(\mathfrak{h}(V)) \rightarrow H^2(\omega_X).$$
Moreover, an infinitesimal deformation is tangent to a symplectic leaf iff it is in the kernel of the map $H^1(\mathfrak{g}(V)) \to H^1((\mathfrak{g}/\mathfrak{h})(V))$ and thus the symplectic leaves are the fibers of the map $\mathcal{S}pl_G \to \mathcal{T}ors_{G/H}$ taking $V$ to $V/H$.

Then a mild variation on the argument of [39, §3.1] shows that the above bivector induces a symplectic structure on any smooth symplectic leaf. In particular, this implies that $\mathcal{S}pl_G$ is Poisson as long as (a) it is reduced, and (b) the generic symplectic leaf is smooth.

Since the requisite changes to the argument are not completely trivial, we spell them out. Let $V/R$ be a family of simple $G$-torsors over a regular affine $k$-scheme Spec$(R)$, and suppose that $V$ lies in a symplectic leaf, i.e., that $V/H$ is étale-locally on $R$ the pullback of a $G/H$-torsor over $k$. We may then just as well replace $R$ by the relevant étale cover so that $V/H$ is isomorphic to a constant family. We may thus represent $V$ by a cocycle

$$g_{ij} \in \Gamma(U_{ij} \times R; G_R) \quad (11.18)$$

relative to some étale covering $U_i$ of $X$, with the property that each $g_{ij}H \in \Gamma(U_{ij}; G/H)$. (All we get a priori is that $g_{ij}H$ represents a constant class in $H^1_{et}(X; G/H)$, but since $H$ is smooth we can étale locally on $X_R$ lift the gauge transformations needed to make the cocycle itself constant.) The Kodaira-Spencer map of this family is then represented by the cocycle

$$\beta_{ij} = d_R g_{ij} g_{ij}^{-1} \in Z^1(\mathfrak{h}(V) \otimes \Omega_R), \quad (11.19)$$

which since $\Omega_R \cong T^*_R$ may be viewed as a map from $T_R$ to cocycles. Then the pairing associated to the bivector is defined on a pair of vectors in $T_R$ as

$$(t_1, t_2) \mapsto \tau(\beta_{ij}(t_1) \cup \beta_{ij}(t_2)) = \tau(\beta_{ij}(t_1), \text{Ad}(g_{ij})\beta_{jk}(t_2)) \in Z^2(\mathfrak{h}(V)). \quad (11.20)$$

Since this pairing is alternating on cohomology, the cocycle

$$\frac{1}{2} \tau(\beta_{ij}(t_1), \text{Ad}(g_{ij})\beta_{jk}(t_2)) - \frac{1}{2} \tau(\beta_{ij}(t_2), \text{Ad}(g_{ij})\beta_{jk}(t_1)) \quad (11.21)$$

represents the same class. (That the resulting cohomology class is independent of the choices made in defining $\beta$ follows by its relation to the well-defined bivector, but is also reasonably straightforward to verify directly.) We may write the corresponding 2-form by viewing $\beta$ as a cocycle in the tensor product algebra $U(\mathfrak{h}) \otimes \wedge^* \Omega_R$, and observing that $\tau$ gives a well-defined function on the elements of the universal enveloping algebra of degree $\leq 2$. We thus obtain a cocycle

$$\gamma_{ijk} = \frac{1}{2} \tau(\beta_{ij} \text{Ad}(g_{ij})\beta_{jk}) \in Z^2(\omega_X) \otimes \Omega^2_R, \quad (11.22)$$

and the corresponding class in $H^2(\omega_X) \otimes \Omega^2_R = \Omega^2_R$ is precisely the 2-form we need to show is closed.

We first note that rewriting $\beta_{jk}$ using the cocycle condition

$$\beta_{ij} - \beta_{ij} + \text{Ad}(g_{ij})\beta_{jk} = 0 \quad (11.23)$$

gives

$$\gamma_{ijk} = \frac{1}{2} \tau(\beta_{ij}\beta_{ik} - \beta^2_{ij}). \quad (11.24)$$

We may also compute the exterior derivative of $\beta$ as

$$d_R \beta_{ij} = -\beta^2_{ij}, \quad (11.25)$$

132
which makes sense since the square of an element of $\mathfrak{h} \otimes \Omega_R$ lies in $\mathfrak{h} \otimes \Omega_R^2$. (This calculation may be performed in any faithful representation of $G$, so reduces to the analogous statement in $\text{GL}_n$.) We thus find that

$$d_R\gamma_{ijk} = \frac{1}{2} \tau(d_R(\beta_{ij} \beta_{ik})) = -\frac{1}{2} \tau(\beta_{ij}^2 \beta_{ik}) - \frac{1}{2} \tau(\beta_{ij} \beta_{ik}^2) = -\frac{1}{6} d\tau(\beta_{ij}^3), \quad (11.26)$$

where the Čech coboundary calculation reduces to checking that if $\beta, \beta'$ are two elements of $\mathfrak{h} \otimes \Omega_R^1$, then

$$\tau(\beta^2 \beta') = \tau(\beta' \beta) = \tau(\beta' \beta^2). \quad (11.27)$$

It follows that $d_R\gamma_{ijk}$ is the coboundary of a class in $Z^1(\omega_X) \otimes \Omega_R^3$, and thus the 2-form represented by $\gamma$ is indeed closed.

Remark. Although we divided by 3 above, the calculation can still be made to work in characteristic 3. The key observation is that the alternating ternary form associated to $\frac{1}{3} \tau(\beta^3)$ may be expressed as $(t_1, t_2, t_3) \mapsto \tau(\beta(t_1), [\beta(t_2), \beta(t_3)])$.

This calculation does not quite suffice to show that the bivector is Poisson, as to finish the argument requires that $\mathfrak{sp}_1$ be reduced and the symplectic leaves be smooth. (In general, all we can conclude from the above calculation is that the trivector arising from the Jacobi identity vanishes on the Zariski closure of the points which are smooth in their symplectic leaf.)

Since $\mathfrak{sp}_1$ is reduced if its is geometrically smooth, we reduce to understanding smoothness at a point $V$. The obstructions at $V$ to $\mathfrak{sp}_G$ and the corresponding symplectic leaf lie in $H^2(\mathfrak{g}(V))$ and $H^2(\mathfrak{h}(V))$ respectively, so we need to understand those spaces. These are dual to $H^0(\mathfrak{h}(V))$ and $H^0(\mathfrak{g}(V))$, and simplicity of $V$ implies that the natural map $H^0(\mathfrak{Z}(\mathfrak{g})) \to H^0(\mathfrak{g}(V))$ is an isomorphism, so is $H^0(Z(\mathfrak{g}) \cap \mathfrak{h}) \to H^0(\mathfrak{h}(V))$. (In particular, the obstruction space to $\mathfrak{sp}_G$ at $V$ is 0 iff $\Gamma(\mathfrak{Z}(G) \cap H)$ is discrete, and for the symplectic leaf iff $\Gamma(\mathfrak{Z}(G))$ is discrete, but of course the spaces can have nontrivial obstructions yet still be smooth.) Now, suppose $N$ is a smooth connected normal subgroup of $G$ such that $\tau(\mathfrak{n}, \Gamma(\mathfrak{Z}(\mathfrak{g}) \cap \mathfrak{h})) = 0$. Then by pairing with $H^0(\mathfrak{h}(V)) = H^0(Z(\mathfrak{g}) \cap \mathfrak{h})$, we find that the natural map $H^2(\mathfrak{n}(V)) \to H^2(\mathfrak{g}(V))$ is 0, and thus $H^2(\mathfrak{v}(V)) \cong H^2((\mathfrak{g}/\mathfrak{n})(V))$. The latter is precisely the obstruction space to $\mathfrak{sp}_G$ at $V/N$, and we thus conclude that a deformation of $V$ extends in $\mathfrak{sp}_G$ iff the corresponding deformation of $V/N$ extends in $\mathfrak{sp}_{G/N}$, so we may reduce to understanding smoothness on the latter. Similarly, if $N$ also satisfies $\tau(\mathfrak{Z}(\mathfrak{g}), \mathfrak{n} \cap \mathfrak{h}) = 0$, then $H^2(\mathfrak{h}(V)) \cong H^2((\mathfrak{g}/\mathfrak{h} \cap \mathfrak{n})(V))$ and thus a deformation of $V$ in its symplectic leaf extends iff the corresponding deformation of $V/N$ has an extension which is trivial as an extension of $V/HN$. We should also note that each condition holds for $N_1$ and $N_2$, and thus we may, if we choose, take $N$ to be the unique maximal smooth connected normal subgroup satisfying the conditions.

These conditions on $N$ are somewhat subtle in complete generality, but in most cases it turns out that we can take $N$ to be the derived subgroup $G'$ of $G$ (i.e., the smallest normal subgroup of $G$ with abelian quotient). We first note that since $N$ and $H$ are smooth, it suffices to check the conditions over the generic point of $X$, which in particular shows that the second condition is strictly stronger than the first. Moreover, if $z \in \mathfrak{Z}(\mathfrak{g}(\mathfrak{k}(X)))$, $x \in \mathfrak{g}(\mathfrak{k}(X))$, $g \in G(\mathfrak{k}(X))$, then

$$\tau((\text{Ad}(g) - 1)x, z) = \tau(x, (\text{Ad}(g^{-1}) - 1)z) = 0, \quad (11.28)$$

and thus

$$\tau((\text{Ad}(G) - 1)\mathfrak{g}, \Gamma(\text{Lie}(\mathfrak{Z}(G)))) = 0. \quad (11.29)$$

In most cases (in characteristic 0, in particular), the Lie algebra of the derived subgroup is precisely this span, so that we may take $N = G'$. In that case, we find that $G/N = G^{ab}$ is abelian. So if
the algebraic group $\mathcal{S}p_{G_{\text{ab}}}$, is reduced, then $\mathcal{S}p_{G_{\text{ab}}}$ is smooth, and if the kernel of the homomorphism $\mathcal{S}p_{G_{\text{ab}}} \to \mathcal{S}p_{G_{\text{ab}}/HC_G}$ is smooth, then the symplectic leaves of $\mathcal{S}p_{G_{\text{ab}}}$ are smooth.

We thus see that in characteristic 0 (or if $\Gamma(Z(G))$ is discrete), the above construction always gives a smooth Poisson moduli space with smooth symplectic leaves, while in most other cases this typically reduces to a question about torsors over abelian group schemes. (This is of course directly analogous to what we found above for simple complexes.)

In particular, if $A$ is the maximal order corresponding to a noncommutative rational or rationally ruled surface, then we may take $G = \text{GL}_n(A)$, $H = \text{GL}_n(A, I_Q)$ above, so that the moduli space of simple reflexive $A$-modules may be identified with $\mathcal{S}p_{Q}$, and the bivector coming from the group scheme construction agrees with that coming from the interpretation as sheaves on a noncommutative surface. Modifying the groups slightly leads to other examples of Poisson moduli spaces of torsors. Indeed, $\tau$ induces a perfect pairing on $\mathfrak{gl}_n(O_Q)$ taking values in $(\omega_X \otimes k(Z))/\omega_X$, or, by taking residues, in $\omega_Q$. Thus if $G$, $H$ are two smooth subgroups of $\text{GL}_n(O_Q)$ such that $\mathfrak{g} = \mathfrak{h}^{\perp}$, then we may use their preimages in $\text{GL}_n(A)$ in the above calculation. In particular, we may take $G$ associated to the intersection of a parabolic subgroup of $\text{GL}_n(A \otimes k(X))$ with $\text{GL}_n(A)$, in which case $\mathfrak{g}^{\perp}$ is the Lie algebra of the group coming from the corresponding unipotent radical. In that case, the smoothness conditions reduce to the conditions for the original case, so we again obtain a Poisson moduli space with smooth symplectic leaves given by the fibers over $\mathcal{S}tor_{G/H}$. This corresponds to reflexive sheaves on $X$ with a filtration of $M|_Q$ by locally free sheaves of the appropriate ranks, with the symplectic leaves given by the fibers over the map to the associated graded of the filtration. (Compare [13].) This suggests in general that there should be a well-behaved (and Poisson) moduli space of simple objects in perf($X$) equipped with a filtration of $M|_Q$ by perfect objects. (Note that this is not quite fibered over $\mathcal{S}p_{X/S}$, as the notion of “simple” includes only those automorphisms that preserve the filtration. However, there is a fibration of derived moduli stacks and the fibers depend only on $M|_Q$, so this morally ought to reduce to a purely commutative question.)

As mentioned, the above argument only applies to sheaves, and thus new ideas are likely to be required for more general objects. Given that the symplectic leaves of $\mathcal{S}p_{X/S}$ are most naturally interpreted as fibers of a map to a derived stack this suggests (to B. Pym, who then suggested it to the author!) that one should look more closely at the morphism $\mathcal{M}_X \to \mathcal{M}_Q$. One can show (work in progress with Pym based on a result of Toën [48]) that when $S$ is a field of characteristic 0, this morphism is in fact a Lagrangian map to the 1-shifted symplectic derived stack $\mathcal{M}_Q$. This induces a 0-shifted Poisson structure on $\mathcal{M}_X$, and further gives 0-shifted symplectic structures on the fibers of the map. This in particular implies that the symplectic leaves of the derived stack of simple objects are indeed (0-shifted) symplectic, but the presence of obstructions means that this does not trivially imply the corresponding fact for the algebraic space. This does, however, give an alternate proof for the case of reflexive sheaves in characteristic 0, and thus, via the usual reductions, for general sheaves.

One should also note that the notions of shifted symplectic and Poisson structures have only been defined in characteristic 0, and the existence of commutative Poisson surfaces in characteristic 2 with nonreduced symplectic leaves implies that the main results being used in the construction cannot even be true as stated in arbitrary characteristic. That said, a full proof over general Noetherian base schemes of characteristic 0 would imply Poisson-ness on the Zariski closure of the characteristic 0 locus of the universal moduli space $\mathcal{S}p_{X/M}$.

Even this is not necessarily the “right” proof of the Poisson structure; in light of the discussion following Theorem 5.13, we expect that the symplectic structure on the moduli space of 1-dimensional sheaves disjoint from $Q$ is the semiclassical limit of a noncommutative deformation of
the moduli space (with parameter \(\text{Pic}^0(Q)/\text{Pic}^0(C)\)), and that there should be derived equivalences between these deformations extending the derived autoequivalences of the abelian fibration arising in the fully commutative case.

If \(F: \text{coh} \, X \to \text{coh} \, X'\) is an equivalence of categories, then there is a canonical natural isomorphism \(F\theta \cong \theta F\), and thus we can transport the anticanonical natural transformation \(\theta \to \text{id}\) through \(F\). In particular, we obtain a notion of a Poisson equivalence, in which the natural transformations \(\theta F \to F\) and \(F\theta \to F\) agree modulo the canonical natural isomorphism. We then find that a Poisson equivalence of categories induces a Poisson isomorphism between the moduli spaces of simple objects. (Presumably something similar applies for the derived moduli stacks. Also, we should really be saying “bivector-preserving”.) When \(X = X'\), we note that the anticanonical natural transformation is uniquely determined by the restriction-to-\(Q\) functor and a linear functional on \(H^1(O_Q)/H^1(O_C)\) (the image of the map \(H^1(O_Q) \to H^2(\omega_X)\)), and thus an autoequivalence of \(X\) is Poisson iff the induced automorphism of \(Q\) acts trivially on \(H^1(O_Q)/H^1(O_C)\). Note that there will typically be no nontrivial automorphisms of \(Q\) fixing \(q\), and thus the map being Poisson will be automatic.

Now, given a finite group \(G\), we may consider an action of \(G\) on \(\text{coh} \, X\) in the following weak sense: to each \(g \in G\), we associate a Poisson autoequivalence \(F_g\) of \(\text{coh} \, X\), in such a way that \(F_e = \text{id}\) and \(F_gF_h\) is isomorphic to \(F_{gh}\). Then \(G\) acts on \(\text{Spl}_X\) preserving the Poisson structure, and the fixed subspace of this action will inherit a Poisson structure. (Note that without additional consistency conditions on the natural isomorphisms, this does not give an action of \(G\) on the derived moduli stack or its truncation.)

In the commutative case, such an action of \(G\) on \(\text{coh} \, X\) is determined by a combination of its action on point sheaves and a class in \(H^1(G; \text{Pic}(X))\), determining its action on the structure sheaf. Then a simple sheaf \(M\) corresponds to a \(G\)-fixed point of \(\text{Spl}_X\) iff for each \(g \in G\), there is an isomorphism \(M \cong F_gM\). If we fix a system of such isomorphisms (which should be the identity for \(g = e\)), then we have an induced isomorphism \(F_{gh}M \cong M \cong F_hM \cong F_gF_hM\) for each \(g, h\), and those isomorphisms will satisfy the obvious consistency conditions. In particular, since we can write \(F_gM \cong (g^{-1})^*M \otimes L_g\) with \(L_{gh} \cong L_g \otimes (g^{-1})^*L_h\), we find that there are induced choices for the latter morphisms making them consistent. In other words, any \(G\)-fixed point of \(\text{Spl}_X\) promotes the class in \(H^1(G; \text{Pic}(X))\) to an equivariant gerbe (with trivial underlying gerbe), and this makes the corresponding sheaf \(M\) a twisted \(G\)-equivariant sheaf. (This choice is not unique, as we can twist the isomorphisms \(M \cong F_gM\) by any class in \(H^1(G; k^*)\).) When the twisting is trivial, these are sheaves on the orbifold quotient \([X/G]\), which is itself (in characteristic prime to \(|G|\)) derived equivalent to a commutative projective surface via the derived McKay correspondence [14]. (More precisely, it is derived equivalent to the minimal desingularization of the scheme-theoretic quotient \(X/G\).)

Something similar holds in the noncommutative setting: the only natural automorphisms of the identity functor are scalars, and thus the obstruction to making the natural isomorphisms \(F_gF_h \cong F_{gh}\) compatible is a class in \(H^3(G; k^*)\), which vanishes as long as there is any fixed point in \(\text{Spl}_X\). If that class vanishes, then the different compatible choices form a torsor over \(H^2(G; k^*)\), and each such choice gives a disjoint (possibly empty) subset of \((\text{Spl}_X)^G\). Each fixed point then corresponds to a collection of (twisted) \(G\)-equivariant sheaves, which themselves form a torsor over \(H^1(G; k^*)\). We thus see that these fixed subspaces are closely related to the moduli space of simple (twisted) \(G\)-equivariant sheaves, though in addition to the \(H^1(G; k^*)\) action, we must also bear in mind that a simple equivariant sheaf need not have simple underlying sheaf, and thus the fixed subspaces are at best quotients of open subsets of the “correct” moduli spaces. (This issue goes away if we consider the stack version, where we must fix a consistent family of natural isomorphisms,
but should then get the full moduli stack of $G$-equivariant objects, suitably defined.) Presumably there is also an analogue of the derived McKay correspondence in this case as well.

We can also obtain Poisson automorphisms of $\mathcal{S}pl_X$ associated to contravariant equivalences. To construct such automorphisms, we first note that for any $d \in \mathbb{Z}$, we have a contravariant derived equivalence $M \mapsto (R \text{ad } M)[d]$. This in general changes the surface, by inverting $q$, but we can sometimes fix this by composing with an abelian equivalence $\text{coh } X \cong \text{coh } X$, as which above will tend to give a Poisson autoequivalence.

We finally turn to the more classical types of moduli spaces, classifying stable (or semistable) sheaves. The usual argument of Langton \cite{Langton} shows that the stable moduli space (an open subspace of $\mathcal{S}pl_{X/S}$) is separated and the semistable moduli space is proper, but of course one expects in general that they should be (quasi-)projective. The standard construction involves inequalities proved by induction involving general hyperplane sections, and thus is difficult to extend in general. (Though of course for rank 1 sheaves, we have already shown this above!) In the elliptic rational case, this issue was finessed for 1-dimensional sheaves, and it turns out that the basic ideas carry over to general ruled surfaces. (The question of projectivity of the moduli space of semistable sheaves of rank $> 1$ remains open.)

Looking at the argument used in \cite{Langton}, we see that the key results are Corollary 11.64 and Proposition 11.65 op. cit. The first result in turn reduces to Lemma 11.42 op. cit., which holds on general rational or rationally ruled surfaces in the following form, with the same proof.

**Lemma 11.11.** \cite{Langton} Lem. 11.42 Let $X/k$ be a noncommutative rational or rationally ruled surface of genus $g > 1$, and let $M \in \text{coh } X$ be globally generated. Then for any line bundle $L$ such that $c_1(M) + c_1(L) - Q$ is ineffective and $\text{Ext}^p(L, \mathcal{O}_X) = 0$ for $p > 0$, we have $\text{Ext}^p(L, M) = 0$ for $p > 0$.

Of course, the condition that $\text{Ext}^p(L, \mathcal{O}_X) = 0$ holds for rational surfaces if $-c_1(L)$ is nef and $-c_1(L) \cdot Q > 0$, and for rationally ruled surfaces of higher genus if $-c_1(L) - (2g - 1)f$ is nef.

We then find the following by the same argument as in the elliptic case. Call an ample divisor class $D_a$ “strongly ample” if $D_a - 2gf$ is nef and, if $g = 0$, $D_a \cdot Q \geq 2$. Clearly, every ample divisor class has a positive multiple which is strongly ample, and replacing it by the latter leaves the associated stability condition unchanged.

**Corollary 11.12.** \cite{Langton} Cor. 11.64 Let $D_a$ be a strongly ample divisor class. If $M$ is a semistable 1-dimensional sheaf on $X$ with $c_1(M) \cdot D_a = r > 0$ and $\chi(M) > r^2(r + 1)$, then $M$ is acyclic and globally generated.

Similarly, for the other result we need, the argument carries over and reduces to the following fact.

**Lemma 11.13.** \cite{Langton} Lem. 11.41 If $M$ is a pure 1-dimensional sheaf of Chern class $df$ on a noncommutative quasi-ruled surface, then there is a filtration $M_i$ of $M$ such that each subquotient $M_{i+1}/M_i$ is a pure 1-dimensional sheaf of Chern class $f$ and such that

$$\chi(M_1) \geq \chi(M_2/M_1) \geq \cdots \geq \chi(M/M_{d-1}).$$

(11.30)

**Proof.** The one part of the proof op. cit. that needs to be established is that a globally generated sheaf of rank 0 and Chern class $df$ has Euler characteristic at least $d$. If $D$ is a divisor class such that both $D$ and $df - D$ are effective, then (since $f$ is nef and $f^2 = 0$) $D \cdot f = 0$, and thus $D \propto f$, so that we may reduce to the case of a quotient of $\mathcal{O}_X$, where it is immediate from Corollary 10.16.
Corollary 11.14. \cite{42} Prop. 11.65] Let $D$ be a strongly ample divisor class on the noncommutative rational or rationally ruled surface $X$. Then for any pure 1-dimensional sheaf $M$ and any line bundle $L$ of class $-D$, there is a homomorphism $\phi : L \to \mathcal{O}_X$ such that $\text{Hom}(\text{coker} \phi, M) = 0$.

**Proof.** As in \cite{42}, we may reduce to the case that $M$ is irreducible and disjoint from $Q$ (in particular ruling out noncommutative planes and odd Hirzebruch surfaces). Moreover, by considering those $\phi$ that vanish to suitable order on $Q$, we may arrange to have $D \cdot e_m = 0$ (in some blowdown structure), and then reduce to the corresponding question on the blowdown. (One caveat is that for ruled surfaces of positive genus, the conclusion does not actually hold for $g = 0$, $m = 7$, $D = 2Q$ case of the reduction.) This reduces to ruled surfaces, where we note that the existence of a sheaf disjoint from $Q$ implies the parity is even and either $g = 0$ and $Q$ is integral of class $2s + 2f$, or $g \geq 0$ and $Q$ is the sum of two (possibly identical) curves of class $s + (1 - g)f$. Thus by considering $\phi$ that vanishes on an integral component of $Q$, we may similarly reduce to the case that either $D \cdot f = 0$ or, when $g = 0$ and $Q$ is integral, $D \cdot f = 1$. Since $M$ has Chern class a positive multiple of $s + (g - 1)f$ and the kernel of a nonzero morphism $\text{coker} \phi \to M$ has Chern class $D - c_1(M)$, we can rule out the $D \cdot f = 0$ case entirely, while the remaining case may be dealt with as in the case that $Q$ is elliptic: the support of $\text{coker} \phi|_Q$ is the same as that of $\ker \phi|_Q$, which is easy to control since $\ker \phi$ is an extension of sheaves of class $Q$ and $Q$ is integral. \qed

These results imply an analogue of the Le Potier-Simpson bound and from that a proof of projectivity.

Lemma 11.15. \cite{42} Lem. 11.66] Let $D_a$ be a strongly ample divisor class. If $M$ is a semistable 1-dimensional sheaf with $c_1(M) \cdot D_a = r$, then $h^0(M) \leq \max((r + 1)^3 + \chi(M), 0)$.

Theorem 11.16. \cite{42} Thm. 1.67] Let $D$ be an effective divisor class and let $D_a$ be an ample divisor class. Then the moduli problem of classifying $S$-equivalence classes of $D_a$-semistable sheaves $M$ with $\text{rank}(M) = 0$, $c_1(M) = D$ and $\chi(M) = l$ is represented by a projective scheme $M_{D,a}$. The stable locus $M_{D,a}^{\text{stable}}$ is a Poisson subscheme, which is smooth if $D \cdot Q > 0$, as is the Zariski closure of the sublocus with $M|_Q = 0$ if $D \cdot Q = 0$. If $\mathbb{Z}[M] \subset K_0^{\text{num}}(X)$ is a saturated sublattice, then the stable locus admits a universal family.

As in \cite{42}, there are a number of cases in which we can identify the (semi)stable moduli space as a particular projective rational surface. The proofs in \cite{42} used the corresponding special case of the derived equivalences coming from Theorem 5.13 but the arguments are difficult to translate directly, as they depended strongly on the fact that when $Q$ is smooth, any simple object in $D_{\text{coh}}^0(Q)$ is a shift of a stable sheaf.

Luckily, we can mostly replace this by the following fact.

Lemma 11.17. Let $X/k$ be a noncommutative rational surface over an algebraically closed field, with anticanonical curve $Q$ such that $Q^2 = 0$ and no component of $Q$ has self-intersection $< -2$, and let $r, l$ be relatively prime integers with $r > 0$. Also let $D_a$ be an ample divisor class such that any $D_a$-semistable 1-dimensional sheaf with $c_1(M) = rQ$, $\chi(M) = l$ is $D_a$-stable. Then the moduli space of such sheaves supported on $Q$ is isomorphic to $Q$, and the Fourier-Mukai functor associated to the universal family is a derived autoequivalence of $Q$.

**Proof.** If $Q$ is smooth, this follows as in \cite{42}. Otherwise, we choose a blowdown structure such that $D_a$ is in the fundamental chamber. We then claim that we can embed $Q$ as a fiber in a commutative
rational elliptic surface $X'/k$ (with generically smooth fibers and a section), in such a way that there is an ample divisor on $X'$ inducing the same stability condition on $Q$.

Embedding $Q$ as a fiber of some $X'$ is straightforward; indeed, in characteristic not 2 or 3, we may simply obtain $X'$ from $X$ by passing to the corresponding commutative surface, blowing down a $-1$-curve, then blowing up the base point of the anticanonical linear system. In characteristic 2 or 3, we observe that the quasi-elliptic fibrations form a closed substack of the moduli stack of rational elliptic surfaces, and thus to show that the substack having $Q$ as a fiber contains elliptic fibrations, it suffices to show this for the closure of the substack (letting us degenerate $Q$). The maximally degenerate Kodaira types on a rational elliptic surface are $I_0$, $I_1^*$, and $II^*$; the first cannot appear on a quasi-elliptic fibration, while the latter two can only appear in characteristic 2 or 3 respectively. It thus suffices to observe that the elliptic curve

$$E/\mathbb{F}_2(t) : y^2 + xy = x^3 + tx^2 + x$$

has rational minimal proper regular model with a fiber of type $I_1^*$, while the elliptic curve

$$E/\mathbb{F}_3(t) : y^2 = x^3 + x + t$$

has rational minimal proper regular model with a fiber of type $II^*$.

Having chosen $X'$, let $D'$ be a divisor on $X'$ that has the same restriction to $Q$ as a positive integer multiple of $D_0$. (In the direct construction of $X'$, we may of course take $D' = D_0$, but note that this need not be ample on $X'$.) If we apply the algorithm to put $D'$ in the fundamental chamber, then any time we would wish to reflect in an effective root, that root cannot be a component of $Q$, and thus performing that reflection will have no effect on the induced stability condition. We may thus assume that $D'$ has nonnegative intersection with every simple root, and then by adding a suitable multiple of $Q$, that it has positive intersection with $e_8$. If it is not ample, then this is because it has intersection 0 with some component of a fiber other than $Q$; if we multiply $D'$ by 3 and then add all components of other fibers that it does intersect, this again has no effect on the stability condition, but strictly decreases the set of bad components. We thus need do this only finitely many times before eventually getting an ample divisor as desired, which we can then perturb as needed to eliminate any remaining strictly semistable sheaves of the desired invariants.

Now, the surface $X'$ has a pencil of generically smooth anticanonical curves, so we may choose a smooth anticanonical curve $Q'$ in $X'$. Thus by [42, Thm. 11.70], the moduli space of $D'$-semistable sheaves on $X'$ with the specified invariants is isomorphic to $X'$, and the isomorphism respects the elliptic fibration. It follows therefore that the subscheme corresponding to sheaves supported on $Q$ is isomorphic to $Q$ as required. Moreover, the universal family on $X'$ induces a derived autoequivalence by the proof op. cit., and this restricts to a derived autoequivalence of $Q$. □

We recall the notation used above in Theorem 5.13: we fix a (possibly degenerate) commutative del Pezzo surface $Y$ with anticanonical curve $Q$, and let $X_{z,q}$ be the 2-parameter family of noncommutative surfaces obtained from $Y$ by blowing up a point and taking the noncommutative deformation, with parameters $z \cong \text{det}(\mathcal{O}_Q|Q)$ and $q \cong \text{det}([\text{pt}]|Q)$.

**Proposition 11.18.** Let $r, d$ be relatively prime integers with $r > 0$, and let $z, q$ be such that $z^r q^d$ is torsion, of exact order $l$. Then the moduli space of stable 1-dimensional sheaves on $X_{z,q}$ with Chern class $rQ$ and Euler characteristic $ld$ is nonempty and contains irreducible sheaves.

**Proof.** Let $R$ be a dvr with residue field $k$ and field of fractions $K$ with $\text{char}(K) = 0$, and let $Y^+/R$ be a lifting of $Y$ to $R$ as an anticanonical del Pezzo surface in such a way that the generic fiber of $Q^+$ is smooth. Then (up to an étale extension of $R$), we may lift $q$ and $z$ as well (inside the
smooth scheme where the torsion condition is satisfied), so as to obtain a lift $X_{+,q}$. (Moreover, the ample line bundle on the special fiber lifts to an ample line bundle.) The semistable moduli space of the generic fiber of the lift is nonempty by [42, Prop. 12.8], and the component containing stable sheaves disjoint from $Q$ is a smooth surface. The limit in the special fiber of any sheaf in that component satisfies $\theta M \cong M$, and thus dimension considerations (and properness) imply that the semistable moduli space of the special fiber also contains sheaves disjoint from $Q$. That the generic such sheaf is irreducible (thus stable) follows as in the proof op. cit. for the generic fiber. 

**Remark.** If $l$ is a nontrivial multiple of the order of $q$, then the generic semistable sheaf on $X^+$ is a direct sum, so is not simple, and thus semicontinuity shows that this is inherited by all semistable sheaves, including on the special fiber, so that there are no stable sheaves in this case.

**Remark.** In [42], it was also shown that the obstruction to a existence of a sheaf over the generic point of the stable moduli space containing sheaves disjoint from $X$ is equivalent to having a sub- or quotient sheaf of Chern class $c_1(M) = rQ$, $\chi(M) = d$ is stable. Then the corresponding semistable moduli space is isomorphic to $X_{w,1}$.

**Theorem 11.19.** With $Y$, $Q$ fixed, let $w \in \operatorname{Pic}^0(Q)$. Let $r, d$ be relatively prime integers with $r > 0$, and let $D_w$ be an ample divisor class such that any semistable 1-dimensional sheaf on $X_{w-d,w^r}$ with $c_1(M) = rQ$, $\chi(M) = d$ is stable. Then the corresponding semistable moduli space is isomorphic to $X_{w,1}$.

**Proof.** It follows as in the proof of [42, Thm. 11.70] for the $Q$ smooth case that any component $M$ of the stable moduli space containing sheaves disjoint from $Q$ (which exist by the Proposition) is derived equivalent to $X_{w-d,w^r}$. Composing with the derived equivalence coming from Theorem 5.13 gives a derived equivalence $D^b_{\text{coh}}M \cong D^b_{\text{coh}}X_{w,1}$ preserving rank and Euler characteristic. If $w$ is not torsion, this already induces the desired isomorphism, by [23, Thm. 3.2]. Otherwise, $X_{w,1}$ is a genus 1 fibration (with one fiber of the form $\text{ord}(w)Q$), and the derived equivalence respects this fibration. It follows that it takes smooth points of integral fibers to shifts of smooth points of integral fibers, and thus the support of the corresponding Fourier-Mukai kernel is 2-dimensional, so that the proof of [23] still applies.

Since the subscheme of the semistable moduli space consisting of sheaves supported on $Q$ is geometrically isomorphic to $Q$, so geometrically connected, it follows that there is at most one component of the semistable moduli space containing such sheaves, and thus $M$ is the only component of the semistable moduli space, as required. 

One thing which is not quite settled by the above discussion is when the moduli space of simple (or stable) sheaves (with fixed class in $K^\num_0(X)$, say) is nonempty. This is most interesting in the case of 1-dimensional sheaves, as these are the ones that correspond to differential or difference equations, and in particular in the case of 1-dimensional sheaves disjoint from $Q$. For such sheaves, we could also ask a harder question, namely whether there are any irreducible sheaves, i.e., such that any nonzero subsheaf has the same Chern class. Such a sheaf corresponds to an equation which is irreducible in a quite strong sense: there is no gauge transformation over $k(C)$ that makes the equation become block triangular, or its singularities become simpler. (The singularities becoming simpler corresponds to having a sub- or quotient sheaf of Chern class $f - e_i - e_j$ or $e_i - e_j$.)

For simple sheaves in general, the above smoothness results give the following reduction (analogous to the one we used above for reflexive sheaves).

**Proposition 11.20.** Let $X/R$ be a split noncommutative rationally ruled surface over the dvr $R$ with field of fractions $K$, and let $[M] \in K^\num_0(X)$ be a class such that $\text{rank}([M]) \neq 0$ or $c_1([M]) \cdot Q \neq 0$. For such a class $[M]$, there exists a derived equivalence $D^b_{\text{coh}}X \cong D^b_{\text{coh}}Y$ with $Y$ a smooth scheme where the torsion condition is satisfied, so as to obtain a lift $X_{+,q}$. (Moreover, the ample line bundle on the special fiber lifts to an ample line bundle.) The semistable moduli space of the generic fiber of the lift is nonempty by [42, Prop. 12.8], and the component containing stable sheaves disjoint from $Q$ is a smooth surface. The limit in the special fiber of any sheaf in that component satisfies $\theta M \cong M$, and thus dimension considerations (and properness) imply that the semistable moduli space of the special fiber also contains sheaves disjoint from $Q$. That the generic such sheaf is irreducible (thus stable) follows as in the proof op. cit. for the generic fiber. 

**Remark.** If $l$ is a nontrivial multiple of the order of $q$, then the generic semistable sheaf on $X^+$ is a direct sum, so is not simple, and thus semicontinuity shows that this is inherited by all semistable sheaves, including on the special fiber, so that there are no stable sheaves in this case.

**Remark.** In [42], it was also shown that the obstruction to a existence of a sheaf over the generic point of the stable moduli space containing sheaves disjoint from $X$ is equivalent to having a sub- or quotient sheaf of Chern class $c_1(M) = rQ$, $\chi(M) = d$ is stable. Then the corresponding semistable moduli space is isomorphic to $X_{w,1}$.

**Theorem 11.19.** With $Y$, $Q$ fixed, let $w \in \operatorname{Pic}^0(Q)$. Let $r, d$ be relatively prime integers with $r > 0$, and let $D_w$ be an ample divisor class such that any semistable 1-dimensional sheaf on $X_{w-d,w^r}$ with $c_1(M) = rQ$, $\chi(M) = d$ is stable. Then the corresponding semistable moduli space is isomorphic to $X_{w,1}$.

**Proof.** It follows as in the proof of [42, Thm. 11.70] for the $Q$ smooth case that any component $M$ of the stable moduli space containing sheaves disjoint from $Q$ (which exist by the Proposition) is derived equivalent to $X_{w-d,w^r}$. Composing with the derived equivalence coming from Theorem 5.13 gives a derived equivalence $D^b_{\text{coh}}M \cong D^b_{\text{coh}}X_{w,1}$ preserving rank and Euler characteristic. If $w$ is not torsion, this already induces the desired isomorphism, by [23, Thm. 3.2]. Otherwise, $X_{w,1}$ is a genus 1 fibration (with one fiber of the form $\text{ord}(w)Q$), and the derived equivalence respects this fibration. It follows that it takes smooth points of integral fibers to shifts of smooth points of integral fibers, and thus the support of the corresponding Fourier-Mukai kernel is 2-dimensional, so that the proof of [23] still applies.

Since the subscheme of the semistable moduli space consisting of sheaves supported on $Q$ is geometrically isomorphic to $Q$, so geometrically connected, it follows that there is at most one component of the semistable moduli space containing such sheaves, and thus $M$ is the only component of the semistable moduli space, as required. 

One thing which is not quite settled by the above discussion is when the moduli space of simple (or stable) sheaves (with fixed class in $K^\num_0(X)$, say) is nonempty. This is most interesting in the case of 1-dimensional sheaves, as these are the ones that correspond to differential or difference equations, and in particular in the case of 1-dimensional sheaves disjoint from $Q$. For such sheaves, we could also ask a harder question, namely whether there are any irreducible sheaves, i.e., such that any nonzero subsheaf has the same Chern class. Such a sheaf corresponds to an equation which is irreducible in a quite strong sense: there is no gauge transformation over $k(C)$ that makes the equation become block triangular, or its singularities become simpler. (The singularities becoming simpler corresponds to having a sub- or quotient sheaf of Chern class $f - e_i - e_j$ or $e_i - e_j$.)

For simple sheaves in general, the above smoothness results give the following reduction (analogous to the one we used above for reflexive sheaves).

**Proposition 11.20.** Let $X/R$ be a split noncommutative rationally ruled surface over the dvr $R$ with field of fractions $K$, and let $[M] \in K^\num_0(X)$ be a class such that $\text{rank}([M]) \neq 0$ or $c_1([M]) \cdot Q \neq 0$. For such a class $[M]$, there exists a derived equivalence $D^b_{\text{coh}}X \cong D^b_{\text{coh}}Y$ with $Y$ a smooth scheme where the torsion condition is satisfied, so as to obtain a lift $X_{+,q}$. (Moreover, the ample line bundle on the special fiber lifts to an ample line bundle.) The semistable moduli space of the generic fiber of the lift is nonempty by [42, Prop. 12.8], and the component containing stable sheaves disjoint from $Q$ is a smooth surface. The limit in the special fiber of any sheaf in that component satisfies $\theta M \cong M$, and thus dimension considerations (and properness) imply that the semistable moduli space of the special fiber also contains sheaves disjoint from $Q$. That the generic such sheaf is irreducible (thus stable) follows as in the proof op. cit. for the generic fiber. 

**Remark.** If $l$ is a nontrivial multiple of the order of $q$, then the generic semistable sheaf on $X^+$ is a direct sum, so is not simple, and thus semicontinuity shows that this is inherited by all semistable sheaves, including on the special fiber, so that there are no stable sheaves in this case.

**Remark.** In [42], it was also shown that the obstruction to a existence of a sheaf over the generic point of the stable moduli space containing sheaves disjoint from $X$ is equivalent to having a sub- or quotient sheaf of Chern class $c_1(M) = rQ$, $\chi(M) = d$ is stable. Then the corresponding semistable moduli space is isomorphic to $X_{w,1}$.
0. If there is a separable extension \( l/k \) and a simple sheaf \( M_l \) of this class on \( X_l \), then there is a flat family of sheaves on the base change of \( X \) to an étale extension of \( R \) such that the special fiber is isomorphic to \( M_l \) and the generic fiber is simple.

**Proof.** Since any separable extension \( l/k \) lifts to an étale extension of \( R \), we may assume \( l = k \). The conditions on \([M]\) ensure that the moduli space of simple sheaves is unobstructed, and thus the point corresponding to \( M_k \) extends to an étale neighborhood, and is in turn étale locally represented by a sheaf.

This has a variant in the disjoint-from-\( Q \) case.

**Proposition 11.21.** Let \( X/R \) be a split noncommutative rationally ruled surface over the dvr \( R \) with field of fractions \( K \), and let \([M] \in K_0^{\text{num}}(X/K)\) be a 1-dimensional class such that \( \det([M]|_Q) \in \text{Pic}^0(C_K) \). If there is a separable extension \( l/k \) and a simple sheaf \( M_l \) of this class on \( X_l \) with \( M_l|_Q = 0 \), then there is a flat family of sheaves on the base change of \( X \) to an étale extension of \( R \) such that the special fiber is isomorphic to \( M_l \) and the generic fiber is simple and disjoint from \( Q \).

**Proof.** Although the moduli space of sheaves is obstructed, the determinant condition ensures that the obstruction is “orthogonal” to \( R \), and thus we still have the desired étale local extensions.

**Proposition 11.22.** Let \( X/R \) be a noncommutative rationally ruled surface over the dvr \( R \), and let \( M \) be an \( R \)-flat coherent sheaf such that \( M_k \) is an irreducible 1-dimensional sheaf. Then so is \( M_K \).

**Proof.** Suppose \( M_K \) is not irreducible, and let \( N_K \) be an irreducible pure 1-dimensional quotient of \( M_K \). Then \( N_K \) extends to \( R \) (albeit not necessarily as a quotient of \( M \)), and we may further arrange for that extension \( N \) to have pure 1-dimensional fibers. (Indeed, by properness, we may arrange for \( N_k \) to be semistable!) Then semicontinuity tells us that \( \dim \text{Hom}(M_k, N_k) \geq \dim \text{Hom}(M_K, N_K) > 0 \), so that there is a nonzero homomorphism from \( M_k \) to \( N_k \). But the kernel and image of this homomorphism have nonzero Chern class, contradicting irreducibility of \( M_k \).

In particular, if we start with a geometrically irreducible (thus simple) sheaf on \( k \) and use the previous Propositions to lift it to a family of simple sheaves on an étale cover of \( R \), the generic fiber of that family will also be geometrically irreducible.

In general, if we are given a surface \( X/K \) and a class in \( K_0^{\text{num}}(X) \) and want to know whether simple sheaves (or simple sheaves disjoint from \( Q \)) of the given class exist (over \( \bar{K} \), but then by smoothness over \( K^{\text{sep}} \)), these results suggest the following strategy. (This is inspired by the strategy used in [5, §8] to prove noncommutative planes are Noetherian.) First, since the moduli stack of surfaces is locally of finite type over \( Z \), the point corresponding to \( X \) factors through a field of finite transcendence degree over its prime field, and thus \( X \) itself is the base change of a surface defined over such a field. We thus reduce to the case that \( K \) itself has finite transcendence degree. Any irreducible Cartier divisor on the closure of \( X \) in the moduli stack induces a valuation on \( K \) and an extension of \( X \) to an étale extension of the corresponding valuation ring. By the Propositions, if the desired simple sheaves exist on the special fiber of this family, then they exist on some separable cover of \( K \), and thus it will suffice in general to settle the question in the case that \( K \) is finite! (It will be helpful to make one small refinement: we may choose the smooth neighborhood in the moduli stack in such a way that every surface in the closure of \( X \) has an anticanonical curve with the same combinatorial structure, and in the rational case remains smooth or nodal when appropriate.)
The advantage of having $K$ be finite is that since $\text{Pic}^0(Q_K)/\text{Pic}^0(C_K)$ is finite, $q$ will necessarily have finite order, and thus any surface over a finite field is a maximal order. This opens up the ability to use commutative techniques in constructing the desired sheaves. This is particularly powerful in the case of irreducible 1-dimensional sheaves, since we can then consider the support of the sheaf.

We thus consider the following problem. For any Chern class $D \in \text{NS}(X)$ and Euler characteristic $\chi \in \mathbb{Z}$, we want to know if there are irreducible sheaves on $X/K^{\text{sep}}$ with the given invariants (and, if $D \cdot Q = 0$, disjoint from $Q$). The usual reductions clearly apply: if $D$ has negative intersection with a component of $Q$, then it must be that component to be irreducible, so we may as well assume that all such intersections are nonnegative. We may then attempt to reduce $D$ to the fundamental chamber. If this fails because $D \cdot f$ becomes negative or because we attempt to reflect in an effective simple root, this shows that a sheaf of class $D$ cannot be irreducible, unless $D$ is actually equal to the offending simple root. (In that case, we know that an irreducible sheaf exists whenever $D$ and $\chi$ satisfy the appropriate determinant condition, and the result will be disjoint from $Q$.)

We thus reduce to the case that $D$ is in the fundamental chamber, letting us ignore the possibility that the specializations we apply to $K$ may introduce additional $-2$-curves. (We have already assumed that they do not change the structure of $Q$.) When $X$ is given by a maximal order $A$ of degree $l$, we may identify the Néron-Severi groups of $X$ and its center $Z$, and find by Proposition 7.17 that the support of a sheaf of Chern class $D$ on $X$ is a divisor of class $D$ on $Z$. Conversely, given an integral curve $C_D$ on the center which has this class and is transverse to the anticanonical curve, the fiber of $X$ over $K(C_D)$ will be a central simple algebra. The Brauer group of $K^{\text{sep}}(C_D)$ is trivial (since it has transcendence degree 1 over a separably closed field), and thus there is some separable extension $L/K$ such that $A \otimes L(C_D) \cong \text{Mat}_l(L(C_D))$. We may WLOG assume that $L = K$ and thus that $A \otimes K(C_D)$ has a simple module of dimension $l$ as a vector space over $K(C_D)$. If we view this as an $O_{C_D}$-module, we may certainly extend it to a torsion-free coherent sheaf $M'$ on $C_D$, and can then obtain a coherent $A_{|C_D}$-module with the same generic fiber as the image of $A \otimes M' \to M' \otimes K(C_D)$. This $A_{|C_D}$-module is of course also a coherent $A$-module $M$. Any nonzero subsheaf of $M$ has the same generic fiber over $C_D$, so has 0-dimensional quotient, and thus $M$ is an irreducible sheaf of the desired Chern class. Directly controlling the Euler characteristic of this sheaf is somewhat tricky, but is unnecessary. Indeed, if the support is transverse to $Q$ but not disjoint, then we can add any integer to the Euler characteristic by modifying the sheaf at such a point. If the support is disjoint from $Q$, we can still add any multiple of $l$ to the Euler characteristic, and this is enough to give any Euler characteristic satisfying the requisite determinant condition.

In the rational case, we obtain the following for irreducible sheaves disjoint from $Q$. Note that since changing the Euler characteristic multiplies the determinant of restriction by a power of $q$, we have a natural restriction map $\text{NS}(X) \to \text{Pic}(Q)/\langle q \rangle$. Let $Q_l, 0 \leq l \leq m$ denote the pullback to $X$ of the class of the anticanonical curve on $X_l$.

**Proposition 11.23.** Let $X/k$ be a noncommutative rational surface, and let $D \in \text{NS}(X)$, $\chi \in \mathbb{Z}$ be such that (a) $D$ is nef and in the fundamental chamber, and (b) if $[M] \in K_0^{\text{max}}(X)$ is the class of rank 0 sheaves with Chern class $D$ and Euler characteristic $\chi$, then $\det([M]|_Q) \cong O_Q$. Then there is an irreducible sheaf $M$, disjoint from $Q$, of class $[M]$ unless either (a) $D = rQ_8$ and $Q_8|Q \in \text{Pic}(Q)/\langle q \rangle$ has order $r'$ strictly dividing $r$, or (b) $D = rQ_8 + e_8 - e_9$ and $Q_8|Q \in \langle q \rangle$.

**Proof.** If $X$ is a maximal order, then the given conditions ensure that the corresponding linear system on the center contains irreducible divisors disjoint from the anticanonical curve ([41] Thm. 4.8)), and thus per the discussion above ensures the existence of suitable irreducible sheaves on $X$. 141
If \( D \notin \mathbb{Z} Q_8 \cup (e_8 - e_9) + \mathbb{Z} Q_8 \), then this is already enough to give the desired existence result on general surfaces over fields, by induction along valuations. To make this work in the remaining cases, we need merely observe that we can always choose a valuation on a separable extension of \( K \) in such a way that the order of \( Q_8 \) in \( \text{Pic}(Q)/\langle q \rangle \) does not change, and thus when we reach a finite field will again have the requisite irreducible curves.

\[ \Box \]

**Remark.** Analogous results of course apply to the case that \( D \cdot Q > 0 \), since we again [18, 41] know the possible ways such a divisor class on the center can fail to be generically irreducible.

The situation in the two remaining cases is more subtle. The first case was dealt with in Proposition 11.18 (and the remark following), completely determining in which subcases irreducible sheaves can exist. In the second case, irreducible sheaves in fact never exist. We may assume \( q \) non-torsion (since otherwise the support makes sense and is reducible) and first note that by twisting by a suitable multiple of \( e_7 \), we may ensure that there are irreducible sheaves disjoint from \( Q \) with Chern class \( Q_8 \) and Euler characteristic 0; twisting by \( e_9 \) then leaves this condition alone and allows us to set \( \chi = 1 \), and ensures the existence of a sheaf \( O_{e_8 - e_9} \). The argument of [42, Prop. 11.68] carries over to show that the generic irreducible sheaf with the given invariant is acyclic, so has a unique global section. The image of that global section must have the same Chern class, but then must have the same Euler characteristic by disjointness from \( Q \), and thus the sheaf is globally generated. Let \( I \) be the kernel of the global section, and note that \( I \) is torsion-free of rank 1, Chern class \( -r Q_8 - e_8 + e_9 \), and Euler characteristic 0 (and in fact \( R \Gamma(I) = 0 \)). Moreover, since \( \theta M \cong M \) is acyclic, \( \text{Hom}(I, O_X) \cong \text{Hom}(O_X, O_X) \). To obtain a contradiction, it will suffice to show that \( \text{Hom}(I, O_X(e_9 - e_8)) \neq 0 \), since then the unique map \( I \to O_X \) factors through \( O_X(e_9 - e_8) \), implying that \( M \) has a nonzero morphism to \( O_{e_8 - e_9} \).

It is of course equivalent to ask for \( \text{Hom}(\theta O_X(e_8 - e_9), ad) \neq 0 \). It will thus (since torsion-free sheaves of rank 1 are reflexive when \( q \) is torsion) suffice to show that if \( I \) is a torsion-free sheaf of rank 1, Chern class \( r Q_8 + e_8 - e_9 \) and \( R \Gamma(I) = 0 \), then \( \text{Hom}(O_X(-Q_8 + e_8 - e_9), I) \neq 0 \). By semicontinuity, we may reduce to the generic surface \( X \) having sheaves disjoint from \( Q \) with Chern class \( Q_8 \) and Euler characteristic 0 (but with no sheaf of the form \( O_{e_8 - e_9}(d) \)). Since both sheaves are in \( O_X^+ \), we may transport the question to the corresponding commutative surface \( X' \), and since the generic surface has \( Q \) smooth, we may apply [42, Prop. 11.53] to see that \( I \) maps to a torsion-free sheaf on \( X' \). Twisting reduces to showing that if \( I' \) is the ideal sheaf of \( r \) points in \( X' \), then there is a morphism from \( O_X(-r Q_8) \) to \( I' \), and this is a trivial consequence of the fact that \( X' \) is elliptic.

It should of course be possible to give similar results for higher genus noncommutative ruled surfaces, with the main obstruction being the requirement to understand precisely when effective classes in the Néron-Severi group of a *commutative* anticanonical ruled surface are generically irreducible.

We finish with some remarks on (semi)stable moduli spaces of torsion-free sheaves. For sheaves of rank \( r > 1 \), the situation is more complicated, as the proof in the commutative case of the requisite inequalities involves an intersection of the sheaf with a generic pair of hyperplanes, and it is unclear what the noncommutative analogue of such a configuration might be. However, we can still prove a number of results about such moduli spaces even without knowing they are quasiprojective (or schemes). The main result along those lines is the following, a direct analogue of [42, Thm. 11.78], with the same proof.

**Theorem 11.24.** Let \( D_a \) be an ample divisor class on the noncommutative rational surface \( X \), let \( r > 0 \), \( D \in \text{Pic}(X) \), \( \chi \in \mathbb{Z} \) be such that \( \text{gcd}(r, D \cdot D_a, \chi) = 1 \), and let \( M \) be the corresponding stable moduli space, with universal family \( M_M \). Then \( M \) is either connected or empty, and its Chow ring
is generated by the Chern classes of $R\text{Hom}(N, M_M)$ where $N$ ranges over a system of generators of $K_0(X)$.

This should be taken as including a number of other results, e.g., that the moduli space is bounded and the gcd condition ensures the existence of a universal family (both of which carry over to more general surfaces); see [42, §11.5] for a discussion of the case that $X$ has smooth anticanonical curve, all of which carries over without much difficulty to the general case. (It also includes an alternate proof that the moduli spaces of rank 1 sheaves are connected.) Note that since $\mathcal{M}$ is smooth (since it is unobstructed), connectivity implies irreducibility. Also, by considering the degree 1 part of the Chow ring, we obtain a surjective homomorphism $K_0(X) \to \text{Pic}(\mathcal{M})$. In addition, we find that the resulting presentation of the Chow ring is locally constant as we allow $X$ to vary (subject to the condition that $\mathcal{M}$ is nonempty).

It is unclear whether an analogous result holds for more general rationally ruled surfaces. It remains the case in general that the class of the diagonal in the Chow group of $M \times M$ may be computed using Porteous’ formula as $c_{\dim \mathcal{M}}(R\text{End}(M_M)[1])$. The argument in the rational case then uses a full exceptional collection to expand this in terms of the given generators, and thus fails in general. However, in the general case we also have a nontrivial morphism from $\mathcal{M}$ to the identity component of the Grothendieck group, and might reasonably hope to resurrect the result as a statement about the fibers.

Note that unlike projectivity, which we only know for rank $\leq 1$, this result on the Chow ring is only known for positive rank, and it is unclear whether we should expect it to hold for 1-dimensional sheaves.

### 12 Differential and difference equations

The construction of noncommutative ruled surfaces via differential and difference (or hybrid) operators means that we can think of sheaves on such surfaces as analogous to $D$-modules, with the caveat that the category of $D$-modules is a deformation of a quasi-projective surface (the cotangent bundle of the curve). In particular, we expect that we should be able to identify a class of sheaves corresponding to differential (or difference) equations, or more precisely to meromorphic (possibly discrete) connections on vector bundles. (We set aside the hybrid and commutative cases, as the action by operators is sufficiently far from faithful to make it difficult to interpret sheaves in this way. Though of course the commutative case can be interpreted in terms of Higgs bundles or their discrete analogues, see [41].)

This is simplest to achieve in the untwisted case with $\bar{Q} = Q$. Let $M$ be a pure 1-dimensional sheaf on such a ruled surface. Then the semiorthogonal decomposition gives a long exact sequence

$$0 \to \rho_1^*\rho_{-1*}M \to \rho_0^*\rho_0* M \to M \to \rho_1^*R^1\rho_{-1*}M \to \rho_0^*R^1\rho_0* M \to 0 \quad (12.1)$$

Suppose that $M$ is $\rho_{-1*}$-acyclic (so $\rho_0*$-acyclic), and that $W = \rho_{-1*}M$ and $V = \rho_0* M$ are vector bundles. Then $M$ is uniquely determined by the corresponding element of

$$\text{Hom}(\rho_1^*W, \rho_0^*V) \cong \text{Hom}_{\bar{Q}}(\pi_1^*W, \pi_0^*V). \quad (12.2)$$

In the differential case, $\bar{Q}$ is the double diagonal in $C \times C$, and thus there is a natural map

$$\text{Hom}_{\bar{Q}}(\pi_1^*W, \pi_0^*V) \to \text{Hom}_C(W, V) \to \text{Hom}_Q(\pi_1^*W, \pi_1^*V). \quad (12.3)$$

If the map from $W$ to $V$ is injective (i.e., if $M$ is transverse to $Q$), then it is generically invertible, and thus we may compose with its inverse to get a meromorphic map from $\pi_1^*V$ to $\pi_0^*V$ such that the
corresponding meromorphic endomorphism of $V$ is the identity. But this is precisely a meromorphic
connection on $V$! Conversely, given a meromorphic connection on $V$, we can choose a subsheaf
$W \subset V$ with torsion quotient such that the induced map $\pi_1^*W \to \pi_0^*V$ is holomorphic, and thus
obtain a representation as above. This sheaf is not unique (we can clearly replace $W$ by any subsheaf
of $W$ with torsion quotient), but the property is preserved under taking sums, and thus there is a
maximal such subsheaf, giving us a canonical representation of the meromorphic connection as a
sheaf. (We further see as in [41] that $\max$ such subsheaf, giving us a canonical representati
on of the meromorphic connection as a
obtain a representation as above. This sheaf is not unique (we can clearly replace
$Q$ interpretation by any automorphism of
map $\pi$ such that
that the present convention differs by that of [41] in that it is covariant rather than contravariant,
thus there is a
multiple
such representations.

A similar calculation in the nonsymmetric difference cases gives a discrete analogue of a mero-
morphic connection, namely a meromorphic map
\begin{equation}
A : \tau_q^*V \longrightarrow V,
\end{equation}
where $\tau_q$ is the appropriate automorphism of $C$. (When $\tau_q$ is translation by $1 \in \mathbb{G}_a$, this is a “d-
connection” as in [3].) Again, there is a canonical way to take such a discrete connection and turn
it back into a sheaf on the ruled surface. The symmetric case is only slightly more complicated:
the discrete connection lives on $Q$ rather than $C$, and gives a meromorphic map
\begin{equation}
A : \tau_q^*\pi_0^*V \longrightarrow \pi_0^*V
\end{equation}
such that $s_1(A)A = 1$, with the map $\pi_1^*W \to \pi_0^*V$ coming from a factorization of $A$ as guaranteed
by Hilbert’s Theorem 90. (See the discussion of the commutative case in [41].)

In the symmetric difference case, since the connection lives on $Q$, we may feel free to twist the
interpretation by any automorphism of $Q$ (which will, of course, act on all the various parameters
including $q$). This freedom survives in a somewhat modified version in the nonsymmetric difference
case, as there is still a hidden dependence on $Q$: we had to choose a component of $Q$ to fix the
isomorphism between $C_0$ and $C_1$ and thus to determine the discrete connection. In particular,
the discrete connection is more naturally viewed as living on that component of $Q$. We may thus
again twist the interpretation by automorphisms of $Q$ that preserve that component. (Of course, if
the automorphism fixes that component, then it will not affect the interpretation.) There are also
automorphisms that swap the two components, the most natural of which is the deck transforma-
tion corresponding to the degree 2 map $Q \to C_0$. In the $q$-difference case, this transformation takes
\begin{equation}
v(qz) = A(z)v(z) \quad \text{to} \quad v(z/q) = A(z/q)^{-1}v(z)
\end{equation}
when $V$ is trivial, and the other nonsymmetric difference cases are analogous. (In fact, the deck
transform also has this effect in the symmetric difference cases, this being precisely the condition
to be a symmetric difference equation.) Similarly, in the differential case, we most naturally have a
connection on $C = Q^{\text{red}}$, with the deck transform acting trivially since it fixes $C$.

When the sheaf bimodule is no longer just the structure sheaf of $Q$, the situation is more
complicated. In the invertible sheaf case, we may view it as a twisted connection; this is not too
difficult to deal with in the difference cases, but is already quite subtle in the differential case. And
although many of the non-invertible (but torsion-free) cases are in principle not twisted, and thus
come with an explicit representation via untwisted operators, the identification as an untwisted
sheaf is only up to nonunique isomorphism, and thus we have multiple such representations.

Consider the differential case again. The issue is that we want in the end to have a meromorphic
map $\pi_1^*V \longrightarrow \pi_0^*V$ on the double diagonal, but instead are given a meromorphic map $\pi_1^*V \longrightarrow$
canonical flat connection, which now corresponds to a section that is no longer disjoint from $\pi$.\Hom(\cdot)$ and thus $W$, for maximality of $\rho$, words, to translate meromorphic connections to sheaves on the ruled surface, we need only specify the ruling. (Note that we can still get an interpretation when $L$ is trivial. Beyond that, we can of course add any holomorphic differential to the canonical flat connection on $\mathcal{O}_C$.) From this perspective, the reason why the untwisted invertible case has a canonical interpretation as connections is that it has a canonical choice of $\Sigma$. Even this is not unique, however: e.g., in the differential case, we can add any holomorphic differential to the canonical flat connection on $\mathcal{O}_C$. (In this case, the automorphism group of the ruled surface acts transitively on such sections.) Similarly, twisting by line bundles $L_i$ with $\pi'_0L_0 \cong \pi'_1L_1$ has the effect of tensoring with a holomorphic connection on $L_0$; if $L_0$ is degree 0, then such a connection exists, but there is no canonical choice unless $L_0$ is trivial. Beyond that, we can of course add any meromorphic differential to the canonical flat connection, which now corresponds to a section that is no longer disjoint from $Q$.

Once we include the section in the data, we see that the interpretation as connections is preserved by elementary transformations. That is, if we start with $X_0$ with section $\Sigma$, then blowing up a point gives a surface $X_1$ and the minimal lift $\alpha_i^*\Sigma$. (We recall from [39][42] that if $M$ has no 0-dimensional subsheaf, then $\alpha_i^*M$ is defined to be the image of the natural map $\alpha_i^*M \to \alpha_i^*\Sigma$, and similarly for minimal lifts through iterated blowups.) This has no map to or from $\mathcal{O}_{e_i}(-1)$, and thus when we blow down $f - e_i$ to get $X_0'$, the image of $\alpha_i^*\Sigma$ will still be a section. It moreover agrees with the original section on the generic fiber over $C$, so is obtained from the original meromorphic map $\mathcal{O}_Q \dashrightarrow \mathcal{E}$ by using the natural identification of the generic fibers of $\mathcal{E}$ and $\mathcal{E}'$. This lets us give a more geometric interpretation of how the section comes into play: we simply perform elementary transformations until $\Sigma$ is disjoint from $Q$, which forces the resulting surface to be the standard untwisted surface, with $\Sigma$ determined up to a holomorphic differential (in the differential case) or a scalar factor (in the nonsymmetric elliptic difference case), as appropriate.

Since the interpretation as a meromorphic connection essentially depends only on the generic fiber over $C$, we find the following: a map $\phi : M \to N$ of pure 1-dimensional sheaves such that the kernel and cokernel have Chern class proportional to $f$ induces a gauge transformation between the corresponding connections. Indeed, this map is an isomorphism on the generic fiber, and thus induces an isomorphism between the generic fibers of $\rho_0M$ and $\rho_0N$ compatible with the two connections. But this is the same as specifying a meromorphic map $\rho_0M \dashrightarrow \rho_0N$ that gauges the connection on $\rho_0M$ to the connection on $\rho_0N$. Such a gauge transformation is essentially a discrete isomonodromy transformation, with the caveats that it may introduce or remove apparent singularities, and that "isomonodromy" (though traditional) is not really the right word when the equation has irregular singularities. Rather, the key property of the transformation is that any local meromorphic solution of the equation corresponding to $\rho_0M$ induces a local meromorphic
solution of the equation corresponding to $\rho_0, N$, and vice versa. In the differential case, this not only implies that their monodromy representations agree, but that they have the same Stokes data at irregular singularities.

An important source of such transformations comes from the minimal lift operation and twisting by line bundles. Indeed, if we lift to a blowup, twist by a line bundle of the form $O_X(\pm e_i)$, then take the direct image, then the generic fiber of the result is unchanged, so the effect on the connection is a gauge transformation (corresponding to a modification of $V$ at the point lying under $e_i$). One consequence is that following [39 Lem. 6.8], we can always arrange by a sequence of such canonical gauge transformations to get a sheaf and a blowup such that the minimal lift is disjoint from $Q$. This process seems to correspond to one of removing apparent singularities, and at the very least has the effect that any further twists by exceptional line bundles preserve disjointness from $Q$. (Note that if we specify the section $\Sigma$ as the image of a sheaf on the blowup, then twisting $\Sigma$ by exceptional line bundles will not preserve the condition that its image on $C$ be the structure sheaf, so will introduce an overall twist by a line bundle as mentioned above.)

This mostly describes the action of twisting by line bundles; the only remaining detail for exceptional bundles is the description of the specific subspace of $V|_{\pi(e_i)}$ along which one should modify $V$, but this is relatively straightforward in most cases: we simply take the sum of the subspaces corresponding to indecomposable singularities (see below) for which the separating blowup involves $e_i$. (The answer is slightly more complicated in the more special case in which $e_i$ came from blowing up a smooth point of $Q$ that gets blown up more than once in the separating blowup; in that case, the full space associated to the singularity has a nilpotent matrix $N$ acting on it (coming from the Jordan block structure), and the subspace has the form $\ker(N^l)$ if it corresponds to the $l$th time that point was blown up.)

Twisting by a line bundle of Chern class $f$ is also easy to understand, once we remember to keep track of the action on $\Sigma$: we thus find that twisting the surface by any line bundle in $\rho_0^* \text{Pic}(C)$ acts trivially on the corresponding (discrete) connection.

Before considering twisting by $s$, we first consider the action of $R^1 \text{ad}$. This commutes with elementary transforms, so we may reduce to the untwisted case. We should note, of course, that the adjoint does not preserve the canonical section $\Sigma$, so that it will be somewhat more convenient to include a twist by a line bundle, and thus consider $M \mapsto R^1 \text{ad} M \otimes \omega_C^{-1}$. It moreover suffices to consider how this behaves on a suitable localization of $C$, since we can use the known effect on $\Sigma$ to guide the gluing on $M$. In particular, we may as well consider only how $M$ restricts to the generic point of $C$, so that in particular all of the vector bundles are trivial and $M$ corresponds to a module over a $\mathbb{Z}$-algebra of the form $\overline{S}$. We know how the adjoint acts on such modules, and thus find that this acts via the composition of the (naïve) dual on the corresponding equation and the deck transform over $C$. To be precise, if $M$ corresponds to the $q$-difference equation

$$v(qz) = A(z)v(z),$$

then $R^1 \text{ad} M \otimes \omega_C^{-1}$ corresponds to

$$v(z/q) = A(z/q)^t v(z)$$

and similarly for the other types of difference equations. Similarly, in the differential case, the operation takes

$$v'(z) = A(z)v(z) \quad \text{to} \quad v'(z) = -A(z)^t v(z).$$

In either case, composing by the deck transform of $Q \to C_0$ recovers the standard duality on equations, e.g., taking $v(qz) = A(z)v(z)$ to $v(qz) = A(z)^{-t}v(z)$. Here we should note that although
this duality comes from the natural duality on $GL_n$-torsors, most other functors on $GL_n$-torsors do not have nice translations into the sheaf framework, for the simple reason that they tend to greatly increase the complexity of the singularities (not to mention acting non-linearly on the order of the equation).

To understand the twist by $s$, we consider another contravariant symmetry, namely taking the transpose of the morphism $B : \pi_1^* W \to \pi_0^* V$ to get a morphism

$$B^t : \pi_0^* \mathcal{H}om(V, \mathcal{O}_C) \to \pi_1^* \mathcal{H}om(W, \mathcal{O}_C)$$

(12.10)

corresponding to a sheaf on the noncommutative ruled surface arising by swapping the roles of $C_0$ and $C_1$ in the sheaf bimodule. We thus obtain a (discrete) meromorphic connection on $W^*$ from the original (discrete) meromorphic connection on $V$, and this operation is clearly a contravariant involution. This is closely connected to the adjoint, since if $M$ has presentation given by $B$, then $R^1 \text{ad} M$ has a presentation of the form

$$0 \to \rho_2^* \text{Hom}(V, \omega_C) \to \rho_1^* \text{Hom}(W, \omega_C) \to R^1 \text{ad} M \to 0$$

(12.11)

in which the map is essentially given by $B^t$. We thus see that (in the untwisted case) transposing $B$ takes $M$ to $R^1 \text{ad} M \otimes L$, where $L$ is a suitable line bundle of Chern class $s + (1 - g)f$ determined by the condition that $\Sigma \cong R^1 \text{ad} \Sigma \otimes L$. So to twist by $s$, we need merely take the adjoint and then apply the above operation. Note that the combined operation is again expressible as an isomonodromy transformation, the one caveat being that in the symmetric case, it changes the symmetry.

The above calculations suffice to allow one to express the twist by any line bundle as an isomonodromy transformation. One case worth singling out is twisting by $\theta \mathcal{O}_X$. This twist is not quite given by $\theta$, for the simple reason that twisting by $\theta \mathcal{O}_X$ changes the identification of $Q$ with the anticanonical curve. We thus find that twisting by $\theta \mathcal{O}_X$ is given by the pullback through a translation, or in other words takes

$$v(qz) = A(z)v(z) \quad \text{to} \quad v(qz) = A(qz)v(z).$$

(12.12)

(Note that since $A(qz) = A(qz)A(z)A(z)^{-1}$, this is indeed an isomonodromy transformation.)

The discussion of [41] in the commutative case suggests that for a 1-dimensional sheaf $M$ on a ruled surface (which we may suppose untwisted with $Q = \overline{Q}$), the singularities of the corresponding connection are determined by the sheaf $M|_Q$. This is somewhat tricky to deal with in general, but the previous discussion suggests that we should instead consider sheaves on iterated blowups that are disjoint from $Q$, in which case the singularities should be determined by the surface $X_m$ and the Chern class of $M$. In the commutative case, the precise correspondence to singularities was determined in [41] §5.4, but this required fairly explicit calculations in affine patches of blowups, making it nontrivial to carry out the analogous calculation in the noncommutative setting.

In the case of a rational surface, this can be avoided in the following way. We first note that the blowups needed to separate a sheaf $M$ on $X_0$ from $Q$ depend only on local information, and thus we may feel free to modify $M$ at points not in the orbit of the support of $M|_Q$, or in other words to apply an isomonodromy transformation which is invertibly holomorphic on the orbit. (This modifies $M$ by sheaves of Chern class $\infty f$ with direct image outside the orbit.) This makes the separating blowup slightly more complicated, but we can recognize which blowups were needed on the original surface from the images of the corresponding points on $Q$, so do not lose information. In particular, by a suitable such modification, we may arrange for $V$ to be isomorphic to $\mathcal{O}_C^p$. We then find that $R\Gamma(M(-f)) = 0$, and thus $M$ induces a family $M_q$ of objects as we vary $q$ leaving
the commutative surface associated to \( X(-f) \) unchanged. Moreover, changing \( q \) has no effect on either \( W \) or the map \( \rho_1^*W \to \rho_2^*V \), and thus \( M_q \) is actually a family of sheaves (injectivity does not depend on \( q \)), and corresponds to a family of equations \( hv'(z) = A(z)v(z), v(z + \hbar) = A(z)v(z), \) or \( v(qz) = A(z)v(z) \) with \( A \) independent of \( h \) or \( q \). In addition, the minimal lift of \( M \) to the separating blowup also satisfies \( R\Gamma(M(-f)) = 0 \), and thus the separating blowup is essentially independent of \( h \) or \( q \). (We may need to exclude countably many values of the noncommutative parameter where \( M \) picks up apparent singularities.) As a result, we may reduce to the case that \( X \) is the commutative surface associated to \( X \). As an initial example, for the nonsymmetric difference case, an indecomposable singularity (depending only on the separating blowup), which appears with multiplicity \( c_1(M) \cdot e_i \) in the equation corresponding to \( M \).

The nonsymmetric elliptic difference case is also straightforward; although we cannot as easily reduce to the commutative case, we need merely observe that \( M|_Q \) is the cokernel of the restriction to \( Q \) of the map \( W \to V \otimes S_0 \), which we may think of as a pair of maps on the two components of \( Q \). The matrix \( A \) of the equation is simply the ratio of those two maps, and thus we may read off the singularities of \( v(z + q) = A(z)v(z) \) from the zeros and poles of \( A \), just as with finite singularities in the \( q \)- and additive difference cases.

It remains to consider the higher genus differential cases. Here we note again that the blowup is determined by the local structure of the equation, but now the relevant point of \( C \) lies under a singular point of \( Q \) (since \( Q \) is nonreduced!), and thus we may base change to the local ring at that point. Moreover, any sufficiently good approximation to the connection (relative to the associated valuation) will give rise to the same sequence of blowups, and thus we may pass to the complete local ring. But then the same reasoning lets us approximate the equation by one over \( k(z) \), and thus reduce to the rational case.

One application of the singularity classification is that it gives a convenient way to compute centers of maximal orders in sufficiently large characteristic. That is, we can recognize a surface by looking at the singularities of the connection (or generalized Higgs bundle) corresponding to a sheaf with Chern class a sufficiently ample divisor on the surface, or more precisely from those properties of the singularities that do not depend on the specific choice of sheaf. Thus to understand the structure of the center, it suffices to understand how taking the direct image to the center affects the separating blowup. This in turn reduces to understanding indecomposable singularities. Finite singularities are straightforward to control, so we focus on the singularities of equations lying over singular points of \( Q \), letting us work over the appropriate complete local ring.

As an initial example, for the nonsymmetric \( q \)-difference case, an indecomposable singularity is the restriction of scalars to \( k[[z]] \) of an equation of the form \( v(qz) = z^{a/b}B(z)v(z) \) for \( B(z) \in \text{GL}_m(k[[z^{1/b}]]) \). (Here we assume we are working over a field of sufficiently large characteristic to avoid wild ramification. Also, we need to choose a \( b \)-th root of \( q \) to extend the action of \( z \to qz \) to the given Puiseux series.) If \( q \) has order \( n \), we may compute the direct image of the corresponding sheaf as the restriction of scalars to \( k[[z^n]] \) of the equation

\[
v(q^n z) = \prod_{0 \leq i < n} (q^i z)^{a/b} B(q^i z)v(z) = (z^n)^{a/b} q^{an(n-1)/2b} \prod_{0 \leq i < n} B(q^i z)v(z). \quad (12.13)
\]

The associated separating blowup depends only on the leading term of this matrix, and is thus determined by \( a/b \) and the matrix

\[
q^{an(n-1)/2b} B(0)^n, \quad (12.14)
\]

while the separating blowup corresponding to the original sheaf determines the Jordan block structure of \( B(0) \). (That \( a/b \) does not change follows from the fact that it is purely combinatorial: it
corresponds to a sequence of blowups in nodes of the anticanonical curve, which must therefore map to nodes. That an \( n \)th power is involved similarly follows from the fact that the map from \( Q \) to \( Q' \) is the quotient by \( \theta \) since \( Q' \) is reduced.) The same calculation applies in the symmetric \( q \)-difference case (as the classification of singularities is the same).

The additive difference case is somewhat trickier to deal with. The direct image can in general be computed as the restriction of scalars to \( k[[z^p - z]] \) of \( v(z + p) = A(z + p - 1) \cdots A(z)v(z) \), but it is nontrivial to compute a sufficiently good estimate of the latter product in the case of an indecomposable singularity. Such singularities correspond to equations of the form

\[
v(z + 1) = \alpha z^{a/b}(1 + \sum_{1 \leq i < b} c_i z^{-1/b} + z^{-1}B(z))v(z), \tag{12.15}
\]

where \( c_1, \ldots, c_{b-1} \in k, B \in \text{Mat}_n(k[[z^{-1/b}]]) \), and the difficulty is that we need to compute the corresponding product to precision \( o(z^{-p}) \). This turns out to be doable, as long as the characteristic is larger than \( b \). (If the characteristic is too small, there are two issues: the computation of the requisite blowups may involve wild ramification, and the anticanonical curve of the blowup may have components of multiplicity \( > p \), which complicates the action of taking the center on the moduli stacks.) We first note that we can factor this into a scalar contribution and a matrix contribution, where the matrix is \( 1 + O(1/z) \).

**Lemma 12.1.** Let \( k \) be a field of characteristic \( p \), and let \( b \) be a positive integer prime to \( p \). If \( B \in \text{Mat}_n(k[[z^{-1/b}]]) \) is such that \( B = 1 + B_0 z^{-1} + o(z^{-1}) \), then \( B(z + p - 1) \cdots B(z) = 1 + (B_0^p - B_0)z^{-b} + o(z^{-p}) \).

**Proof.** This is a polynomial equation in the coefficients of \( B \) to order \((z^{-1/b})^{b+1}\), and thus it suffices to consider the generic case. In particular, we may assume that \( B_0 \) is diagonalizable (so WLOG diagonal) with eigenvalues \( \lambda_i \), such that \( \lambda_i - \lambda_j \notin \mathbb{F}_p \) for \( i \neq j \). But then there is a matrix \( C \in 1 + o(1) \) such that \( C(z + 1)B(z)C(z)^{-1} \) is diagonal, with

\[
B_{ij}(z) = 1 + z^{-1}f_i((z^p - z)^{-1/b}) \tag{12.16}
\]

for suitable power series \( f_i \). (Gauging by a matrix \( C \) such that \( C - 1 \) has a single nonzero coefficient \( C_{ij} - \delta_{ij} = \alpha z^{-a/b} \) adds \( \alpha(\lambda_i - \lambda_j - a/b)z^{-a/b-1} \) to \( B_{ij} \), and thus we may set the \( o(1/z) \) part of \( B \) arbitrarily, except for those terms of degree \(-1\) modulo \( p \).)

We then have

\[
\prod_{0 \leq j < p} B_{ij}(z + j) = \prod_{0 \leq j < p} \frac{z + j + f_i((z^p - z)^{-1/b})}{z + j} = \frac{(z + f_i((z^p - z)^{-1/b})^p - (z + f_i((z^p - z)^{-1/b}))}{z^p - z} = 1 + \frac{f_i((z^p - z)^{-1/b})^p - f_i((z^p - z)^{-1/b})}{z^p - z} = 1 + \frac{f_i(0)^p - f_i(0)}{z^p - z} + o(z^{-p}) \tag{12.17}
\]
as required.

For the scalar factor, we assume \( b < p \), and rewrite it using the polynomial \( \exp_p(z) = \sum_{0 \leq i < p} z^i/i! \), which is invertible under composition and approximately a homomorphism.
Lemma 12.2. Let $k$ be a field of characteristic $p$, and let $1 \leq b < p$. Then for $g \in z^{-1/b}k[[z^{-1/b}]]$ and $f = \exp_p(g)$, we have

$$
\prod_{0 \leq i < b} \exp_p(g(z + i)) = \exp_p(g(z)^p + g^{(p-1)}(z))|_{z=z^{-1/b}} + o((z^p - z)^{-1}).
$$

(12.18)

Proof. Since $\exp_p$ is a homomorphism to order $O(z^{-p/b}) = o(1/z)$, and we have already seen that this holds when $\exp_p(g(z)) = 1 + o(1/z)$, we see that both sides are homomorphisms to the desired order, and thus it suffices to prove the result for $\exp_p(g(z)) = 1 - \alpha z^{-1/b}$. In that case, we may take

$$
g(z) = - \sum_{1 \leq i < b} i^{-1} \alpha^i z^{-i/b} + o(1/z)
$$

and thus

$$
g(z)^p + g^{(p-1)}(z) = -\left(\sum_{1 \leq i < b} i^{-1} \alpha^i p z^{-ip/b}\right) + b^{-1} \alpha^b z^{-p} + o(z^{-p})
$$

(12.20)

so that we need to show

$$
\prod_{0 \leq i < p} (1 - \alpha(z + i)^{-1/b}) = \exp_p\left(-\sum_{1 \leq i < b} i^{-1} \alpha^i p (z^p - z)^{-i/b} + b^{-1} \alpha^b(z^p - z)^{-1}\right) + o((z^p - z)^{-1})
$$

$$
= (1 - \alpha^p (z^p - z)^{-1/b})(1 + b^{-1} \alpha^b(z^p - z)^{-1}) + o((z^p - z)^{-1})
$$

$$
= 1 - \alpha^p (z^p - z)^{-1/b} + b^{-1} \alpha^b(z^p - z)^{-1} + o((z^p - z)^{-1}).
$$

(12.21)

Replacing $\alpha$ by $1/\lambda$ and multiplying both sides by $\lambda^p$ turns the left-hand side into the minimal polynomial of $z^{-1/b}$ over $k(((z^p - z)^{-1/b}))$, and thus to show that the given estimate holds, it suffices to plug in $z^{-1/b}$ and show that the value is sufficiently small. Thus the claim follows from the fact that

$$
z^{-p/b} - (z^p - z)^{-1/b} + b^{-1} z^{(b-p)/b}(z^p - z)^{-1} = O(z^{2-2p-p/b}),
$$

(12.22)

which we may verify by expanding both powers of $z^p - z$ using the binomial series. \qed

We thus see that for an equation

$$
v(z + 1) = \alpha z^{a/b}\left(\exp_p\left(\sum_{1 \leq i < b} c_i z^{-i/b} + B_0 z^{-1}\right) + o(1/z)\right)v(z),
$$

(12.23)

the direct image to the center is given by the the restriction of scalars to $k[[((z^p - z)^{-1})]$ of the matrix

$$
\alpha^p(z^p - z)^{a/b}\left(\exp_p\left(\sum_{1 \leq i < b} c_i^p(z^p - z)^{-i/b} + (B_0^p - B_0)(z^p - z)^{-1}\right) + o((z^p - z)^{-1})\right).
$$

(12.24)

Note that the same calculations also let us compute the requisite product for a symmetric equation.

The differential case is similar; if we think of the equation as $Dv = Av$, then the direct image is the restriction of scalars of the action of $D^p$. An indecomposable equation over $k((z))$ is the restriction of scalars of an equation

$$
v' = (f(z) + B(z))v(z),
$$

(12.25)

where $B \in z^{-1} \text{Mat}_n(k[[z^1]])$ and $f \in k((z^{1/b}))$. Since $D \mapsto D - f$ is an automorphism, we may compute the action of $D^p$ by first computing the action with $f(z) = 0$ and adding $f(z)^p + f^{(p-1)}(z)$.
The contribution of $B$ may be computed in the generic case, when $B$ is again diagonalizable by a suitable gauge transformation, and we find that the contribution is $B(z)^p + B^{(p-1)}(z) + o(z^{-p})$, giving the action of $D^p$ to sufficiently high precision. Here we see quite explicitly that the action of passing to the center on the parameters is more complicated when $b > p$; any term of $f$ with exponent $< -1$ but congruent to $-1$ modulo $p$ contributes a term with exponent $< -p$ to $f^{(p-1)}$, and thus the corresponding coefficient does not only appear as a $p$-th power.

In the discussion above, we saw that twisting by line bundles corresponds to discrete isomonodromy transformations. In the differential (and ordinary difference) cases, these do not in general exhaust the full set of monodromy- (or Stokes-, or whatever the analogue for ordinary difference equations might be) preserving transformations: there are also typically continuous flows between moduli spaces coming from, e.g., the fact that the relevant fundamental group depends only on the topology of the given punctured Riemann surface. Although the traditional explanations of these flows are largely analytic in nature (they are mediated by the Riemann-Hilbert correspondence), we can hope that the infinitesimal flow may have a more algebraic/geometric interpretation in our context.

The typical form of such a flow (we consider the differential case, but the difference case is analogous) is (locally) given by a Lax pair, i.e., a pair of equations

$$v_z = Av, \quad v_w = Bv$$

satisfying the consistency condition ($v_{zw} = v_{wz}$)

$$A_w = B_z + [B, A].$$

(Here $A$ and $B$ are analytic in $w$ but algebraic in $z$.) To first order, this corresponds to an infinitesimal deformation of $A$, or equivalently to the self-extension of the equation given by

$$\begin{pmatrix} A & A_w \\ 0 & A \end{pmatrix} = \begin{pmatrix} A & B_z + [B, A] \\ 0 & A \end{pmatrix}.$$  

(12.28)

But this is in turn the gauge transformation of the trivial self-extension by a block unipotent matrix corresponding to $B$. Since this is meant to come from a flow that preserves the complexity of the singularities, we see that the corresponding sheaf is the direct image on $X_0$ of an extension of $M$ to a first-order deformation of the separating blowup. Moreover, we want this deformation to preserve the combinatorics of $Q$ (both because we want to preserve the complexity of the singularities and because we wish to avoid obstructed deformations), and thus in particular any singular point of $Q^{\text{red}}$ that must be blown up will continue to be blown up after the deformation. Thus we may just as well blow up such singular points before considering any further deformations, replacing $X_0$ by some $X_{m_1}$ that still remains invariant under the deformation, but now satisfying the condition that $M$ meets $Q^{\text{red}}$ only in the smooth locus.

Now, the restriction to $Q$ of the corresponding sheaf on $X_{m_1}$ must correspond to a flat deformation of $M|_Q$. This is important because the translation between sheaves and equations is only modulo sheaves of Chern class $\propto f$, but any such sheaf will contribute to the restriction to $Q$. We thus find that an isomonodromy transformation corresponds (locally on $C$) to a class in $\text{Ext}^1(M, M)$. Moreover, the block upper triangular meromorphic gauge transformation that trivializes it corresponds to an explicit trivialization of the induced extension of $M$ by $M^+$ where $M^+$ is a corresponding extension of a sheaf of Chern class $\propto f$ by $M$. Such an explicit trivialization corresponds to a representation of the self-extension of $M$ as the image of a class in $\text{Hom}(M, M^+/M)$.  

151
(Note that this is now actually globally defined on $C$, since it corresponds to a class in the bottom-left corner of the relevant hypercohomology spectral sequence.) Assuming that $M$ has no quotient of Chern class $\propto f$, the image of such a morphism will be 0-dimensional, and thus in order for the extension to exist, we must have $M^+ \subset M(D)$ for some divisor $D$ which is a nonnegative linear combination of components of $Q$.

In other words, isomonodromy transformations that deform the separating blowup without deforming $X_0$ correspond to morphisms $M \to M(D)/M$. Moreover, since we are more precisely interested in isomonodromy transformations that are consistent across an entire symplectic leaf, this morphism should depend only on $M|Q$. Here there is a subtle point to bear in mind: although every point in the symplectic leaf has isomorphic restriction $M|Q$, the universal family need not admit such an isomorphism globally. Thus our assignment of a morphism $M \to M(D)/M$ given $M|Q$ must respect automorphisms of $M|Q$. In particular, we may apply this to the induced morphism $M \to M|Q(D)$, or equivalently $M|Q \to M|Q(D)$, which must in particular commute with the local action of $O_Q^*$. Since we are working over a field of characteristic 0, $(D)$ acts nontrivially on any component of $Q$ appearing in $D$, so that the left and right actions of $O_Q^*$ only agree modulo $D \cap (Q - Q^{\text{red}})$. (Indeed, since $M$ only meets $Q^{\text{red}}$ in smooth points, the localization to that point (in the sense of Proposition \ref{proposition:localization}, which suffices to control the category of 0-dimensional sheaves) has the form $k\langle (u,v)/[[u,v] - v^\mu \rangle$ where $\mu$ is the multiplicity of the corresponding component, see Proposition \ref{proposition:localization}.) This lets us compute the action of conjugation by $v^d$ for any $d$ and verify that it is nontrivial for $d < \mu$ which is not a multiple of the characteristic.) We thus find that the morphism factors through $D - (D \cap Q^{\text{red}})$, and thus that we may reduce to the case $D = Q^{\text{nr}} := Q - Q^{\text{red}}$, and thus need to understand the natural maps $M|Q \to M|Q^{\text{nr}}(Q^{\text{nr}})$.

If such a map corresponds to an unobstructed deformation of the separating blowup, then it in particular induces deformations of the support of $M|Q^{\text{red}}$ along $Q^{\text{red}}$. If the deformation of a given point is trivial (in particular if the component it lies on has multiplicity 1 in $Q$), then we may again blow it up, making $M|Q^{\text{red}}$ smaller. We thus see that we have at most one dimension of such deformations for each time we blow up a smooth point of $Q^{\text{red}}$ lying on a component of multiplicity $> 1$ of $Q$. To see that this bound is tight, it suffices to show that the map to the tangent space is surjective at every point in the support of $M|Q^{\text{nr}} \cap Q^{\text{red}}$. Fixing such a point, we may work in the category of 0-dimensional sheaves supported at that point, or equivalently (as we have already discussed) in the category of finite-length modules over $R_\mu = k\langle (u,v)/[[u,v] - v^\mu \rangle$, and in particular in the subcategory of such modules annihilated by $v^{\mu - 1}$. This is the category of modules over a commutative ring, and in that category, the functor $\_\langle Q^{\text{nr}} \rangle$ is just tensoring with the invertible bimodule generated by $v^{1-\mu}$, so that in particular the element $v^{1-\mu}$ induces a natural transformation $M|Q^{\text{nr}} \to M|Q^{\text{nr}}(Q^{\text{nr}})$. Moreover, this element induces a derivation on $R_\mu$ taking $v$ to 0 and $u$ to $1 - \mu$, and thus in particular does not preserve the maximal ideal; it follows immediately that the corresponding deformation moves the base point as required.

A major simplifying assumption made above was that the surface $X_0$ itself was not being deformed. (This is not an issue in the ordinary difference case, when there are no such deformations!) If we wish to relax this assumption, then there are some additional issues that arise. The first is that, as we have seen, the relation between sheaves and equations depends not only on the surface but on a choice of section, and there is only a canonical such choice in the untwisted case. Thus to have an actual isomonodromy transformation, we either need to restrict to the untwisted case or allow the normalizing section to deform along with the surface. Focusing on the first case (which is in any event sufficient: we can always separate the normalizing section along with the sheaf of interest, at which point changing the blowdown structure reduces to the case $X_0$ untwisted, and determining which deformations act trivially on the sheaf of interest is then straightforward), we
see that the only remaining degree of freedom is the possibility to deform \(C\) itself. Such a deformation is given by a class in \(H^1(T_C)\), or in other words by a 1-cocycle \(z_{ij}\) in the space of first-order holomorphic differential operators on \(C\). Given a differential equation on \(C\), we can then construct an extension to the deformation in the local form

\[
\begin{pmatrix}
1 & z_{ij}D \\
0 & 1
\end{pmatrix}
\begin{pmatrix}
D - A & 0 \\
0 & D - A
\end{pmatrix}
\begin{pmatrix}
1 & -z_{ij}D \\
0 & 1
\end{pmatrix}
= 
\begin{pmatrix}
D - A & [D - A, z_{ij}D] \\
0 & D - A
\end{pmatrix}
= 
\begin{pmatrix}
D - A & -z_{ij}'D - z_{ij}A' \\
0 & D - A
\end{pmatrix}
\] (12.29)

This is equivalent (add \(z_{ij}'\) times the second row to the first) to the equation

\[v' = \begin{pmatrix} A & -z_{ij}A' - z_{ij}'A \\ 0 & A \end{pmatrix} v,\] (12.30)

which is locally the isomonodromy transformation by \(-z_{ij}A\). (Note that if \(z_{ij}\) is sufficiently close to constant at a singular point, then this is locally just the standard isomonodromy transformation moving that singular point, while if it vanishes at the singular point, the singular point does not move and the combinatorics of the singularity does not change.) To see that this is globally monodromy preserving, we note that we obtain a local system for each open subset in the covering, and the \(z_{ij}\) induce compatible isomorphisms between the local systems on the overlaps, and in particular ensure that at any point of \(U_j \setminus U_{ij}\) where the equation is regular, the monodromy in \(U_i\) around that point is trivial. Thus each \(U_i\) extends to a local system on the full complement of the singularities of the equation, and these local systems are compatibly isomorphic. Since Stokes data is entirely local, and the isomorphisms also ensure isomorphisms between Stokes data, the analogous statement continues to hold for non-Fuchsian equations.

We thus see that in addition to the isomonodromy transformations that fix \(X_0\), we also have isomonodromy transformations parametrized by \(H^1(T_C)\). (When \(C \cong \mathbb{P}^1\), we do not gain any new isomonodromy transformations, but should recognize that 3 of the existing isomonodromy transformations correspond to global automorphisms of \(\mathbb{P}^1\); when \(C\) is elliptic, we both gain and lose an isomonodromy transformation in this way.) In particular, it is straightforward to determine the number of such deformations in general: in the differential case, we start with \(\chi(T_C) = 3g - 3\) and then as we pass to the separating blowup, add 1 each time we blow up a smooth point of \(Q_{\text{red}}\) lying on a multiple component. Given the role of \(Q_{\text{nr}}\) above, we note that an easy induction shows that the expected number of such deformations can be encapsulated in a single quantity, to wit \(-\chi(O_{Q_{\text{nr}}}(Q_{\text{nr}})))\), this time computed on the separating blowup, with the same number holding in the ordinary difference case as well. (In particular, this explains the existence of a continuous isomonodromy transformation of the symmetric difference equations considered in [36].)

In particular, we find that the number of isomonodromy transformations explained by the above considerations is actually intrinsic to the surface. This suggests that there should be a more geometrical description of these deformations. We have not quite been able to do this, but note the following very suggestive facts.

First, if we consider how the continuous and discrete isomonodromy transformations act on the given piece of the moduli stack of surfaces, we see that they are essentially complementary: in the parametrization of singularities coming from [41, §5.4], the parameters that move under continuous isomonodromy transformations are precisely the ones that do not move under discrete isomonodromy transformations. Moreover, the continuously movable parameters have a particularly nice interpretation in finite (sufficiently large) characteristic: they are the parameters that get taken to their \(p\)-th powers when passing to the center. In particular, we find that an infinitesimal
deformation of such a parameter induces the trivial deformation of the center! This also applies
to the transformations that deform \( C \), since the corresponding curve on the center is the image
under Frobenius. Conversely, the parameters that move under discrete isomonodromy transforma-
tions are acted on nontrivially by \( \pi_1(Q) \), and thus taking the center induces a separable map on
those parameters. We thus see that there is at least formally a correspondence between continu-
ous isomonodromy transformations in characteristic 0 and center-preserving deformations in finite
characteristic. . .

Second, in finite characteristic, the associated deformations not only come with extensions of
1-dimensional sheaves disjoint from \( Q \), but of any quasi-coherent sheaf disjoint from \( Q \), for the
simple reason that a center-preserving deformation of an Azumaya algebra is trivial! This suggests
more generally that a continuous isomonodromy transformation should correspond to a deformation
of \( X_m \) equipped with an explicit trivialization of the induced deformation of \( X_m \setminus Q \) (i.e., of the
“quasiprojective” category obtained by inverting the natural transformation \( \pi_1(Q) \to \text{id} \)), possibly
with some additional conditions imposed to ensure the lack of obstructions.

Even without a full geometric understanding of continuous isomonodromy transformations, the
above considerations at least suffice to tell us that they exist when expected, and, with limited
exceptions, respect changes in blowdown structure. (The exceptions come from the fact that we
treated deformations of \( X_0 \) separately from the deformations that move base points of blowups;
the latter are treated in a way that is intrinsic to the surface!) There is no particular issue with
elementary transformations, as those at most have the effect of a scalar gauge transformation, so
do not affect continuous isomonodromy. Thus the only issue is the Fourier transform. Since this
only arises when \( X \) is rational, we find that the issue in that case is not so much deformations but
infinitesimal automorphisms. There are four cases of noncommutative \( \mathbb{P}^1 \times \mathbb{P}^1 \)’s with nonreduced
\( Q \), and in each case the multiple components have multiplicity 2. By adjunction, we find that
\( \mathcal{O}_{Q_{\text{nr}}}(Q_{\text{nr}}) \cong \omega_{Q_{\text{nr}}}(Q_{\text{nr}} - Q_{\text{red}}) \), and thus \( \mathcal{O}_{Q_{\text{nr}}}(Q_{\text{nr}}) \) controls the deformation theory of the pair
\( (Q_{\text{nr}}, Q_{\text{nr}} \cap (Q_{\text{red}} - Q_{\text{nr}})) \). In particular, there is an induced map from infinitesimal automorphisms
of the surface to global sections of \( \mathcal{O}_{Q_{\text{nr}}}(Q_{\text{nr}}) \), and in each case that map is surjective. Moreover,
in each case any automorphism of the surface acts on equations by a change of variables, so indeed
gives a trivial isomonodromy transformation. (Note that the automorphisms of the surface do not in
general act faithfully on equations once one takes into account the action on the normalizing section
\( \Sigma \). Moreover, the kernel of the action on equations is not preserved by the Fourier transform!)

In particular, we find that the 2-dimensional moduli spaces arising from Theorem 11.19 admit
continuous isomonodromy transformations precisely when the curve \( Q \) is nonreduced. (A
fuller geometric understanding would presumably tell us that the consistency conditions for those
isomonodromy transformations are precisely the usual Painlevé equations. This is true in the cases
involving second-order equations, since then we can reduce to the corresponding differential case.)

We also find that the second order difference equations admitting continuous isomonodromy
transformations controlled by Painlevé transcendents have “matrix Painlevé” analogues that again
admit continuous isomonodromy transformations, which again will produce the same nonlinear
consistency equations as the corresponding differential cases, and similarly that the equations con-
sidered in [22] associated to 4-dimensional moduli spaces are either of this form or have second-order
difference or differential Lax pairs.

Since the Lax pairs for Painlevé coming from Theorem 11.19 are of particular interest, it seems
worth spelling them out. In the simplest case, for Painlevé VI, the typical form of such a Lax pair is
as a connection on a vector bundle of rank \( 2r \) and degree \( d \) (with \( r \geq 1 \) and \( \gcd(r, d) = 1 \)), with four
Fuchsian singularities and residues having two \( r \)-dimensional eigenspaces with fixed eigenvalues.
The main difficulty is that although the theory guarantees the existence of a universal sheaf in
this case, and thus tells us that there is a rational parametrization of the corresponding family of connections, it does not give us any particular idea on how to write down such a parametrization.

In the special case $d = 1$, we can write the equation down in an alternate form which is somewhat easier to parametrize; the cost is the introduction of an apparent singularity, but we can use the location of that singularity as one of the parameters. The idea is that although the matrix form of an equation is more natural for our purposes, we can also in general write equations in “straight-line” form (i.e., as a linear relation between the higher derivatives of a single function). This is non-unique in general, but in our case there is a natural choice coming from the generically unique global section of the sheaf. Indeed, we have noted that $M$ is generically acyclic, and generically irreducible, and an irreducible acyclic sheaf with the given invariants is generated by its unique global section. The kernel of the global section is a torsion-free sheaf of rank 1, and twisting by $c_1(M) = rQ$ makes the torsion-free sheaf a point of the 1-point Hilbert scheme of $X$. A generic point of that Hilbert scheme in turn has a unique map from the line bundle $O_X(-f)$, the cokernel of which is a sheaf of the form $O_f(-1)$. We thus generically obtain a complex

$$0 \rightarrow O_X(-rQ - f) \rightarrow O_X \rightarrow M \rightarrow 0 \quad (12.31)$$

which is exact except at $O_X$ where the cohomology has Chern class $f$. Thus the morphism $O_X(-rQ - f) \rightarrow O_X$ represents the same equation as $M$, apart from introducing a single apparent singularity.

In the Painlevé VI case, this morphism corresponds to an equation

$$\sum_{0 \leq i \leq 2r} c_i(z)(t(t - 1)(t - \lambda))^i f^{(i)}(z) = 0 \quad (12.32)$$

such that each $c_i(z)$ is a polynomial of degree at most $4r - 2i + 1$. This equation is regular except at $0, 1, \lambda, \infty$ and the unique root $v$ of $c_{2r}(z)$ (which we assume is not one of the four usual singularities).

Each exponent at one of the true singularities induces an arithmetic progression $e, e + 1, \ldots, e + r - 1$ of corresponding exponents of the straight-line equation. The exponents at $v$ must be nonnegative integers, and thus the global constraint on the exponents implies that they must be $0, 1, \ldots, 2r - 2$ and $2r$; we also must have that the equation is integrable at this point.

We start with $\sum_{0 \leq i \leq 2r} (4r - 2i + 2) = (2r + 1)(2r + 2)$ undetermined coefficients, and each of the eight original exponents imposes $r(r + 1)/2$ linear conditions, resulting in a $2r + 2$-dimensional space of equations (that automatically satisfies the remaining condition on the exponents at the apparent singularity; that the linear conditions are independent follows from the fact that $\chi(O_X(rQ + f)) = 2r + 2$). Fixing the leading term (i.e., fixing $v$ and the overall scalar) gives a $2r$-dimensional affine space of equations, and the integrability condition at $v$ imposes one quadratic condition for each exponent below the gap, so $2r - 1$ conditions. It follows from the general theory that the intersection of these quadrics is a rational curve, and in fact (since the map to $v$ is the natural ruling on the Hilbert scheme) is arithmetically $\mathbb{P}^1$; that is, it admits a parametrization over the field generated by $v$ and the exponents. Moreover, we also find that these straight-line equations admit a continuous isomonodromy transformation (presumably given by the Painlevé VI equation), as well as a lattice of discrete isomonodromy transformations, which are actually $r$-fold iterations of the usual Bäcklund transformations of the space of initial conditions of PVI. (The full lattice can still be obtained geometrically in this setting, but now corresponds to the translation part of the affine Weyl group action, and thus the atomic translations are actually given by formal integral transformations!)

It is worth noting that not every systematic family of infinitesimal deformations preserving the complexity of singularities corresponds to an isomonodromy transformation. Indeed, when
$g(C) > 0$, we have a $2g$-dimensional family of such deformations that do not change the singularities at all. The point is that on the untwisted ruled surface, although there is a natural choice of section, the corresponding sheaf is no longer rigid when $g > 0$, and thus we obtain a $2g$-dimensional family of regular connections on line bundles of degree 0. Tensoring an equation by such a connection gives a new equation with the same singularities, and thus the tangent space at the natural section induces an infinitesimal deformation of the equation. By the Riemann-Hilbert correspondence, the connection corresponding to a nontrivial section necessarily has nontrivial monodromy, since it is not isomorphic to the connection on $\mathcal{O}_C$ corresponding to the equation $v' = 0$; since the tensor product of connections has tensor product monodromy, we see that these actions do not, in fact, preserve monodromy. This is likely to complicate the geometric interpretation of continuous isomonodromy transformations, especially since on anything other than an untwisted surface, the association between sheaves and equations is only determined modulo precisely such tensor products! One way to resolve this would be to consider only the projective monodromy (i.e., the image in $\text{PGL}$, say by taking the adjoint representation, of the monodromy or Galois group), at the cost of including additional deformations (since the above $2g$-dimensional space of deformations indeed preserve the projective monodromy).

The above action of a (symplectic) group scheme on the moduli space interacts nicely with the natural map $\det R\rho_*$ from the moduli space to $\text{Pic}(C)$. Indeed, tensoring with a connection on a line bundle simply tensors the determinant with the $n$-th power of that bundle, assuming the original connection is on a rank $n$ vector bundle. We thus see in particular that the Lagrangian subgroup $\Gamma(\omega_C)$ fixes the map to $\text{Pic}(C)$, which presumably plays the role of a moment map for the action. In particular, this suggests that the quotient by $\Gamma(\omega_C)$ of any fiber over $\text{Pic}(C)$ should again be symplectic.

Something similar holds in the elliptic difference case, where again the moduli space of first order “equations” (isomorphisms $q^*\mathcal{L} \cong \mathcal{L}$ for $\mathcal{L}$ a line bundle of degree 0) is a symplectic group scheme with a Lagrangian subgroup (now $\mathbb{G}_m$) respecting $\det R\rho_*$. Of particular interest are cases in which the quotients of fibers by the Lagrangian subgroup are 0-dimensional (so essentially rigid), or 2-dimensional (open symplectic leaves of Poisson surfaces). The calculations we did above for $-1$-curves and $-2$-curves can be carried out more generally to find all possible divisors $D$ in the fundamental chamber such that $D \cdot Q = 0$ and $D^2 = 2g - 2$ or $D^2 = 2g$ (since the overall dimension is $D^2 + 2$, the reduction has dimension $D^2 + 2 - 2g$). The only possibility that exists for $g > 1$ is (with respect to an even ruling) $D = s + (g - 1)f$, which is of course just the case of first-order equations with no singularities. For $g = 1$, we obtain three additional cases, namely the case $D = 2s + f - 2e_1$ with $D^2 = 0$ and the cases $D = 2s + f - e_1 - e_2$, $D = 3s + f - 2e_1$ with $D^2 = 2$. The first case can be ruled out because it would correspond via an elementary transformation to a sheaf disjoint from $Q$ on an odd ruled surface, and such sheaves cannot exist; the third case can also be ruled out by considering the possible decompositions of $Q$ on $X_1$. The remaining case $D = 2s + f - e_1 - e_2$ was studied in the differential case by [21], where it was found that the moduli space is rational, and the continuous isomonodromy transformations (deforming the elliptic curve) are controlled by a special case of the usual Painlevé VI equation.

Let us consider the elliptic difference analogue more closely. We may use elementary transformations to ensure that both singular points lie on the same component of $Q$. An equation then corresponds to a holomorphic map $V \to \mathcal{L}_1 \otimes q^*V$ where $V$ is a rank 2 vector bundle on $E$ with fixed determinant, the determinant of the map vanishes at $x_1$, $x_2$, and $\mathcal{L}_1(-x_1 - x_2) \otimes q^{\deg(V)} \cong \mathcal{O}_C$. The action of the Lagrangian subgroup simply multiplies the map by a scalar, so that we are really looking at the projective space of such maps, modulo the action of $\text{Aut}(V)$. The simplest version takes the determinant of $V$ to have odd degree, say 1, as then (with limited exceptions) $V$ will be the unique indecomposable bundle of that determinant. In particular, we find that
\[ \dim \text{Hom}(V, \mathcal{L}_1 \otimes q^*V) = 4, \] with the determinant giving a quadratic map
\[ \text{Hom}(V, \mathcal{L}_1 \otimes q^*V) \rightarrow \Gamma((\det(V))^{-1} \otimes \mathcal{L}_1^2 \otimes q^* \det(V)). \] (12.33)

Since the latter line bundle has degree 2, we obtain a pencil of quadrics inside the \( \mathbb{P}^3 \) of maps, with an open subset of the desired moduli space being given by the complement of the base of the pencil inside the quadric corresponding to \( x_1 \). To identify the specific quadric surface and the embedding of the curve \( C \), note that any injective morphism as described factors through a unique bundle \( M_i \) such that \( M_i/V \cong \mathcal{O}_{x_1} \), and similarly for \( M_2 \). These bundles have degree 2, so are generically a sum of two line bundles of degree 1, so that the set of injective morphisms with a given \( M_i \) is a \( \mathbb{G}_m \)-torsor. (When \( M_i \) is not a sum of line bundles, it is a nontrivial self-extension of a line bundle, and we must replace \( \mathbb{G}_m \) by \( \mathbb{G}_a \).) Since each \( M_i \) is classified by a quotient of \( \text{Pic}^1(C) \) by an involution, we see that these give rulings of the quadric. To see how this meets the image of \( C \), note that such sheaves correspond to morphisms which are not injective, and thus to points on the boundary of the relevant \( \mathbb{G}_m \)-torsor (or \( \mathbb{G}_a \)-torsor). Such sheaves are determined by giving the degree 1 line bundle through which they factor, and each such bundle lies on a unique \( M_i \). In particular, the map \( \text{Pic}^1(C) \rightarrow \mathbb{P}^1 \) corresponding to \( M_i \) is the quotient by the involution \( \mathcal{L} \mapsto \det(V)(x_i) \otimes \mathcal{L}^{-1} \), since \( \det(M_i) = \det(V)(x_i) \). As long as \( x_1 \) and \( x_2 \) are distinct, these give distinct rulings, and thus completely determine the anticanonical quadric surface.

This is not quite the correct moduli space, for the simple reason that \( V \) need not be stable in general. If \( \mathcal{L}_1(-x_1) \) and \( \mathcal{L}_1(-x_2) \) are nontrivial, then the only unstable bundles that admit morphisms with the correct nonzero determinant are those of the form \( \mathcal{L} \oplus \det(V) \otimes \mathcal{L}^{-1} \) with \( \mathcal{L}^2 \cong \det(V) \otimes \mathcal{L}_1 \). Modulo the action of \( \text{Aut}(V) \), each choice of \( \mathcal{L} \) gives rise to an \( \mathbb{A}^1 \) worth of additional points in the moduli space, except that one sheaf on each \( \mathbb{A}^1 \) has nontrivial stabilizer (modulo the action of the Lagrangian subgroup, that is) of order 2, and thus corresponds to a singular point of type \( A_1 \).

It follows that the true moduli space is obtained as follows from the data \( \det(V), \mathcal{L}_1, x_1, x_2 \) and \( q \); embed \( C \) in \( \mathbb{P}^1 \times \mathbb{P}^1 \) by the line bundles \( \det(V)(x_1) \) and \( \det(V)(x_2) \), then for each point \( y_i \) such that \( \det(V) \otimes \mathcal{L}_1(-2y_i) \) is trivial, blow up \( y_i \) twice, and finally contract the four \(-2\)-curves that result. In particular, apart from the presence of singular points, this is precisely the space on which a special case of the elliptic Painlevé equation acts. Since the isomonodromy transformations induce isomorphisms of the quasiprojective moduli space, they necessarily correspond to isomorphisms between these surfaces. The correspondence is somewhat more complicated than just a direct relation between the isomonodromy equation and elliptic Painlevé, for the simple reason that the \( q \) parameter of the latter is actually twice the original \( q \), and thus the elliptic Painlevé translation group can only give an index two subgroup of the true group of isomonodromy transformations.

This relates to the fact that due to the relations between the parameters, there are additional isomorphisms between the moduli spaces; in particular, changing \( \det(V) \) has no effect, and there is even an action of \( \text{Pic}^0(C)[2] \) corresponding to twisting \( V \) by a 2-torsion line bundle. Modulo this residual freedom, reflecting by the four orthogonal roots \( f - e_{2i-1} - e_{2i} \) and then by \( s - f \) has the desired effect on the parameters, and thus establishes an isomorphism of moduli spaces agreeing with the isomonodromy transformation modulo automorphisms. It is straightforward to verify that the only automorphisms come from \( \text{Pic}^0(C)[2] \) (an automorphism is determined by its action on the root lattice of \( \tilde{E}_8 \), and must preserve the intersection form, the map to \( \text{Pic}^0(C) \), and the set of effective roots), and thus the isomorphisms agree for \( C \) with no rational 2-torsion, and thus in general.

The relation between differential equations on an elliptic curve with a single singularity (say at 0) and Fuchsian differential equations with four singular points is easy enough to explain in one
sense: it simply corresponds to rewriting the equation in terms of the function $x$ on the elliptic curve. As long as the original equation is invariant under $z \mapsto -z$, this change of variables can be performed, and gives a rational equation with singular points 0, 1, $\infty$ and $\lambda$, with the exponents at those singular points determined from the original exponents at 0. At that point, of course, the isomonodromy transformation deforming the elliptic curve translates directly to an isomonodromy transformation deforming $\lambda$.

This raises the question of how the given noncommutative surfaces are related. More generally, given an algebraic map $\phi : C \to C'$, we should expect some relationship between noncommutative surfaces rationally ruled over $C$ of differential type and noncommutative surfaces rationally ruled over $C'$ of differential type. The most natural form such a relation could take would be that of a morphism (i.e., an adjoint pair of functors $\pi_*$, $\pi^*$ between the two categories). Indeed, given an equation on $C'$ we can certainly pull it back, while an equation on $C$ has a direct image equation on $C'$ (of order $\deg(\phi)$ times the original order), so that the relation we considered in the elliptic case boils down to writing the elliptic equation as a pullback. The analogous functors for actual sheaves will be somewhat complicated by ramification, and indeed it seems likely that the codomain of the morphism of noncommutative surfaces will end up being singular in general, as it was in the elliptic difference case considered above. (Although we have not discussed singular noncommutative surfaces, they are easy enough to construct: simply take the $\mathbb{Z}$-algebra corresponding to a divisor on the boundary of the nef cone. But of course we would like to know that the result only depends on the face of the nef cone containing that divisor, and will need to understand the categories.)

Similar sources of morphisms should arise in the difference settings; not only should there be a direct analogue to the above coming from morphisms between the respective curves that are equivariant with respect to $q$ or the infinite dihedral group, one also expects morphisms taking equations $v(qz) = A(z)v(z)$ to $v(q^kz) = A(q^{k-1}z) \cdots A(z)v(z)$, as well as morphisms related to forgetting the symmetry of a symmetric difference equation. These are closely related to the notion of $G$-equivariant sheaf discussed above in the moduli space context, with some caveats. For a non-symmetric difference equation, the map from

$$v(qz) = A(q^{k-1}z) \cdots A(z)v(z) \quad \text{to} \quad v(qz) = A(q^kz) \cdots A(qz)v(z) \quad (12.34)$$

corresponds to twisting by a line bundle (assuming that $A$ has no apparent singularities, at least!), and thus we find that translation by $q$ has the same effect as twisting by a line bundle and permuting the blowups, so that the sheaf is indeed isomorphic to its image under the corresponding automorphism of order $k$ of the abelian category. Moreover, although we cannot recover $A$ from the new equation alone (we could, e.g., multiply $A$ by any automorphism of order $k$ of the original equation), we can recover it from a specific compatible choice of isomorphism, so that the original equation truly does represent a $\mathbb{Z}/k\mathbb{Z}$-equivariant sheaf on the new surface. This also applies to the case of a nonsymmetric difference equation obtained by forgetting the symmetry of a symmetric difference equation, where now the automorphism has order 2 and acts on $Q$ in such a way as to swap the components while preserving $q$. The map from $q$-difference equations to $q^k$-difference equations is more subtle in the symmetric case, and is only the quotient by an automorphism when $k = 2$; the difficulty more generally is that the symmetry combines with the cyclic group to form the dihedral group of order 2$k$. Of course this means that we can still view the morphism as a map between two different quotients of the category of nonsymmetric equations. Similar comments apply to the case of a $q$-difference equation equation invariant under $z \mapsto \zeta_k z$.

Also of interest in this context are the symmetries of the moduli space coming from duality, which include cases in which the discrete connection takes values in GO, GSp, or U (or in the corresponding Lie algebra, in the differential case). Here it is worth noting that second order
equations *always* have such a symmetry, since $\text{GL}_2 \cong \text{GSp}_2$, or more concretely since for a $2 \times 2$ matrix $A$, $\det(A) A^{-t} = J AJ^{-1}$, where $J$ is any nonzero alternating matrix. (In the differential case, this becomes $\text{tr}(A) - A^t = J AJ^{-1}$.) More precisely, given a sheaf of Chern class $2s + df - e_1 - \cdots - e_m$, the symmetry is given by composing the canonical adjoint, the longest element of $W(D_m)$, and the twist by a suitable line bundle, with the latter in general depending on $\det(A)$. (Thus in the higher genus case, this is really a symmetry of the subspace of the moduli space on which the determinant of the equation has been fixed.) This does not preserve $\Sigma$, so switching back to the original $\Sigma$ introduces the requisite scalar gauge. This description only works as stated when none of the roots of $D_m$ are effective, but can be fixed easily enough, at least generically. Indeed, we can typically produce a *derived* equivalence corresponding to the longest element of $W(D_m)$, and this will take our sheaf to a sheaf unless that sheaf has a subquotient of the form $O_{\alpha}(d)$ for $\alpha$ a root of $D_m$ (which essentially says that the equation has apparent singularities). The only issue (apart from nonuniqueness of the derived equivalence) would be if we were ever trying to reflect in an effective simple root of $D_m$ that was not irreducibly effective. But this cannot happen: this would imply that $Q$ had a component of the form $f - e_i - \cdots - e_i$ or $e_i - \cdots - e_i$, but these have negative intersection with the Chern class of our sheaf.

Although this symmetry in principle survives the Fourier transform, it does so in a particularly obscure form, and indeed it is not clear whether the resulting symmetry has any simpler description than as a conjugate by the Fourier transform. However, it can still lead to interesting consequences when combined with other symmetries. An interesting case is related to the Lax pair for Painlevé VI of [31], a differential equation of the form $\text{VI of } \alpha (z + A_0)v$ where $A_0, A_1 \in \mathfrak{so}(8)$. Since $\text{rank}(A_1) = 2$, applying the Mellin transform gives a second-order difference equation, and this equation inherits a contravariant symmetry from the original $\mathfrak{so}(8)$ structure. This symmetry combines with the contravariant symmetry coming from having rank 2 to give a nontrivial covariant symmetry, and one then finds that a suitable scalar gauge transformation puts that symmetry in the form $A(z) = A(-z)^{-1}$. In other words, this second-order equation is a symmetric difference equation, which turns out to be precisely the linear problem arising in [36]. (One can also verify that the same thing happens for the other two eighth-order differential equations arising via triality.)

It may be instructive to work the above example backwards. If we start with the linear problem of [36] and forget the symmetry, then the result (modulo scalar gauge) is a sheaf of Chern class $2s + 4f - e_1 - \cdots - e_{12}$ on a surface on which $Q$ decomposes as

\[
(s - e_5 - e_7 - e_9 - e_{11}) + (s - e_6 - e_8 - e_{10} - e_{12}) + 2(f - e_1 - e_2) + (e_1 - e_3) + (e_2 - e_4), \tag{12.35}
\]

with the original symmetry being reflected via the composition of swapping $e_{2i-1}$ with $e_{2i}$ for each $i$ and a suitable involution on $Q$. The corresponding contravariant symmetry involves the product of reflections in the roots $f - e_5 - e_6$, $f - e_7 - e_8$, $f - e_9 - e_{10}$, $f - e_{11} - e_{12}$ (once we have taken into account the fact that some roots of $D_{12}$ are components of $Q$), and thus still does not behave well under the inverse Mellin transform. However, if we reflect the sheaf in $f - e_6 - e_8$ and $f - e_{10} - e_{12}$, then the contravariant symmetry only involves a permutation of the blowups. This still does not allow a Mellin transform—there are now too many singularities on one of the two horizontal components of $Q$—but we can fix this by repeatedly performing an elementary transformation in the point where that component meets the vertical component. (I.e., blow up that point, permute that blowup to be the first blowup, then take the elementary transform.) After doing that four times, the result is a sheaf with Chern class $2s + 8f - 2e_1 - 2e_2 - 2e_3 - 2e_4 - e_5 - \cdots - e_{16}$ on a surface with anticanonical curve decomposing as

\[
Q = (s - e_9 - e_{10} - e_{11} - e_{12} - e_{13} - e_{14} - e_{15} - e_{16}) + (s - e_1 - e_2 - e_3 - e_4) + 2(f - e_1) + 2(e_1 - e_2) + 2(e_2 - e_3) + 2(e_3 - e_4) + 2(e_4 - e_5 - e_6) + (e_5 - e_7) + (e_6 - e_8), \tag{12.36}
\]

159
with a contravariant symmetry involving permuting \( e_9 \) through \( e_{16} \) and an involution on \( Q \). It follows that the inverse Mellin transform is an 8th order equation that still has such a contravariant symmetry, and thus after a scalar gauge to make the trace vanish preserves a bilinear form.

The above example points out two things: First, there is a fair amount of freedom in how we obtained a sheaf having both a transform and a contravariant symmetry surviving that transform in a recognizable form. Indeed, although it was natural to perform the elementary transformations in the point “at infinity” on the offending component, we could instead have performed any four such transformations that respected the involution acting on \( Q \). Most of the time this would still produce an 8th order equation with a contravariant symmetry (albeit rather different qualitative behavior), but including finite singularities of the difference equation in the set also gives rise to 6th or even 4th order equations. Second, it is unclear how to tell a priori that the above construction gives an equation in \( \mathfrak{so}_8 \) rather than \( \mathfrak{sp}_8 \).

Geometrically, the source of this symmetry appears to be the fact that in the commutative case, the linear system consists entirely of hyperelliptic curves. Another natural instance where this happens is the matrix Painlevé case (on a rational surface) \( D = 4s + 4f - 2e_1 - \cdots - 2e_7 - e_8 - e_9 \), where the linear system consists of genus 2 curves. There is indeed a symmetry in this case as well, though the action on equations is much more difficult to describe, as it involves acting by the longest element of \( W(E_8 \oplus A_1) \) and (in the elliptic case) reflecting in the degree 2 divisor class \( x_8 + x_9 \). It turns out (since \( D|Q \sim 0 \)) that these operations give a covariant equivalence to the adjoint surface, and thus induce a contravariant autoequivalence of the original surface.

This suggests that in addition to any intrinsic interest in understanding morphisms between noncommutative surfaces, such an understanding would also be quite fruitful in the application to special functions, e.g., by systematically explaining quadratic (or higher-order) transformations. In addition, the symmetries of the moduli space associated to dualities may give some insight into the structure of the moduli spaces of meromorphic \( G \)-connections (or discrete \( G \)-connections) for more general structure groups than \( \text{GL}_n \). Note that we cannot expect there to be any reasonable interpretation of a \( G \)-structure on a sheaf per se, for the simple reason that the order of the corresponding equation depends on a choice of ruling on the surface, so that changing the ruling may prevent the corresponding \( V \) from being a \( G \)-torsor. (Indeed, this already happens when \( G = \text{GL}_n \) and \( n \) is not the minimal order of an interpretation of \( M \) as an equation.) Thus any notion of \( G \)-structure on a sheaf must at the very least be taken relative to a choice of ruling, and possibly a choice of section \( \Sigma \).

### Appendix A Generalized Fourier transforms

One of the main motivations for the derived category approach we have used above is the sheer proliferation of cases that would otherwise need to be considered. For instance, in the case of the Fourier transform (i.e., swapping the rulings of \( \mathbb{P}^1 \times \mathbb{P}^1 \)), there are 16 different cases that naturally arise (not even including some of the issues in characteristic 2), and one would in each case need to show that the two representations via operators not only satisfy the same relations, but also give rise to the same category of sheaves. We do not attempt the latter directly, but for applications to special functions, it is still useful to understand the former. The main use is that, given a new linear problem for an integrable system of isomonodromy type, one would generally like to know whether it is truly new, or if it can be reduced to a known linear problem. In particular, if we translate it into a sheaf on an appropriate noncommutative surface, then there is a blowdown structure relative to which its Chern class is in the fundamental domain, and thus will give a simplest form for the equation (in particular, of lowest order). (This may not be unique, of course, but there will be only
finite many such forms.) The relation to the original linear problem is via the appropriate element of $W(E_{m+1})$, and we have already seen that $W(D_m)$ acts by scalar gauge transformations, so that the only truly nontrivial action involves the Fourier transform. Thus a suitable understanding of the Fourier transform will let us understand all of the minimal linear problems equivalent to a given linear problem.

One tricky issue is that on the untwisted (rational) ruled surfaces for which we have natural interpretations of equations, the divisor class $s - f$ is always effective, and thus we do not have a Fourier transform (as an abelian equivalence, that is). Thus there is invariably an issue with twisting to consider. One approach would be to choose the normalizing section $\Sigma$ to have Chern class $s + f$; this is ample when $s - f$ is ineffective, and thus there is always such a sheaf. This has the disadvantage of introducing additional parameters, and thus additional ways for things to degenerate; we obtain a total of 48 different possibilities for the possible structure of the anticanonical curve on the separating blowup for such a $\Sigma$. (To be precise, if we take into account the order in which the points are blown up, there are 225 cases, but they fall into 48 orbits.) It is also somewhat cumbersome to compute the transform in this form, as $\Sigma$ normalizes equations, but does not quite normalize an algebra of operators: the issue is that $\Sigma$ is not invariant under twisting by line bundles, so we can only use this normalization to control operators acting on the trivial vector bundle. This approach is still workable, as we can still use it to compute the kernel of a suitable formal integral transform (or, more precisely, the equations satisfied by the kernel), which is enough to enable the computation of the Fourier transform on equations in straight-line form.

An alternate approach is to simply find some representation in terms of operators in each of the 16 cases, and then check that there are isomorphisms as required. The main disadvantage of this approach is that we need to represent the full category of morphisms between line bundles on $X_0$, and there is a great deal of nonuniqueness in that representation. In particular, if we assign to each line bundle a first-order equation, with specified gauge equivalences between them, then we can gauge by the resulting system to obtain a new representation. (Note that $\Sigma$ only specifies the equation associated to the trivial bundle!) We can also similarly gauge by a system of automorphisms of $Q$, with the resulting effect on matrix equations being to pull back by the automorphism associated to the trivial bundle. Although this nonuniqueness makes it relatively easy to find representations, there is a significant cost when it comes to understanding limits: to degenerate one case to another, it may be necessary to make a suitable gauge transformation first.

If we consider applying such a representation to computing the Fourier transform of an equation, we find that there is a considerable simplification available. The point is that the sheaves $\mathcal{O}_X, \mathcal{O}_X(-s), \mathcal{O}_X(-f), \mathcal{O}_X(-s-f)$ form a strong exceptional collection, and thus if $M, M(-s), M(-f), M(-s-f)$ are all acyclic, then $M$ has a resolution of the form

$$0 \to \mathcal{O}_X(-s-f)^a \to \mathcal{O}_X(-f)^b \oplus \mathcal{O}_X(-s)^c \to \mathcal{O}_X^d \to M \to 0.$$  \hspace{1cm} (A.1)

In other words, $M$ can be expressed as the solution of a system of $b + c$ equations in $d$ unknowns, with each equation either being a linear equation (with coefficients in $\text{Hom}(\mathcal{O}_X(-f), \mathcal{O}_X)$) or a first-order difference/differential equation (coming from $\text{Hom}(\mathcal{O}_X(-s), \mathcal{O}_X)$). We can recover the corresponding (discrete) connection by using the linear equations to express the $d$ unknowns as the global sections of a vector bundle, and observing that the remaining equations describe a (discrete) connection on that vector bundle. But then to understand how the Fourier transform acts on equations, it suffices to understand how it acts on suitable sections of $\text{Hom}(\mathcal{O}_X(-f), \mathcal{O}_X)$ and $\text{Hom}(\mathcal{O}_X(-s), \mathcal{O}_X)$. Moreover, the condition for a pair of maps from those 2-dimensional spaces to operators (with the first mapping to multiplication operators and the second to first-order operators)
to extend to a representation of the category is basically that there be two more such maps, from \(\text{Hom}(\mathcal{O}_X(-s-f), \mathcal{O}_X(-s))\) and \(\text{Hom}(\mathcal{O}_X(-s-f), \mathcal{O}_X(-f))\), such that the compositions span a 4-dimensional space. Note that by a judicious use of the gauge freedom, we can choose the representation so that twisting by \(s + f\) does not affect the representation: gauge by a suitable square root of the anticanonical natural transformation. We can furthermore arrange in this way for all of the spaces of multiplication operators to agree, at which point we can deduce all of the spaces of degree \(s\) given one such space and the compatibility condition.

For instance, in the (symmetric) elliptic difference case, we choose a ramification point of \(Q \to \mathcal{C}_0\) to make it an honest elliptic curve, and then use the remaining gauge-by-automorphisms freedom (at the cost of choosing an element \(q/2\) to ensure that all of the operators are invariant under \(z \mapsto -z\). Then there is a representation in which the typical operator of degree \(f\) is proportional to \(\vartheta(z \pm u) := \vartheta(z + u, z - u) := \vartheta(z + u)\vartheta(z - u)\), while the typical operator of degree \(s\) is proportional to \(D_q(c \pm u) := \frac{\vartheta(c + u + z, c - u + z)}{\vartheta(2z)} T^{1/2} + \frac{\vartheta(c + u - z, c - u - z)}{\vartheta(-2z)} T^{-1/2}\) (A.2)

where \((T^{\pm 1/2}f)(z) = f(z \pm q/2)\) and \(c\) is a parameter depending not only on the surface but on the domain of the morphism of line bundles. We in particular find (by comparing coefficients of \(T^{1/2}\), say) that the spans of

\[
D_q(c \pm v)\vartheta(z \pm u) \quad \text{and} \quad \vartheta(z \pm u)D_q(c + q/2 \pm v)
\]  

(A.3)

agree and are 4-dimensional, so that these indeed extend to give a representation of a category of the desired form. Moreover, we see (by comparison to [42], or simply by noting that each 2-dimensional space is a space of global sections of a line bundle, and the relations are the same as those satisfied by the global sections) that this actually gives the general form of a relation in the elliptic case, so every noncommutative \(\mathbb{P}^1 \times \mathbb{P}^1\) with smooth anticanonical curve has a representation in this form. The Fourier transform can be viewed as a formal system of operators \(\mathcal{F}_q(c)\) such that \(\mathcal{F}_q(-c) = \mathcal{F}_q(c)^{-1}\) and

\[
\vartheta(z \pm u)\mathcal{F}_q(c) = \mathcal{F}_q(c + q/2)D_q(c + q/2 \pm u).
\]  

(A.4)

(One can in fact take \(\mathcal{F}_q(c)\) to be a certain formal difference operator, as the univariate case of [40, §8], though it is perhaps more natural to view it as a formal integral operator.) In particular, given an equation of the form

\[
\vartheta(z \pm u_1)\lambda_1 \cdot v(z) + \vartheta(z \pm u_2)\lambda_2 \cdot v(z) = 0,
\]  

(A.5)

then \(w = \mathcal{F}_q(c)v\) formally satisfies

\[
D_q(-c + q/2 \pm u_1)\lambda_1 \cdot w(z) + D_q(-c + q/2 \pm u_2)\lambda_2 \cdot w(z) = 0,
\]  

(A.6)

and similarly if

\[
D_q(c + q/2 \pm u_1)\lambda_1 \cdot v(z) + D_q(c + q/2 \pm u_2)\lambda_2 \cdot v(z) = 0,
\]  

(A.7)

then

\[
\vartheta(z \pm u_1)\lambda_1 \cdot w(z) + \vartheta(z \pm u_2)\lambda_2 \cdot w(z) = 0.
\]  

(A.8)

The compatibility condition essentially reduces to

\[
\mathcal{F}_q(c)D_q(u_0, u_1, u_2, u_3) = D_q(u_0 - c, u_1 - c, u_2 - c, u_3 - c)\mathcal{F}_q(c)
\]  

(A.9)
for $u_0 + u_1 + u_2 + u_3 = 2c + q$, where

$$D_q(u_0, u_1, u_2, u_3) := \frac{\vartheta(u_0 + z, u_1 + z, u_2 + z, u_3 + z)}{\vartheta(2z)} T^{1/2} + \frac{\vartheta(u_0 - z, u_1 - z, u_2 - z, u_3 - z)}{\vartheta(-2z)} T^{-1/2}$$

(A.10)

is (modulo scalars) the typical element of degree $s + f$. (In particular, these elements generate a graded algebra which is the quotient of the Sklyanin algebra [40, 47] by a central element of degree 2, see also [43, 38].)

The top ordinary difference case is similar: just replace $\vartheta(z) = z$ and optionally set $q$ to 1. Note that in these cases, it is no longer true that every operator in the appropriate space is proportional to one of the given form (e.g., we now have a multiplication operator 1), but this remains true for a dense set of operators. Also, in these cases, we may interpret $\mathcal{F}_q(c)$ as a fractional power of a suitable symmetric lowering operator (the Askey-Wilson or Wilson operator, as appropriate). Indeed, the limit as $u \to \infty$ of the main identity of the Fourier transform gives

$$\mathcal{F}_q(c) = \mathcal{F}_q(q^{1/2}c) \frac{1}{(1/z - 1/u)}(T^{1/2} - T^{-1/2}),$$

(A.16)

and thus

$$\mathcal{F}_q(q^{-n/2}) = \mathcal{F}_q(1)((1/z - 1/u)^{-1}(T^{1/2} - T^{-1/2}))^n,$$

(A.17)

with $\mathcal{F}_q(1)$ acting trivially. This lowering operator takes symmetric Laurent polynomials to symmetric Laurent polynomials, decreasing the degree, and thus in particular the equation

$$(1/z - 1/u)^{-1}(T^{1/2} - T^{-1/2})_v = 0$$

(A.18)

may be viewed as the normalizing section $\Sigma$. The additive case similarly corresponds to powers of $2z)^{-1}(T^{1/2} - T^{-1/2})$. (Something similar is true in the elliptic case, see [40, §8], although it is no longer true that the result is actually a power of the operator for $c = q^{-1/2}$.)

The next easiest set of degenerations to consider are those for which $Q$ has two components of class $s + f$, and thus the operators are no longer symmetric. Here we first encounter the
issue mentioned above with limits: in order to obtain a nonsymmetric operator from a symmetric operator, we must conjugate by an automorphism to reintroduce the symmetry as a parameter and then take the limit in that parameter. Thus in the $q$-difference case, we conjugate by $z \mapsto wz$ and take a limit $w \to \infty$. Doing so in a naive fashion makes the operators of interest blow up, and rescaling the operators kills the parameters, so we find that we must also rescale $u$. There remains a further subtle issue, in that we need to rescale the operators of degree $f$ but not of degree $s$, which implicitly means that we need to include an additional scale factor in the Fourier transforms. In the end, we find that the operators of degree $f$ become $z - u$, the operators of degree $s$ become $(-cT^{1/2} + c^{-1}T^{-1/2}) + (u/z)(T^{1/2} - T^{-1/2})$, and the Fourier transform acts by
\[(z - u)\mathcal{F}_q^\prime(c) = \mathcal{F}_q^\prime(q^{-1/2}c)((u/z - q^{-1/2}c)T^{1/2} + (-u/z + 1/q^{1/2}c)T^{-1/2}).\] (A.19)
(We omit the action on elements of degree $s + f$.) This again corresponds to a fractional power of a lowering operator, namely $z^{-1}(T^{-1/2} - T^{1/2})$. Similarly, the additive case involves taking a limit $w \to \infty$ after substituting $z \mapsto z + w$, $u \mapsto u + w$, and gives (again up to rescaling $\mathcal{F}'$ accordingly)
\[(z - u)\mathcal{F}_q^\prime(c) = \mathcal{F}_q^\prime(c + q/2)((u - z - c - q/2)T^{1/2} + (z - u - c - q/2)T^{-1/2}),\] (A.20)
corresponding to fractional powers of $T^{-1/2} - T^{1/2}$. If we then let $q, c \to 0$ at comparable rates, then a similar rescaling gives a transform involving differential operators:
\[(z - u)\mathcal{F}'(\alpha) = \mathcal{F}'(\alpha + 1/2)((z - u)D + (2\alpha + 1)),\] (A.21)
again with $\mathcal{F}'(-\alpha) = \mathcal{F}'(\alpha)^{-1}$. This is essentially the transform of [20] (often called “middle convolution” in the later literature). Moreover, by taking a limit of the corresponding fractional-power-of-lowering-operator interpretation, we see that it can be described via fractional differentiation: $\mathcal{F}'(\alpha) = D^{-2\alpha}$; indeed, one has
\[D^{2\alpha+1}(z - u) = ((z - u)D + (2\alpha + 1))D^{2\alpha}.\] (A.22)

We next turn to the transforms that map between symmetric and nonsymmetric operators, or in geometric terms relate surfaces with $Q = (2s + f) + (f)$ to surfaces with $Q = (s + 2f) + (s)$. Here the main complication is that by making the symmetric operators truly symmetric, we obtain a transform without any parameters, but still need mild dependence of the transform on the domain of the morphism. Luckily, this dependence is very mild, and indeed simply involves a power of $T^{1/2}$. The overall idea is to take the limit as $c \to 0$ of the symmetric $q$-Fourier transform, except that we need to include an overall shift of the parameter on one side to break the symmetry. It also turns out that we need to include an overall gauge on the nonsymmetric side to make the limits work, which we do in such a way as to ensure that the operators take polynomials to polynomials. This gives a pair of inverse transforms $\mathcal{F}_q^\prec$ and $\mathcal{F}_q^\succ$ such that
\[\mathcal{F}_q^\prec q^{-1/2}(z - u)T^{-1/2} = \left(\frac{z - u}{z^2 - 1}T^{-1/2} - \frac{z^{-1} - u}{z^{-2} - 1}T^{1/2}\right)\mathcal{F}_q^\prec\] (A.23)
\[\mathcal{F}_q^\prec((z + 1/z - u - 1/u)T^{-1/2} - z^{-1}T^{1/2})T^{1/2} = (z + 1/z - u - 1/u)\mathcal{F}_q^\prec.\] (A.24)
The additive equivalent is
\[\mathcal{F}_q^\prec T^{-1/2}(z - u) = \left(\frac{z - u - 1/2}{2z}T^{-1/2} + \frac{z + u + 1/2}{2z}T^{1/2}\right)\mathcal{F}_q^\prec\] (A.25)
\[\mathcal{F}_q^\prec((z^2 - u^2)T^{-1/2} - T^{1/2})T^{1/2} = (z^2 - u^2)\mathcal{F}_q^\prec.\] (A.26)
The next cases to consider are those for which $Q$ has components of Chern class $s + f$, $s$, and $f$, which again comes in multiplicative and additive flavors. In these cases, the corresponding commutative Poisson surface is uniquely determined, and thus we have the additional possibility of arranging for the Fourier transform to act as an involution on that surface. There is, however, a technical issue that arises, particularly in the multiplicative case: it turns out that the involution is not Poisson, but rather anti-Poisson. (It has non-isolated fixed points in the open symplectic leaf, so negates the volume form at those points.) As a result, the simplest form of the corresponding Fourier transform turns out to invert $q$. Note also that because $Q$ has components of degrees $s$ and $f$, we can use the corresponding natural transformations to determine the gauge in place of a square root of the anticanonical natural transformation. This has the advantage of expressing the category of line bundles as a Rees algebra relative to a filtration by $\mathbb{N}^2$. The corresponding filtered algebra may be taken to be generated by $z$ (of degree $f$) and by the lowering operator $z^{-1}(1 - T)$ (of degree $s$). These generators satisfy the equivalent relations

$$yx = qxy + (1 - q) \quad \text{and} \quad xy = q^{-1}yx + (1 - q^{-1}),$$

(A.27)

so that swapping $x$ and $y$ gives the algebra with $q$ inverted. The additive case is somewhat simpler, as in that case we can arrange for the involution to be actually Poisson. We obtain a bifiltered algebra with relation

$$[y, x] = y - x$$

(A.28)

and involution that swaps $x$ and $y$, with a representation $x \mapsto z$, $y \mapsto z + T$ in difference operators.

The remaining cases have similar interpretations in terms of bifiltered algebras. The multiplicative case (with $Q = (s) + (s) + (f) + (f)$) is particularly simple: the filtered algebra is simply the $q$-Weyl algebra $yx = qxy$, with representation $x \mapsto z$, $y \mapsto T$ and involution that again inverts $q$. The additive case ($Q = (s) + (s) + 2(f)$) transforms to a differential case ($Q = 2(s) + (f) + (f)$), with filtered algebra

$$[y, x] = y$$

(A.29)

and representations $x \mapsto z$, $y \mapsto T$ and $x \mapsto -tD$, $y \mapsto t$. The corresponding transforms are quite familiar: from the differential side to the discrete side is precisely the Mellin transform, and the inverse is the $z$ transform. (And, of course, the differential-to-discrete direction underlies the standard power series method for solving linear ODEs.) The remaining case ($Q = 2(s) + 2(f)$) is the usual Weyl algebra $[y, x] = 1$, with representations $x \mapsto t$, $y \mapsto D$ and $x \mapsto -D$, $y \mapsto t$. This of course is just the classical Fourier transform.

Our purpose above was to give enough information to enable explicit calculations of the transforms in special functions applications. As such, there are a number of issues we have not attempted to address. One is that in the elliptic case [42] and in the cases involving differential operators (classical), the generalized Fourier transform can be expressed as an integral operator. Of course, in the differential cases, there are potential issues with convergence (e.g., the usual Fourier transform is difficult to define unless the argument decays at infinity), and in particular it is unclear whether there is an actual operator acting on a space containing solutions to the equations of interest. (This was mostly settled in the elliptic case, but even there, the actual contour integral description requires additional constraints on the solutions, so that not every solution appears, just a sufficiently independent set of solutions.) The situation is worse in the discrete cases, as the solutions are only determined up to multiplication by meromorphic functions invariant under the shifts. In particular, one finds that the kernel of the formal integral transform is itself only determined up to shift-invariant functions. One may also be tempted to think that since the Fourier transform takes operators of degree $s + f$ to operators of degree $s + f$, that this means that the Fourier transform
of an explicit solution of such an equation will be easily expressible in closed form. Although this is true in many cases, the indeterminacy of the solution and kernel poses some difficulties. Indeed, all we know is that the integral is a solution of the equation, but this only determines the integral up to a periodic function of $z$, which need not have any nice form.

Another is that at the elliptic level, the transforms have natural multivariate analogues related to Macdonald theory; indeed, the limit to the most general multiplicative case is essentially a fractional power of the Macdonald-Koornwinder lowering operator. This suggests that all 16 of the above transforms should have similar multivariate analogues.

An alternate approach to constructing the list of Fourier transforms involves degenerating the canonical gauge of [12]. In general, any surface of type $F_1$ such that $s$ is not a component of $Q$ has such a canonical gauge, which (up to constants) is given by gauging so that every operator of degree $s$ annihilates 1, while the operators of degree $f$ remain rational functions on $Q$. In particular, if we start with a surface of type $F_0$ and blow up a point which is not on a component of $Q$ of class $s$ or $f$, then either way of blowing down to $F_1$ gives a surface with such a canonical gauge. This makes the limits easier to take (there is no longer a need to consider a change of gauge), at the cost of both splitting some of the cases (e.g., at the top level, there is a subcase in which the point being blown up is a singular point of $Q$) and not applying to the four cases in which every component of $Q$ has class $s$ or $f$. There is a further variant of this approach that applies to these cases as well: simply blow up three points in such a way that there is no component of $Q$ having negative intersection with $s + f - e_1 - e_2 - e_3$, and gauge so that the corresponding operator annihilates 1. Each of these approaches is analogous to the normalization of equations via a choice of section, except that in order to normalize morphisms of line bundles, we must choose a normalizing sheaf for each line bundle, which in the above approach we do by specifying the Chern class and all but one of the points of intersection with $Q$.
