Detecting Identification Failure in Moment Condition Models

Jean-Jacques Forneron

July 31, 2019

Abstract

This paper develops an approach to detect identification failures in a large class of moment condition models. This is achieved by introducing a quasi-Jacobian matrix which is asymptotically singular under higher-order local identification as well as weak/set identification; in these settings, standard asymptotics are not valid. Under (semi)-strong identification, where standard asymptotics are valid, this matrix is asymptotically equivalent to the usual Jacobian matrix. After re-scaling, it is thus asymptotically non-singular. Together, these results imply that the eigenvalues of the quasi-Jacobian can detect potential local and global identification failures. Furthermore, the quasi-Jacobian is informative about the span of the identification failure. This information permits two-step identification robust subvector inference without any a priori knowledge of the underlying identification structure. Monte-Carlo simulations and empirical applications illustrate the results.

JEL Classification: C11, C12, C13, C32, C36.

Keywords: GMM, robust subvector inference, higher-order/weak/set identification.
1 Introduction

The Generalized Method of Moments (GMM) of Hansen & Singleton (1982) is a powerful estimation framework which does not require the model to be fully specified parametrically. Under regularity conditions, the estimates are consistent and asymptotically normal. In particular, the moment conditions should uniquely identify the finite dimensional parameters. This is very difficult to verify in practice and, as noted in Newey & McFadden (1994), is often assumed. Yet, when identification fails or nearly fails, the Central Limit Theorem provides a poor finite sample approximation for the distribution of the estimates. This has motivated a vast amount of research on tests which are robust to identification failure. As discussed in the literature review, much of this work has focused on tests for the full parameter vector. Potentially conservative confidence intervals for scalar parameters can then be built by projecting confidence sets for the full parameter vector (Dufour & Taamouti, 2005) or using a Bonferroni approach (McCloskey, 2017).

The contribution of this paper is two-fold: First, it introduces a quasi-Jacobian matrix which is singular under both local (first-order) and global identification failure and is informative about the coefficients involved in the failure. This is the main contribution of the paper and provides an approach similar to Cragg & Donald (1993) and Stock & Yogo (2005) but in a non-linear setting. Second, the information from the first step allows for two-step identification robust subvector inference, akin to type I inference in Andrews & Cheng (2012) but without a priori knowledge of the identification structure.

To detect identification failures, this paper constructs a quasi-Jacobian matrix which corresponds to the best linear approximation of the sample moments function over a region of the parameters where these moments are close to zero, as defined by a bandwidth. To find the best linear approximation, two loss functions are considered: the supremum norm measures the largest difference between the moments and its approximation while the least-squares criterion focuses on the average difference. The sup-norm approximation provides strong and intuitive results while least-squares can be easily computed by OLS using the moments as a dependent variable.

The asymptotic behaviour of the quasi-Jacobian matrix, computed under these two loss functions, is studied under four identification regimes: strong, semi-strong\(^1\) higher-order local and weak (or set) identification. The GMM estimator is consistent and asymptotically normal in the first two regimes, consistent but not asymptotically normal in the third and

\(^1\)Semi-strong identification is also known as nearly-weak identification (Antoine & Renault, 2009).
is inconsistent in the fourth. Hence, the last two regimes correspond to settings where the finite sample distribution of the estimator is poorly approximated by standard asymptotics. Under (semi)-strong identification, the quasi-Jacobian matrix is asymptotically equivalent to the usual Jacobian matrix. After re-scaling, it is asymptotically non-singular. Under higher-order, weak or set identification the quasi-Jacobian matrix is asymptotically singular with eigenvalues vanishing at rate determined by the bandwidth used in the approximation and the nature of the identification failure. Furthermore, the quasi-Jacobian matrix is vanishing in the span of the identification failure, i.e. directions in which identification fails.

Building on these results, this paper constructs a two-step procedure for testing linear hypotheses on the parameter \( \theta \in \mathbb{R}^{d_\theta} \) of the form:

\[
H_0 : R\theta = c \text{ vs. } H_1 : R\theta \neq c,
\]

for a given restriction matrix \( R \in \mathbb{R}^{m \times d_\theta} \) with \( 1 \leq m \leq d_\theta \) and \( c \in \mathbb{R}^m \). Assuming there is evidence of identification failure, presented by a small value of the smallest eigenvalue of the quasi-Jacobian matrix, the two steps used to conduct inference can be summarized as follows:

i. The first step splits the parameter vector \( \theta \) into two sets of parameters: one set of parameters needs to be fixed given evidence that these might be weakly, set or higher-order identified. \( R\theta \) is also fixed to match the null hypothesis (1). Another set of parameters, for which there is no evidence of identification failure, will be assumed to follow (semi)-strong asymptotics.

ii. The second step relies on projection inference for \( R\theta \) and the parameters that need to be fixed while concentrating out the remaining parameters. The test statistic needs to be robust to identification failure. One can use the S, K or CQLR statistic of Stock & Wright (2000), Kleibergen (2005) and Andrews & Mikusheva (2016b), for instance.

Step 2 has previously been discussed in the literature. The main challenge to implementing this step in practice has been in determining which nuisance parameters are (semi)-strongly identified when the others are fixed. When such decomposition is known ex-ante and identification strength depends on the value of the (semi)-strongly identified parameters, Andrews

---

2 Under strong and semi-strong identification, standard inference using the Wald, QLR or LM test will be valid. Lack of evidence for weak and higher-order identification would indicate that these tests can be used.

3 See e.g. Scheffe (1953); Dufour (1990); Dufour & Taamouti (2005, 2007).

4 See e.g. Kleibergen (2005); Andrews & Mikusheva (2016b), among others.

5 The term (semi)-strong will refer to cases where identification can be either strong or semi-strong.
Cheng (2012) show how to conduct uniformly valid inference. In this paper, this *ex-ante* knowledge is not required since the quasi-Jacobian is vanishing on the span of the identification failure. In practice, a cutoff is required to distinguish between matrices that are vanishing from those that are not. A rule-of-thumb, similar to that of Stock & Yogo (2005), is provided to construct this cutoff when detecting weak/set as well as higher-order identification. It relies on a Nagar approximation of the size distortion under semi-strong asymptotics.

The two-step approach described above is shown to yield tests that are asymptotically valid under certain conditions. In particular, it is assumed that the search for the restrictions in the first step is sequential, nested and pre-determined. In practice, the researcher fixes an increasing number of coefficients until identification is restored, according to the quasi-Jacobian. This more disciplined approach avoids the difficulties of studying data-driven search procedures which would complicate the analysis. Sequential procedures fit naturally in settings where some parameters are more credibly identified than others. The search procedure is shown to restore point identification with probability going to 1. If the remaining parameters are (semi)-strongly identified, then the second step yields valid inference procedures as discussed in the previous literature.

Also, under strong and semi-strong identification, the linear approximation can be used to construct estimates that are asymptotically equivalent to the GMM estimator. This approach effectively replaces the non-smooth/discontinuous moments with smoothed linear moments making global optimization simple. This may be of practical interest. Finally, the quasi-Jacobian can be used in the usual sandwich formula when the moments are non-smooth as in quantile IV and SMM estimation of discrete choice models.

Monte-Carlo simulations illustrate the large sample behaviour of the quasi-Jacobian matrix and the two-step inference procedure in several designs. Those include a non-linear least-squares model where the nuisance parameter is not identified. This is similar to simulations in Andrews & Cheng (2012); Cheng (2015) but without assuming the identification structure is known.

The approach is then applied to two empirical settings. The first application considers the Euler equation in U.S. data. This is a well known example where identification is suspected to fail. The methods developed in this paper suggest that the discount rate is (semi)-strongly identified while the risk-aversion parameter is poorly identified as suggested in Stock &

---

6Weak or higher-order identification of these parameters can be detected using the above, so this is not particularly restrictive assuming these are the only other possible identification regimes.
Some investigation into the source of the identification failure reveals that the moments are highly redundant and amount to a single moment condition.\footnote{This implies that one should use one of the singulary and identification robust tests developed in Andrews & Guggenberger (2019).} The second application considers quantile IV estimation of the demand for fish \cite{Chernozhukov et al. 2007}. The results suggest weak identification of the price elasticity of demand.

**Structure of the Paper**

After a review of the literature and an overview of the notation used in the paper, Section \ref{sec:setting} introduces the setting, the linear approximations, precise definitions of the identification regimes considered and the main assumptions used in the paper. Section \ref{sec:asymp} derives the asymptotic behaviour of the \textit{quasi-Jacobian} matrix. Section \ref{sec:inference} describes the two-step inference procedures in more details including: the Algorithms used to determine which parameters to fix, the rules-of-thumb for choosing the cutoffs and the asymptotic results for the inference procedures. Section \ref{sec:monte-carlo} provides a Monte-Carlo example to illustrate some of the results from the previous sections. An empirical example is provided in Section \ref{sec:empirical}. Section \ref{sec:conclusion} concludes. Appendices \ref{app:proofs} and \ref{app:proofs3} provide the proofs for the main results of Sections \ref{sec:asymp} and \ref{sec:inference} respectively. The Supplement consists of Appendices \ref{app:additional}, \ref{app:additional2}, \ref{app:additional3}, \ref{app:additional4}, \ref{app:additional5} and \ref{app:additional6} which provides additional and preliminary results for the main text and their proofs as well as additional Monte-Carlo and Empirical results.

**Related Literature**

The literature on the identification of economic models is quite vast. An extensive review is given in \cite{Lewbel 2018}. Within this literature, this paper mainly relates to three topics: local and global identification of finite dimensional parameters in the population, detecting identification failure in finite samples and identification robust inference.

\cite{Koopmans & Reiersol 1950} provide one of the earliest general formulation of the identification problem at the population level. To paraphrase the authors, the main problem is to determine whether the distribution of the data, assumed to be generated from a given class of models, is consistent with one, and only one, set of structural parameters. In the likelihood setting, \cite{Fisher 1967}; \cite{Rothenberg 1971} give sufficient conditions for local and global identification of the structural parameters as the unique solution to a non-linear system of equations. These include the well-known rank condition and strict convexity. For GMM,
Komunjer (2012) introduced weaker conditions for global identification. In the present paper, singularity of the quasi-Jacobian will appear when either global or local identification fails for a large class of moment conditions.

In linear models, global identification amounts to a rank condition on the slope of the moments. This insight was used to construct several pre-testing procedures in linear IV models for identification failure (Cragg & Donald, 1993; Stock & Yogo, 2005). Pre-tests based on the null of strong identification were given by Hahn & Hausman (2002) in linear IV and Inoue & Rossi (2011); Bravo et al. (2012) in non-linear models. Note that pre-testing for strong identification in the first step can be problematic for two-step inference procedures when power is low in the first step. For non-linear models, Wright (2003) tests the local identification condition with a rank test at every point of a robust confidence set. Antoine & Renault (2017) rely on a distorted J-statistic to detect local identification failure. Arellano et al. (2012) develop a test for underidentification when a single coefficient is unidentified. In this paper, identification strength is summarized by the smallest eigenvalue of the quasi-Jacobian matrix under weak and set identification. This is both convenient and easy to communicate. Residual curvature also matters when pre-testing for higher-order identification as discussed in Section 4.2.2.

Given the impact of (near) identification failure on standard inferences, a large body of literature has developed identification robust tests. Most consider inference of the full parameter vector. Few consider the topological features of the identified set to conduct inferences, with the notable exception of Andrews & Mikusheva (2016a). For subvector inferences, a common approach is to construct a confidence set for the full vector and project it on the dimension of interest (Dufour & Taamouti, 2005, 2007) or to use a Bonferroni correction (McCloskey, 2017). These methods might be conservative. To increase power, one can concentrate out nuisance parameters that are known to be strongly identified. A series of papers starting with Andrews & Cheng (2012) considers uniformly valid subvector inferences in a class of model where the identification structure is known and identification strength is driven by some (semi)-strongly identified coefficients. As discussed in Andrews & Mikusheva (2016b), computing the least favorable distribution required for their uniform (type II) inference may be numerically challenging or unfeasible in some settings. Under

8 See e.g. Choi & Phillips (1992); Dufour (1997); Staiger & Stock (1997) in the case of IV regression.
9 See e.g. Anderson & Rubin (1949); Stock & Wright (2000); Moreira (2003); Kleibergen (2005); Andrews & Mikusheva (2016b); Chen et al. (2018).
10 However, as discussed in Section 4 Remark 2 when the nuisance parameters are completely unidentified projection inference may actually have exact asymptotic coverage.
11 These include Andrews & Cheng (2013, 2014); Cheng (2015) and Han & McCloskey (2019); Cox (2017).
higher-order local identification, the estimates are consistent but with non-standard limiting
distribution (Rotnitzky et al. 2000; Dovonon & Hall 2018). This issue is known but much
less studied than weak and set identifications. Dovonon et al. (2019) study the properties
of identification robust tests in second-order identified models. Lee & Liao (2018) show how
to conduct standard inference in second-order identified models with known identification
structure.

Notation
For any matrix (or vector) $A$, $\|A\| = \sqrt{\sum_{i,j} A^2_{i,j}} = \sqrt{\text{trace}(AA^\prime)}$ is the Frobenius (Euclidian)
norm of $A$. For any rectangular matrix $A$, the singular value $|\lambda_j(A)|$ refers to the $j-th$
eigenvalue of $(A^\prime A)^{1/2}$. $\lambda_{\text{max}}(A), \lambda_{\text{min}}(A)$ refer to the largest and smallest value of $|\lambda_j(A)|$,
respectively. With some abuse of notation, these singular values will be referred to as eigen-
values. For a weighting matrix $W_n(\theta)$, the norm $\|\bar{g}_n(\theta)\|_{W_n}^2$ is computed as $\bar{g}_n(\theta)^\prime W_n(\theta) \bar{g}_n(\theta)$.

For any two positive sequences $a_n, b_n$, $a_n \asymp b_n \iff \exists C, C > 0, C a_n \leq b_n \leq C a_n, \forall n \geq 1$;
$a_n = o(b_n) \iff \forall \varepsilon > 0, \exists N > 0, \forall n \geq n, a_n \leq \varepsilon b_n$; $a_n = O(b_n) \iff \exists M > 0, \exists N > 0, \forall n \geq n, a_n \leq M b_n$. For $X_n$ a sequence of random variables and $a_n$ positive sequence,
$X_n = o_p(a_n) \iff \forall \varepsilon > 0, P(\|X_n\| \geq a_n\varepsilon) = o(1)$; $X_n = O_p(a_n) \iff \forall \varepsilon > 0, \exists M > 0, \exists N > 0, \forall n \geq N, P(\|X_n\| > a_n M) \leq \varepsilon$.

2 Setting and Assumptions
Following Hansen & Singleton (1982), the econometrician wants to estimate the solution
vector $\theta_0$ to the system of unconditional moment equations:

$$g_n(\theta_0) \overset{\text{def}}{=} \mathbb{E}(\bar{g}_n(\theta_0)) = 0,$$

where $\theta_0 \in \Theta$, a compact subset of $\mathbb{R}^d$, $\dim(g_n) = p \geq d_g$. $\bar{g}_n(\theta) = 1/n \sum_{i=1}^n g(z_i, \theta)$,
$(z_i)_{i=1,..,n}$ is a sample of iid or stationary random variables. Throughout, it is assumed that
at least one such $\theta_0$ exists. The population moments $g_n$ are allowed to depend on $n$, as in
Stock & Wright (2000). $g_n$ is assumed to be continuously differentiable on $\Theta$.

$^{12}$For instance, van der Vaart (1998) when discussion higher-order Taylor expansions in Chapter 3.3, argues
that “it is necessary to determine carefully the rate of all terms in the expansion [...] before neglecting the
‘remainder’.”

$^{13}$This can be achieved in misspecified models by re-centering the moments: $g_n(\theta) - g_n(\theta_0)$ where $\theta_0 = \arg\min_{\theta \in \Theta} \|g_n(\theta)\|_W$. 

6
Given the sample moments $\bar{g}_n$ and a sequence of positive definite weighting matrices $W_n(\theta)$, the GMM estimator $\hat{\theta}_n$ solves the minimization problem:

$$\hat{\theta}_n = \arg\min_{\theta \in \Theta} \|\bar{g}_n(\theta)\|^2_{{W_n}},$$

where $\|\bar{g}_n(\theta)\|^2_{{W_n}} = \bar{g}_n(\theta)'W_n(\theta)\bar{g}_n(\theta)$.

### 2.1 Linear-Approximations and the quasi-Jacobian Matrix

The quasi-Jacobian matrix is defined below as the slope of a local linear approximation $\bar{g}_n$ under a given norm.

**Definition 1. (Sup-Norm and Least-Squares Approximations)** Let $K$ be a kernel function and $\kappa_n$ a bandwidth. The sup-norm approximation $(A_{n,\infty}, B_{n,\infty})$ solves:

$$(A_{n,\infty}, B_{n,\infty}) = \arg\min_{A,B \sup_{\theta \in \Theta} \|A + B\theta - \bar{g}_n(\theta)\| \times \hat{K}_n(\theta)), \quad (3)$$

where $\hat{K}_n(\theta) = K(\|\bar{g}_n(\theta)\|_{{W_n}/\kappa_n})$. The least-squares approximation $(A_{n,LS}, B_{n,LS})$ solves:

$$(A_{n,LS}, B_{n,LS}) = \arg\min_{A,B} \int_{\Theta} \|A + B\theta - \bar{g}_n(\theta)\|^2 \times \hat{K}_n(\theta) d\theta, \quad (4)$$

where $\hat{K}_n(\theta) = K(\|\bar{g}_n(\theta)\|_{{W_n}/\kappa_n} - \|\bar{g}_n(\hat{\theta}_n)\|_{{W_n}/\kappa_n})$. The quasi-Jacobian refers to the $B_{n,LS/\infty}$ computed using either the least-squares (LS) or sup-norm (\infty) approximation.

The sup-norm approximation solves a non-smooth optimization problem and is thus more computationally demanding. However, the theory for $B_{n,\infty}$ is very intuitive and it will be quite useful to understand the relation between the quasi-Jacobian and identification failure. In practice, it will be more convenient to compute the least-squares approximation:

$$\begin{pmatrix} A'_{n,LS} \\ B'_{n,LS} \end{pmatrix} = \left( \int_{\Theta} X(\theta)X(\theta)'\hat{K}_n(\theta)d\theta \right)^{-1} \int_{\Theta} X(\theta)\bar{g}_n(\theta)'\hat{K}_n(\theta)d\theta, \quad X(\theta) = (1, \theta').$$

The two integrals can be approximated using Monte-Carlo sampling, Markov-Chain Monte-Carlo and Sequential Monte-Carlo methods (Robert & Casella 2004). In this paper, quasi-Monte-Carlo integration with the low-discrepancy Sobol sequence was used and provided satisfying results. See e.g. Owen (2003); Lemieux (2009) for an overview of quasi-Monte Carlo integration.

Implementation is straightforward: the Sobol sequence provides a grid for $\theta$ over which $\bar{g}_n$ and $W_n$ are evaluated. One then simply regresses the evaluated moments on the grid points.
and an intercept using weighted least-squares with $\hat{K}_n$ as weights. If $K$ has compact support, one can omit all grid points with $\hat{K}_n(\theta) = 0$ from the regression. The quasi-Jacobian $B_{n,LS}$ collects the slope coefficients in this weighted linear regression.

The theory for $B_{n,LS}$, while similar to $B_{n,\infty}$, involves additional topological arguments and the convergence of a quasi-posterior under higher-order, weak and set identification making the intuition somewhat more difficult to convey.

For linear models such as OLS or linear IV, the approximation is exact and one would find $B_{n,LS} = X'X/n$ and $Z'X/n$. The quasi-Jacobian is close to singular where the regressors are nearly multicollinear in OLS or when the instruments are not sufficiently relevant in IV. The rank of $B_{n,LS}$ is thus informative about the identification failure in these models. This extends to non-linear models.

The following gives an heuristic description of the behaviour of the quasi-Jacobian when identification holds or fails. Formal results will be provided in the next section. First note that the kernel $K$ and bandwidth $\kappa_n$ play a very important role here as they select all potential solutions for the moment condition (2). When the moment equations have a unique solution $\theta_0$, then $\bar{g}_n(\theta) \simeq 0$ holds only in small neighborhoods of $\theta_0$ with high probability. If, in addition, $\bar{g}_n$ is smooth then the discrepancy becomes:

$$\bar{g}_n(\theta) - A - B\theta \simeq [\bar{g}_n(\theta_0) + \partial_\theta \bar{g}_n(\theta_0)(\theta - \theta_0)] - [A + B\theta_0 + B(\theta - \theta_0)]$$

so that $B_{n,LS/\infty} \simeq \partial_\theta \bar{g}_n(\theta_0)$ is a smoothed approximation of the usual Jacobian matrix.

In locally point identified models, the Jacobian and quasi-Jacobian will have full rank. Local, or first-order, identification failure appears when $\partial_\theta \bar{g}_n(\theta_0)$ is singular. $B_{n,LS/\infty} \simeq \partial_\theta \bar{g}_n(\theta_0)$ implies that the eigenvalues of the quasi-Jacobian are informative about local identification failure.

When the model is set identified there are, by definition, at least two solutions $\theta_0 \neq \theta_1$ to the moment equations (2). The linear approximation implies that:

$$A_{n,LS/\infty} + B_{n,LS/\infty}\theta \simeq \bar{g}_n(\theta) = O(\kappa_n), \text{ for } \theta \in \{\theta_0, \theta_1\}.$$ 

For $\kappa_n \simeq 0$ small this implies:

$$B_{n,LS/\infty}[\theta_0 - \theta_1] = O_p(\kappa_n) \simeq 0.$$ 

Given that $\theta_0 - \theta_1 \neq 0$, this implies that the quasi-Jacobian $B_{n,LS/\infty}$ must be close to singular in large samples. Both $\kappa_n$ and $||\theta_0 - \theta_1||$ will determine how close to singular it will be. Overall, both local and global identification failures imply near singularity of the quasi-Jacobian in large samples.
2.2 Identification Regimes

The following describes the four identification regimes considered in this paper. Their implications for the GMM estimator \( \hat{\theta}_n \) are summarized in Table 1. Examples 1, 2 illustrate the definitions.

Table 1: Identification Regimes and Asymptotic Properties of \( \hat{\theta}_n \)

**Example 1** (Non-Linear Least-Squares). *This example is adapted from [Cheng (2015)](https://example.com). Consider the following non-linear regression model:*

\[
y_t = \theta_1 x_{1,t} + \theta_1 \theta_2 x_{2,t} + e_t
\]

with \( x_{1,t}, x_{2,t}, e_t \) iid with mean 0 and variance 1 such that \( \mathbb{V}(x_{1,t}, x_{2,t}, e_t) = I_3 \) and \( \theta = (\theta_1, \theta_2) \in [0, 1]^2 \). The estimating moments \( g_n \) are:

\[
g_n(\theta) = \begin{pmatrix}
\mathbb{E}(y_t x_{1,t}) - \theta_1 \\
\mathbb{E}(y_t x_{2,t}) - \theta_1 \theta_2
\end{pmatrix} = \begin{pmatrix}
1 & 0 \\
\theta_2 & \theta_1,0
\end{pmatrix} \begin{pmatrix}
\theta_1 - \theta_{1,0} \\
\theta_2 - \theta_{2,0}
\end{pmatrix}.
\]

**Example 2** (Possibly Noninvertible MA(1) Model). *This example is adapted from [Gospodinov & Ng (2015)](https://example.com). Consider the MA(1) model:*

\[
y_t = \sigma[e_t - \vartheta e_{t-1}]
\]

where \( e_t \) is iid with mean 0, variance 1 and skewness \( \tau \) known. Using the moments \( \mathbb{E}(y_t^2) \) and \( \mathbb{E}(y_t y_{t-1}) \) only identifies \( \theta \in \{(\vartheta, \sigma_0^2), (1/\vartheta, \sigma_0^2 \vartheta_0^2)\} \) when \( \vartheta_0 \in \mathbb{R}/\{-1, 0, 1\} \). Assuming invertibility (\(|\vartheta_0| \leq 1\)) restores point identification. [Gospodinov & Ng (2015)](https://example.com) show that when \( \tau \neq 0 \), the additional information provided by \( \mathbb{E}(y_t^2 y_{t-1}) \) allows to identify \( \theta \) in the population without imposing invertibility.
Definition 2. (Point Identification) The model is point identified if $\exists \theta_0 \in \text{int}(\Theta)$ such that $\forall \varepsilon > 0$, $\exists \eta(\varepsilon) > 0$:

$$\inf_{\|\theta - \theta_0\| \geq \varepsilon} \|g_n(\theta)\|_W \geq \eta(\varepsilon), \forall n \geq 1,$$

(5)

where $\|g_n(\theta)\|^2_W = g_n(\theta)'W(\theta)g_n(\theta)$, $W(\theta)$ is a non-stochastic positive semi-definite weighting matrix.

Definition 2 corresponds to the case where $\theta_0$ is unique and thus globally identified. Additional regularity conditions combined with this assumption imply that $\hat{\theta}_n$ is consistent for $\theta_0$ (see e.g. Newey & McFadden, 1994, Theorem 2.6).

Definition 3. (Strong Identification) The model is strongly identified if it is point identified and $\exists \varepsilon > 0$ and $C > 0$ such that $\|\theta - \theta_0\| \leq \varepsilon$ implies:

$$\|g_n(\theta)\|_W \geq C\|\theta - \theta_0\|, \forall n \geq 1.$$

(6)

Definition 3 is satisfied when the Jacobian $\partial_\theta g_n(\theta_0)$ has full rank, its smallest eigenvalue is bounded below and, $g_n(\theta) = \partial_\theta g_n(\theta_0)(\theta - \theta_0) + o(\|\theta - \theta_0\|)$ around $\theta_0$. With additional regularity conditions, it implies that $\sqrt{n}(\hat{\theta}_n - \theta_0)$ is asymptotically Gaussian (see e.g. Newey & McFadden, 1994, Theorem 3.2). Standard inferences using the Wald, QLR and LM test are asymptotically valid.

Example 1 (Continued). The Jacobian of the moments evaluated at $\theta = \theta_0$ implies the following:

$$\partial_\theta g_n(\theta_0,n) = \begin{pmatrix} 1 & 0 \\ 0 & \theta_{1,0} \end{pmatrix} \Rightarrow \begin{pmatrix} 1 & 0 \\ -\theta_2 & 1 \end{pmatrix} g_n(\theta) = \partial_\theta g_n(\theta_0,n)(\theta - \theta_0).$$

Note that $1$ is the only eigenvalue of the matrix on the left-hand side which implies that $\|g_n(\theta)\| \geq \|\partial_\theta g_n(\theta_0)(\theta - \theta_0)\|$. $|\theta_{1,0}|$ bounded away from zero implies that the eigenvalues of $\partial_\theta g_n(\theta_0)$ are bounded below as well.

Example 2 (Continued). The estimating moments are given by:

$$g_n(\theta) = \begin{pmatrix} \mathbb{E}(y^2_t) - \sigma^2(1 + \vartheta^2) \\ \mathbb{E}(y_t y_{t-1}) + \sigma^2 \vartheta \\ \mathbb{E}(y^2_t y_{t-1}) + \tau \sigma^3 \vartheta \end{pmatrix} = \begin{pmatrix} \sigma^2_0(1 + \vartheta^2_0) - \sigma^2(1 + \vartheta^2) \\ -\sigma^2_0 \vartheta_0 + \sigma^2 \vartheta \\ -\tau \sigma^3_0 \vartheta_0 + \tau \sigma^3 \vartheta \end{pmatrix}.$$
Suppose that \( \tau \neq 0 \) is bounded away from 0, \( \vartheta \notin \{-1, 0, 1\} \) and \( \sigma \) is bounded away from 0. Point identification holds since: \( \tau \sigma_0^3 \vartheta_0 \neq \text{sign}(\vartheta_0) \tau \sigma_0^3 \vartheta_0^2 \) unless \( \sigma = 0, \tau = 0 \) or \( \vartheta \in \{-1, 0, 1\} \). It can also be shown that the eigenvalues of the Jacobian are bounded below when \( |\tau| \) is bounded away from zero.

**Definition 4.** (Semi-Strong Identification) The model is semi-strongly identified if it is point identified and

\( i. \quad \exists \varepsilon > 0, C, \underline{C} > 0 \) such that \( \|\theta - \theta_0\| \leq \varepsilon \) implies:

\[
C \|\partial_\theta g_n(\theta_0)(\theta - \theta_0)\| \geq \|g_n(\theta)\|_W \geq \underline{C} \|\partial_\theta g_n(\theta_0)(\theta - \theta_0)\|, \quad \forall n \geq 1
\]  

\( \tag{7} \)

\( ii. \quad \lim_{n \to \infty} n \times \lambda_{\min}(\partial_\theta g_n(\theta_0)'\partial_\theta g_n(\theta_0)) = +\infty, \)

\( iii. \quad \text{for any } \theta_1, \theta_2 \text{ such that } \theta_1 \rightarrow \theta_0, \theta_2 \rightarrow \theta_0: \)

\[
\|g_n(\theta_1) - g_n(\theta_2) - \partial_\theta g_n(\theta_2)(\theta_1 - \theta_2)\| = O(\|\partial_\theta g_n(\theta_2)(\theta_1 - \theta_2)\|^2),
\]

\( iv. \quad \text{for any } \theta_1 \rightarrow \theta_0: \)

\[
[\partial_\theta g_n(\theta_1) - \partial_\theta g_n(\theta_0)] [\partial_\theta g_n(\theta_0)'\partial_\theta g_n(\theta_0)]^{-1} [\partial_\theta g_n(\theta_1) - \partial_\theta g_n(\theta_0)]' = o(1).
\]

Definition 4ii. implies that the Jacobian can be vanishing in one or several directions - but not too fast. When \( \lambda_{\min}(\partial_\theta g_n(\theta_0)'\partial_\theta g_n(\theta_0)) \leq O(n^{-1/4}) \), conditions iii.-iv. also imply that the second-order term is vanishing. As a result, the moments remain approximately linear around \( \theta_0 \), as in Definition 3. Together with additional regularity conditions this implies that, after re-scaling, \( (\hat{\theta}_n - \theta_0) \) will be asymptotically Gaussian. However, the convergence is slower than the usual \( \sqrt{n} \)-rate (Antoine & Renault 2009; Andrews & Cheng 2012). Standard inferences using the Wald, QLR and LM tests are asymptotically valid.

**Example 1 (Continued).** Consider the drifting sequence \( \theta_{1,0,n} = c \times n^{-a} \) with \( a \in [0, 1/2) \) and \( c \neq 0: n \times \lambda_{\min}(\partial_\theta g_n(\theta_0)'\partial_\theta g_n(\theta_0)) = c^2 n^{1-2a} \rightarrow +\infty \) if \( c \neq 0 \) and \( 0 \leq a < 1/2 \).

**Definition 5.** (Higher-Order Local Identification) The model is locally identified at a higher order \( r \geq 2 \) if it is point identified and \( \exists \varepsilon > 0, C_j > 0, \underline{C}_j > 0 \) for \( j = 1, \ldots, r \) together with projection matrices \( P_1, \ldots, P_r \) satisfying \( P_r \neq 0, P_j P_{j'} = 0 \) when \( j \neq j' \) such that \( \|\theta - \theta_0\| \leq \varepsilon \) implies:

\[
\sum_{j=1}^{r} C_j \|P_j(\theta - \theta_0)\|^j \geq \|g_n(\theta)\|_W \geq \sum_{j=1}^{r} \underline{C}_j \|P_j(\theta - \theta_0)\|^j, \quad \forall n \geq 1.
\]  

\( \tag{8} \)
Definition 5 corresponds to cases where the moments are not approximately linear around \( \theta_0 \). As a result, the first \( r \geq 2 \) higher-order terms affect the limiting distribution of the GMM estimator \( \hat{\theta}_n \). Together with additional regularity conditions, this assumption implies that some components of \( (\hat{\theta}_n - \theta_0) \) converges at a \( n^{1/2r} \)-rate to a non-Gaussian limiting distribution. Wald, QLR and LM statistics have non-\( \chi^2 \) limiting distributions (see e.g. Rotnitzky et al., 2000; Dovonon & Hall, 2018); standard inferences are not asymptotically valid.

Example 2 (Continued). Suppose that \( \kappa = 0 \) and \( \vartheta_0 = 1 \). Condition iii.a. holds since there is a unique solution and the moments are continuous. Omitting the third moment condition, the Jacobian \( \partial \theta g_n(\theta_0) \) becomes:

\[
\partial \theta g_n(\theta_0) = \begin{pmatrix}
-2\sigma_0^2 \vartheta_0 & -(1 + \vartheta_0^2) \\
\sigma_0^2 & \vartheta_0
\end{pmatrix} = \begin{pmatrix}
-2\sigma_0^2 & -2 \\
\sigma_0^2 & 1
\end{pmatrix}
\]

which is singular and implies first-order identification failure of the model. Taking the derivative again:

\[
\partial^2 \theta, \vartheta g_n(\theta_0) = \begin{pmatrix}
-2\sigma_0^2 \vartheta_0 & -2 \vartheta_0 \\
0 & 1
\end{pmatrix} = \begin{pmatrix}
-2\sigma_0^2 & 0 \\
0 & 1
\end{pmatrix}, \quad \partial^2 \theta, \sigma^2 g_n(\theta_0) = \begin{pmatrix}
-2 & 0 \\
1 & 0
\end{pmatrix}.
\]

Note that \( (1, -1) \) is the eigenvector which spans the null space of the Jacobian, and both second-order derivatives are non-singular on the span of \( (1, -1) \) which implies second-order identification (see Dovonon & Hall, 2018). Indeed, consider the parametrization \( \theta - \theta_0 = (1,1)h_1 + (1,-1)h_2 \), then for \( |h_1| + |h_2| \to 0 \):

\[
g_n(\theta) = \partial \theta g_n(\theta_0) \begin{pmatrix}
1 \\
1
\end{pmatrix} h_1 + \frac{\partial^2 \theta, \vartheta g_n(\theta_0)}{2} \begin{pmatrix}
(h_1 + h_2)^2 \\
h_1^2 - h_2^2
\end{pmatrix} + \frac{\partial^2 \theta, \sigma^2 g_n(\theta_0)}{2} \begin{pmatrix}
h_1^2 - h_2^2 \\
(h_1 - h_2)^2
\end{pmatrix} + o(\| (h_1, h_2) \|^2).
\]

The conditions are then satisfied by taking \( |h_1| + |h_2| \) small enough. More generally, Gospodinov & Ng (2015) show that first-order identification generally fails when \( \kappa \neq 0 \) and \( \vartheta \in \{-1, 1\} \).

Definition 6. (Weak and Set Identification) The model is said to be weakly or set identified if there exists at least two \( \theta_0 \neq \theta_1 \) in the weakly identified set:

\[
\Theta_0 = \{ \theta \in \Theta, \lim_{n \to \infty} \sqrt{n}\| g_n(\theta) \|_W < +\infty \}.
\]

(9)
Definition 6 occurs when global identification fails or nearly fails. Under strong, semi-strong and higher-order identification, a robust and conservative confidence set would concentrate around a single point \( \theta_0 \). Definition 6 collects all models where this phenomenon does not occur. The GMM estimator \( \hat{\theta}_n \) is typically not consistent (Staiger & Stock, 1997; Stock & Wright, 2000; Andrews & Cheng, 2012) and has non-Gaussian limiting distribution. Standard inferences using the Wald, QLR and LM tests are not asymptotically valid.

Definition 6 nests the definition of Stock & Wright (2000) who consider a drifting sequence of moments:

\[
g_n(\theta) = g_1(\gamma) + g_2(\beta, \gamma) \sqrt{n},
\]

where \( \theta = (\beta, \gamma) \), \( g_1, g_2 \) are two functions satisfying Definition 3 for instance. They show that both \( \hat{\gamma} \) and \( \hat{\beta} \) are inconsistent even though \( \hat{\gamma}(\beta) = \arg\min_n \|g_n(\beta, \gamma)\|_{W_n} \) is consistent for a fixed \( \beta \). Definition 6 also nests the setting of Andrews & Cheng (2012) where the identification strength for \( \beta \) is determined by a drifting sequence of a (semi)-strongly identified scalar coefficient \( \gamma_{0,n} \).

Example 1 (Continued). Consider the drifting sequence \( \theta_{1,0,n} = c \times n^{-1/2} \). Take \( \theta = (\theta_{1,0,n}, \theta_2) \) for any \( \theta_2 \in [0, 1] \), then \( \sqrt{n}\|g_n(\theta)\| \to |c| \times |\theta_2 - \theta_0| < +\infty \). As a result, \( \Theta_0 \subseteq \{ \theta = (c, \theta_2), \theta_2 \in [0, 1] \} \).

Example 2 (Continued). Consider the drifting sequence of moments \( \tau_n = c/\sqrt{n} \). The moment conditions become:

\[
g_n(1/\vartheta_0, \sigma_0^2 \vartheta_0^2) = \begin{pmatrix} 0 \\ 0 \\ c\sigma_0^3/\sqrt{n}[\text{sign}(\vartheta_0)\vartheta_0^2 - \vartheta_0] \end{pmatrix}.
\]

This implies that \( \sqrt{n}\|g_n(1/\vartheta_0, \sigma_0^2 \vartheta_0^2)\| \to |c\sigma_0^3[\text{sign}(\vartheta_0)\vartheta_0^2 - \vartheta_0]| < +\infty \). As a result, \( \Theta_0 \) is not a singleton when \( \vartheta_0 \not\in \{-1, 0, 1\} \) and \( \tau_n = O(n^{-1/2}) \).

2.3 Main Assumptions

The following provides the main assumptions on the moments \( \bar{g}_n \), weighting matrix \( W_n \), kernel \( K \) and bandwidth \( \kappa_n \) to derive the results in Section 3 for \( B_{n,LS/\infty} \).

Assumption 1. (Bandwidth, Kernel)

i. (Bandwidth) \( \kappa_n > 0, \forall n \geq 1 \). \( \kappa_n \to 0, \sqrt{n}\kappa_n \to +\infty \) and \( \sqrt{n}\kappa_n^2 \to 0 \) as \( n \to \infty \),
ii. (Compact Kernel) $K$ is Lipschitz-continuous on $\mathbb{R}$ with $K(x) = 0$ for $x \in (-\infty, -1] \cap [1, +\infty)$, $K(x) > 0$ for $x \in (-1, 1)$,

iii. (Exponential Kernel) $K$ is exponential in $x$, i.e. $\exists a \geq 1, C_1 > 0, C_2 > 0$ such that $K(x) = C_1 \exp(-C_2|x|^a)$, $\forall x \in \mathbb{R}$. Define $\bar{\kappa}_n = \kappa_n \log(n)^{1/a}$ and assume $\bar{\kappa}_n \to 0$, $\sqrt{n}\bar{\kappa}_n^2 \to 0$ as $n \to \infty$.

In line with the heuristic discussion above, the bandwidth $\kappa_n$ is assumed to be small. Condition i. ensures that it converge to 0 at a slower than $\sqrt{n}$-rate, but faster than a $n^{1/4}$-rate. When $\kappa_n \leq O(n^{1/4})$, $B_{n,LS/\infty}$ would also capture second-order non-linearities under (semi)-strong identification. When $W_n = \hat{V}_n^{-1}$, a Law of the Iterated Logarithm can be invoked to set:

$$\kappa_n = \sqrt{2 \log(\log[n])/n},$$

so that $\limsup_{n \to \infty} \mathbb{P}\left(\sup_{\theta \in \Theta_0} (\sqrt{n} \|\hat{g}_n(\theta) - g_n(\theta)\|_W \leq \kappa_n)\right) = 1^{14}$ Two types of kernels $K$ are considered. Compact kernels (condition i.), are used in both sup-norm and least-squares approximations. The Lipschitz-continuity condition simplifies some of the proofs in Section 3 but numerical experiments showed almost no numerical difference with the uniform kernel $K(x) = 1_{x \in (-1,1)}$. Exponential kernels are considered only for the least-squares approximation. A simple example is $K(x) = \phi(x)$, the Gaussian density, which provides a quasi-Bayesian interpretation to $\hat{K}_n$ as discussed in Section 3.2. Again, there was only negligible numerical differences in the quasi-Jacobian $B_{n,LS}$ computed with the compact and the exponential kernel in the examples considered in this paper.

Assumption 2. (Sample Moments, Weighting Matrix)

i. (Uniform CLT, Tightness) the empirical process $G_n(\theta) \overset{\text{def}}{=} \sqrt{n} (\hat{g}_n(\theta) - g_n(\theta))$ converges weakly to $G(\cdot)$ a Gaussian process, as $n \to \infty$; $\sup_{\theta \in \Theta} \|G_n(\theta)\| = O_p(1)$,

ii. (Discoverability of $\Theta_0$) the weakly identified set $\Theta_0 = \{\theta \in \Theta, \lim_{n \to \infty} \sqrt{n} \|\hat{g}_n(\theta)\|_W < +\infty\}$ satisfies:

$$\sup_{n \geq 1} \sup_{\theta \in \Theta_0} \sqrt{n} \|g_n(\theta)\|_W < +\infty,$$

iii. (Stochastic Equicontinuity) uniformly in $\|\theta_1 - \theta_2\| \to 0$,

$$\sqrt{n} [\hat{g}_n(\theta_1) - \hat{g}_n(\theta_2) - (g_n(\theta_1) - g_n(\theta_2))] = o_p(1),$$

14See also Andrews & Soares (2010); Andrews & Cheng (2012) for choices of such sequences. In smaller samples, one can also set $\kappa_n = \max(q_{1-\varepsilon}, \sqrt{2 \log(\log[n])/n})$ where $q_{1-\varepsilon}$ is a $1-\varepsilon$ (e.g. 0.99) quantile of a $\chi_p^2$ distribution (recall that $p = \dim(g_n)$).
iv. (Smoothness) $g_n$ is continuously differentiable on $\Theta$; uniformly in $\|\theta_1 - \theta_2\| \to 0$,

$$\|g_n(\theta_1) - g_n(\theta_2) - \partial_\theta g_n(\theta_2)(\theta_1 - \theta_2)\| = O(\|\theta_1 - \theta_2\|^2),$$

v. (Weighting Matrix) $\sup_{\theta \in \Theta} \|W_n(\theta) - W(\theta)\| = o_p(1)$, $W$ is Lipschitz continuous in $\theta \in \Theta$, $\exists \lambda, \Lambda$ such that $0 < \lambda \leq \lambda_{\min}(W_n(\theta)) \leq \lambda_{\max}(W_n(\theta)) \leq \Lambda < +\infty, \forall n \geq 1, \theta \in \Theta$.

The high-level conditions in Assumption 2 are quite common in GMM estimation. Condition i. allows for non-smooth and possibly discontinuous sample moments as in quantile-IV (Chernozhukov & Hansen, 2005) or SMM estimation (Pakes & Pollard, 1989). For primitive conditions see van der Vaart & Wellner (1996) for iid and Dedecker & Louhichi (2002) for strictly stationary time-series data. Condition ii. ensures that the weakly identified set $\Theta_0$ can be conservatively estimated using $\hat{\Theta}_n = \{\theta, \|\bar{g}_n(\theta)\|W_n - \inf_{\theta \in \Theta} \|\bar{g}_n(\theta)\|W_n \leq \kappa_n\}$ so that all directions of the identification failure can be detected. Conditions iii. is the usual stochastic equicontinuity condition (Andrews, 1994). Condition iv. is only required under strong identification. Definition 4 provides stronger conditions to control the higher-order terms. It is not required under higher-order and weak identification. Condition v. is automatically satisfied for $W_n = I_p$, the identity matrix, but also the optimal weighting matrix $W_n = \hat{V}_n^{-1}$ under uniform consistency for $1/n \sum_{i=1}^n [g(z_i, \theta) - \bar{g}_n(\theta)] [g(z_i, \theta) - \bar{g}_n(\theta)]'$ for iid data or the HAC estimator for time-series data and additional conditions on its eigenvalues as well as the Lipschitz continuity. Given the generality of the high-level assumptions, the results accommodate models where a (semi)-strongly identified nuisance parameter $\eta$ is concentrated out:

$$\hat{\theta}_n = \arg\min_{\theta \in \Theta} \|\bar{g}_n(\theta, \hat{\eta}(\theta))\|W_n.$$

The results could be further extended to well identified infinite dimensional nuisance parameters $\eta$; this is left to future research.

### 3 Asymptotic Behaviour of the Linear Approximations

This section derives the asymptotic behaviour of the pair $(A_{n,LS/\infty}, B_{n,LS/\infty})$ under strong and semi-strong identification and characterizes the behaviour of the quasi-Jacobian $B_{n,LS/\infty}$.\footnote{For just-identified models and the exponential kernel, one can use $\hat{\Theta}_n = \{\theta, \|g_n(\theta)\|W_n \leq \kappa_n\}$ instead. For the exponential kernel, one can see that $[X(\theta)X(\theta)'K_n(\theta)d\theta]^{-1} \int X(\theta)\bar{g}_n(\theta)'\bar{\pi}_n(\theta)d\theta = [X(\theta)X(\theta)'\bar{\pi}_n(\theta)d\theta]^{-1} \int X(\theta)\bar{g}_n(\theta)'\bar{\pi}_n(\theta)d\theta$. Since $K$ is exponential $K(\|\bar{g}_n(\theta)\|W_n)$ only appears as a multiplicative constant in $\bar{\pi}_n$ which cancels out in $(A_{n,LS}, B_{n,LS})$. A similar argument appears in the proof of the Bernstein-von Mises Theorem in Bayesian statistics (van der Vaart, 1998; Chernozhukov & Hong, 2003).}
under higher-order and weak/set identification. The sup-norm and least-squares approximations are treated separately. Table 2 summarizes the results. At the population level, the results imply (by taking $\bar{g}_n = g_n$ and $\kappa_n \searrow 0$) that the quasi-Jacobian is the usual Jacobian for first-order globally identified models and is singular under either local or global identification failure. This provides a simple characterization of first-order and global identification failure for GMM in the population.

**Note:** The results in the two bottom rows hold over all directions $v = \theta_0 - \theta_1$ in which the model is weakly identified, i.e. $\theta_0, \theta_1 \in \Theta_0$ in Definition 6 and all directions $v_j$ in which the moments are locally polynomial of order $j \geq 2$ in Definition 5.

### 3.1 Sup-norm approximation

**Theorem 1.** (Behaviour of the Sup-Norm Approximation under Strong Identification)

Suppose that the model is strongly identified and that Assumptions 1 i., ii. and 2 hold. Then the sup-norm approximation satisfies:

$$A_{n,\infty} = \bar{g}_n(\theta_0) - B_{n,\infty} \theta_0 + o_p(n^{-1/2}),$$

$$B_{n,\infty} = \partial_\theta g_n(\theta_0) + o_p(n^{-1/2} \kappa_n^{-1}).$$

Theorem 1 shows that the sup-norm approximation is asymptotically equivalent to the usual expansion $\bar{g}_n(\theta) \simeq \bar{g}_n(\theta_0) + \partial_\theta g_n(\theta_0)(\theta - \theta_0)$. This implies that $(B'_{n,\infty} \hat{V} B_{n,\infty})^{-1}$ is a consistent estimator for the sandwich formula when computing standard errors. This can be particularly useful when $\bar{g}_n$ is non-smooth or discontinuous.

**Theorem 2.** (Behaviour of the Sup-Norm Approximation under Semi-Strong Identification)

Suppose that the model is semi-strongly identified, Assumptions 1 i., ii. and 2 hold, that the
bandwidth $\kappa_n$ and moments $g_n$ are such that:

$$\kappa_n^2 = o \left( \left| \lambda_{\min} \left( \partial_\theta g_n(\theta_0)^t \partial_\theta g_n(\theta_0) \right) \right| \right),$$

then the sup-norm approximation satisfies:

$$A_{n,\infty} = \bar{g}_n(\theta_0) - B_{n,\infty} \theta_0 + o_p(n^{-1/2}),$$

$$B_{n,\infty} H_n = \partial_\theta g_n(\theta_0) H_n + o_p(n^{-1/2} \kappa_n^{-1}),$$

where $H_n = \left[ \partial_\theta g_n(\theta_0)^t \partial_\theta g_n(\theta_0) \right]^{-1/2}$.

Under semi-strong identification, $\sqrt{n} H_n^{-1}(\hat{\theta}_n - \theta_0)$ is asymptotically Gaussian. The rate of convergence of each coefficient depends on the eigenvalues of $H_n^{-1}$ - i.e. the singular values of $\partial_\theta g_n(\theta_0)$ - and its eigenvectors. In practice, the standard errors adjust for the rate of convergence automatically, similarly to series and sieve inferences (Pagan & Ullah, 1999; Chen & Pouzo, 2015), so that the usual $t$-statistic is asymptotically Gaussian. And again, $B_{n,\infty}$ can be used in the sandwich formula to compute standard errors. The scaled convergence of $B_{n,\infty}$ in Theorem 2 has implications in terms of convergence of the spectral decomposition of $B_{n,\infty}$. Indeed, let $v_{j,n}$ be the $j$th right singular vector of $\partial_\theta g_n(\theta_0)$ with singular value $\lambda_{j,n}$, then $B_{n,\infty} v_{j,n} = \lambda_{j,n} \times \left[ I + o_p(n^{-1/2} \kappa_n^{-1}) \right] v_{j,n}$. This implies that $v_{j,n}$ is approximately a right singular vector for $B_{n,\infty}$ with singular value $\lambda_{j,n}$.

**Theorem 3.** (Behaviour of the Sup-Norm Approximation under Higher-Order Local Identification)

Suppose that the model is higher-order locally identified at an order $r \geq 2$ and that Assumptions 1 i., ii. and 2 hold, then the sup-norm approximation satisfies:

$$|\lambda_{\min}(B_{n,\infty})| = O_p(\kappa_n^{1-1/r}),$$

where $\lambda_{\min}(B_{n,\infty})$ is the smallest eigenvalue of $B_{n,\infty}$. Furthermore, for all $v_j \in \text{Span}(P_j)$, $j \in \{1, \ldots, r\}$:

$$B_{n,\infty} v_j = O_p(\kappa_n^{1-1/j}),$$

where $P_j$ are the projection matrices in Definition 5.

---

16 Consider the singular value decomposition $\partial_\theta g_n(\theta_0) = U_n D_n V_n'$ where $D_n$ is the diagonal matrix of singular values. Then $\partial_\theta g_n(\theta_0) H_n = U_n I_d V_n'$; this implies that 1 is an singular value with multiplicity $d_\theta$.

17 $v_{j,n}$ is also an orthogonal eigenvector of $H_n$ and $H_n^{-1}$ by construction.
Theorem 3 shows that $B_{n,\infty}$ becomes singular under first-order identification failure. The rate at which the eigenvalues decay depends on both the order $r \geq 2$ and the bandwidth $\kappa_n$. When moments are increasingly flat around $\theta_0$, i.e. $r$ is larger, then this rate becomes slower and closer to $O_p(\kappa_n)$ which corresponds to the rate under weak or set identification. Also, $B_{n,\infty}$ vanishes in the directions of the first-order identification failure: $\text{Span}(P_2, \ldots, P_r)$. Note that if the Jacobian is non-zero but the second-order term is non-negligible then rank tests on the Jacobian would have low power. Yet, standard inferences could suffer important size distortions. This is illustrated in the Monte-Carlo simulations of Appendix G.3 where the Jacobian vanishes at a $n^{-1/4}$ rate and the second-order term is non-vanishing. The quasi-Jacobian in these simulations is typically much flatter than both Jacobians $\partial_{\theta} \bar{g}_n(\theta_0)$, $\partial_{\theta} \bar{g}_n(\hat{\theta}_n)$.

**Theorem 4.** (Behaviour of the Sup-Norm Approximation under Weak/Set Identification) Suppose that Assumptions 1 i., ii. and 3 hold and that there exists at least two $\theta_0 \neq \theta_1$ in the weakly identified set $\Theta_0$, then the sup-norm approximation satisfies:

$$|\lambda_{\min}(B_{n,\infty})| = O_p(\kappa_n),$$

where $\lambda_{\min}(B_{n,\infty})$ is the smallest eigenvalue of $B_{n,\infty}$. Furthermore, $B_{n,\infty}$ is vanishing on the span of the identification failure:

$$B_{n,\infty}v = O_p(\kappa_n), \forall v \in V = \text{Span}\left\{\theta_0 - \theta_1, \theta_0, \theta_1 \in \Theta_0\right\}.$$
Since the first term is a $O(\kappa_n)$, it implies that:

$$\|A_{n,\infty} + B_{n,\infty}\theta\| \hat{K}_n(\theta) \leq O(\kappa_n),$$

for all $\theta \in \Theta$. Take two $\theta_0, \theta_1 \in \Theta_0$ then there exists $K > 0$ which only depends on $K$ such that, with probability going to $1$, $\hat{K}_n(\theta_0) \geq K > 0$ and $\hat{K}_n(\theta_1) \geq K > 0$. This in turn implies that:

$$\|A_{n,\infty} + B_{n,\infty}\theta_0\| \leq O_p(\kappa_n) \text{ and } \|A_{n,\infty} + B_{n,\infty}\theta_1\| \leq O_p(\kappa_n)$$

$$\Rightarrow \|B_{n,\infty}(\theta_0 - \theta_1)\| \leq O_p(\kappa_n),$$

which leads to the desired results.

**Remark 1. (The Span of the Identification Failure)** Note that the span of the identification failure may be bigger than the number of parameters that need to be fixed in order to restore point identification. For instance, the set $\Theta_0 = \{\theta = (\alpha, \beta), \alpha = \beta^3\}$ implies $V = \mathbb{R}^2$ even though $\beta$ is uniquely determined when $\alpha$ is fixed. There is thus an important difference between the linear span $V$ of the identification failure considered here and the type of non-linear reparameterizations considered in e.g. [Arellano et al. (2012); Stock & Wright (2000); Andrews & Cheng (2012)], among others. In general, a global reparameterization may not exist or would typically not be known. In the above example, one could however fix $\alpha$ and compute the quasi-Jacobian for the constrained model and find that identification is restored for $\beta$. The span $V$ is not always too large, for instance consider the weakly identified set $\Theta_0 = \{\theta = (\alpha, \beta), \alpha^2 + \beta^2 = 1\}$. Both $\alpha$ and $\beta$ should be fixed to restore point identification.

Before turning to the least-squares approximation, the following provides an heuristic discussion for the results above from a topological perspective. The difference in behaviour of the quasi-Jacobian under point and set identification stems from the discrepancy between local neighborhoods defined under the usual norm $\| \cdot \|$ and the pseudo-norm implied by the moments $\|g_n(\cdot)\|$. Here, assuming point identification, bounded second derivative and that the Jacobian’s eigenvalues are bounded away from zero, local neighborhoods are equivalent:

$$\left\{ \theta, \| \theta - \theta_0 \| \leq 0.5 \lambda_{\min}(\partial_{\theta} g_n(\theta_0)) \varepsilon \right\} \subseteq \left\{ \theta, \| g_n(\theta) \| \leq \varepsilon \right\} \subseteq \left\{ \theta, \| \theta - \theta_0 \| \leq 2 \lambda_{\max}(\partial_{\theta} g_n(\theta_0)) \varepsilon \right\},$$

for $\varepsilon > 0$ small enough. However, if the Jacobian’s eigenvalues are not bounded away from zero $\| \theta - \theta_0 \| / \| \partial_{\theta} g_n(\theta)(\theta - \theta_0) \| \geq \lambda_{\min}(\partial_{\theta} g_n(\theta_0))^{-1} \rightarrow +\infty$. This is the first discrepancy between the two topologies. Now, under set identification:

$$\forall C > 0, \exists \varepsilon > 0, \forall \varepsilon \in (0, \bar{\varepsilon}], \left\{ \theta, \| g_n(\theta) \| \leq \varepsilon \right\} \nsubseteq \left\{ \theta, \| \theta - \theta_0 \| \leq C\varepsilon \right\}.$$
The inclusion fails because, under set identification, there exists $\theta_1 \neq \theta_0$, $g_n(\theta_1) = 0$ which is not contained in local neighborhoods of $\theta_0$. This is the second discrepancy between the two topologies. Note that the inclusion from the right-hand side to the left-hand side may hold, however. The linear approximation tries to connect these topologies but, because of the discrepancy, this is not possible and, as shown above, $B_{n,LS/\infty}$ becomes singular as a result. For this phenomenon to occur in finite samples, the bandwidth should be small enough for the topologies to appear distinct yet large enough to capture $\Theta_0$ with high probability.

### 3.2 Least-squares approximation

**Definition 7.** *(Quasi-Posterior $\hat{\pi}_n$)* For any $\theta \in \Theta$, the quasi-posterior $\hat{\pi}_n$ associated with the sample moments $\bar{g}_n$ and the kernel $K$ is:

$$
\hat{\pi}_n(\theta) = \frac{K(\|\bar{g}_n(\theta)/\kappa_n\|_{W_n} - \|\bar{g}_n(\hat{\theta}_n)/\kappa_n\|_{W_n})}{\int_\Theta K(\|\bar{g}_n(\tilde{\theta})/\kappa_n\|_{W_n} - \|\bar{g}_n(\hat{\theta}_n)/\kappa_n\|_{W_n})d\tilde{\theta}}.
$$

The associated posterior mean $\bar{\theta}_n$ and variance $\Sigma_n$ are:

$$
\bar{\theta}_n = \int \theta \hat{\pi}_n(\theta)d\theta, \quad \Sigma_n = \int (\theta - \bar{\theta}_n)(\theta - \bar{\theta}_n)'\hat{\pi}_n(\theta)d\theta.
$$

Definition 7 relates the kernel $\hat{K}_n$ to a quasi-posterior $\hat{\pi}_n$. When $K = \phi$, the Gaussian density, this corresponds to the quasi-posterior of Chernozhukov & Hong (2003), up to a prior $\pi$, for $W_n = \hat{V}_n^{-1}$, the optimal weighting matrix, and $\kappa_n = n^{-1/2}$. They show that, under strong identification, $\bar{\theta}_n = \hat{\theta}_n$ up to an $o_p(n^{-1/2})$ term and $\Sigma_n$ is a consistent estimator for the sandwich formula. It is also related to the Approximate Bayesian Computation (ABC) estimator when $\bar{g}_n$ consists of simulated moments.

Note that the least-squares approximation requires the re-centering $\hat{K}_n(\theta) = K(\|\bar{g}_n(\theta)/\kappa_n\|_{W_n} - \inf_{\theta \in \Theta} \|\bar{g}_n(\theta)/\kappa_n\|_{W_n})$ using $\hat{\theta}_n$ only for over-identified models with the compact kernel. The adjustment is not needed for just-identified models where $\bar{g}_n(\hat{\theta}_n) = 0$ and is automatically implicitly applied with the exponential kernel.

Also, $\Sigma_n$ can be seen as a sufficient statistic for identification failure. Intuitively, if the model is set identified then $\Sigma_n$ should be bounded below in some direction. This is shown to hold when $\Theta_0$ satisfies some topological regularities in Theorem 8. If the model is (semi)-strongly identified, a Bernstein-von Mises type result holds so that $\Sigma_n = o_p(1)$. Furthermore,

---

18See Forneron & Ng (2018) for a discussion of ABC and other simulation-based minimum distance estimators. An important distinction here is that $\bar{g}_n$ is regressed on $(1, \theta')$ whereas ABC typically regresses $\theta$ on $(1, \bar{g}_n)$ using nonparametric methods such as local-linear or neural network regression see e.g. Beaumont et al. (2009); Blum (2010); Blum & François (2010); Creel et al. (2016).

---

20
Lemma 1 shows that \( B_{n,LS} \) is vanishing in some direction if, and only if, \( \Sigma_n \) is non-vanishing in that direction. As a result, intuitions on posterior concentration, as seen by \( \Sigma_n \), directly translate into the behaviour of \( B_{n,LS} \).

**Theorem 5. (Behaviour of the Least-Squares Approximation under Strong Identification)**

Suppose that the model is strongly identified and that Assumptions 1 and 2 hold, then the least-squares approximation satisfies:

\[
A_{n,LS} = \bar{g}_n(\hat{\theta}_n) - B_{n,LS}\hat{\theta}_n + o_p(n^{-1/2})
\]
\[
B_{n,LS} = \partial_\theta g_n(\hat{\theta}_n) + o_p(1),
\]
where \( \hat{\theta}_n \) is the global minimizer of \( \|\bar{g}_n(\theta)\|_W \) on \( \Theta \).

Let \( \hat{\theta}_{n,LS} = -\left( B_{n,LS}'\hat{W}_nB_{n,LS} \right)^{-1}B_{n,LS}'\hat{W}_nA_{n,LS} \) be the estimator derived from the least-squares approximation and \( \hat{W}_n = W_n(\hat{\theta}_n) \), then:

\[
\sqrt{n} \left( \hat{\theta}_{n,LS} - \hat{\theta}_n \right) = o_p(1).
\]

Also, the posterior variance \( \Sigma_n \) satisfies:

\[
\Sigma_n = O_p(\tilde{\kappa}_n^2),
\]
where \( \tilde{\kappa}_n = \kappa_n \) for the compact kernel and \( \tilde{\kappa}_n = \kappa_n \log(n)^{1/a} \) for the exponential kernel.

Theorem 5 implies that the linear approximation \( A_{n,LS}, B_{n,LS} \) can be used to compute approximate global minimizer \( \hat{\theta}_{n,LS} \) of the objective function. This may be particularly useful in estimation problems that involve difficult to optimize, non-smooth, non-convex objective functions.\(^{19}\) The posterior variance concentrates at a rate predicted by the bandwidth \( \kappa_n \). Note that \( \kappa_n \) is replaced with \( \tilde{\kappa}_n = \kappa_n \log(n)^{1/a} \) for the exponential kernel.

**Theorem 6. (Behaviour of the Least-Squares Approximation under Semi-Strong Identification)**

Suppose that the model is semi-strongly identified, that Assumptions 1 and 2 hold and that the bandwidth \( \kappa_n \) and the moments \( g_n \) are such that:

\[
\tilde{\kappa}_n^2 = o \left( \lambda_{\min} \left( \partial_\theta g_n(\theta_0)'\partial_\theta g_n(\theta_0) \right) \right),
\]
\(^{19}\)Note that the idea of smoothing the objective function over \( \theta \) to simplify the optimization problem is not new. For instance, the UOBYQA, NEWUOA and BOBYQA local optimization algorithms of Powell \(2002, 2004, 2006, 2009\) rely on quadratic interpolation to avoid computing numerical derivatives. Some of these are implemented in the NLopt package \(2014\). Here, the role of the smoothing is explicitly accounted for in the asymptotic analysis of \( \hat{\theta}_{n,LS} \) and the kernel allows to make the estimate an approximately global optimizer (up to a \( o_p(n^{-1/2}) \) term) rather than a local one.
where $\bar{\kappa}_n = \kappa_n$ for the compact kernel and $\bar{\kappa}_n = \kappa_n \log(n)^{1/a}$, then the sup-norm approximation satisfies:

$$A_{n,LS} = \bar{g}_n(\hat{\theta}_n) - B_{n,LS}\hat{\theta}_n + o_p(n^{-1/2}),$$

$$B_{n,LS}H_n = \partial_\theta g_n(\hat{\theta}_n)H_n + o_p(n^{-1/2}\bar{\kappa}_n^{-1}),$$

where $\hat{\theta}_n$ is the global minimizer of $\|g_n(\theta)\|_W$ on $\Theta$ and $H_n = (\partial_\theta g_n(\theta_0)\partial_\theta g_n(\theta_0))^{-1/2}$.

Let $\hat{\theta}_{n,LS} = -\left(B'_{n,LS}W_nB_{n,LS}\right)^{-1}B'_{n,LS}W_nA_{n,LS}$ be the estimator associated with the least-squares approximation and $\tilde{W}_n = W_n(\hat{\theta}_n)$, then:

$$\sqrt{n}H_n^{-1}\left(\hat{\theta}_{n,LS} - \hat{\theta}_n\right) = o_p(1).$$

Also, the quasi-posterior variance $\Sigma_n$ satisfies:

$$H_n^{-1}\Sigma_n H_n^{-1} = O_p(\bar{\kappa}_n^2),$$

where $\bar{\kappa}_n = \kappa_n$ for the compact kernel and $\bar{\kappa}_n = \kappa_n \log(n)^{1/a}$ for the exponential kernel.

Theorem $6$ is also similar to Theorem $2$ with an adjustment term, $H_n$, to account for the slower than $\sqrt{n}$-convergence rate of the estimates.

**Lemma 1. (Relationship between $B_{n,LS}$ and $\Sigma_n$)**

Suppose Assumptions $1$ and $2$ hold. For the exponential kernel, assume that the moments satisfy a Hölder-type condition around $\Theta_0$: $\exists \varepsilon > 0, C > 0$ and $\zeta \in (0, 1]$ such that $\|g_n(\theta)\|_W \leq Cd(\theta, \Theta_0)^\zeta$, $\forall n \geq 1$, $\forall \theta \in \Theta$ such that $d(\theta, \Theta_0) \leq \varepsilon$. Given these assumptions, the least-squares approximation, and the quasi-posterior variance satisfy:

$$0 \leq \text{trace} \left( B_{n,LS} \Sigma_n B'_{n,LS} \right) \leq O_p(\bar{\kappa}_n^2),$$

(11)

where $\bar{\kappa}_n = \kappa_n$ for the compact kernel and $\bar{\kappa}_n = \kappa_n \log(n)^{1/a}$ for the exponential kernel. This implies the following inequalities:

i. $\forall j \in \{1, \ldots, d_\theta\}$, $0 \leq \lambda_j \left( B'_{n,LS}B_{n,LS} \right) \lambda_{d_\theta + 1 - j} \left( \Sigma_n \right) \leq O_p(\bar{\kappa}_n^2)$ where the eigenvalues $\lambda_j$ are sorted in increasing order. In particular:

$$0 \leq \lambda_{\min} \left( B'_{n,LS}B_{n,LS} \right) \lambda_{\max} \left( \Sigma_n \right) \leq O_p(\bar{\kappa}_n^2),$$

ii. let $(v_{j,n})_{j=1, \ldots, d_\theta}$ be the eigenvectors of $\Sigma_n$, suppose that for each $j$ there exists a sequence $(r_{j,n})_{n \geq 1}$ such that $v'_{j,n} \Sigma_n v_{j,n} = O_p(r_{j,n}^2)$, then for each $j \in \{1, \ldots, d_\theta\}$:

$$B_{n,LS}v_{j,n} = O_p(\bar{\kappa}_n/r_{j,n}).$$

22
iii. assuming the 
\( r_{j,n}, j = 1, \ldots, d \theta \) are sorted in increasing order then, without loss of generality:

\[ |\lambda_{\min}(B_{n,LS})| = O_p(\tilde{\kappa}_n/r_{d\theta,n}). \]

Lemma 1 is pivotal in deriving the results for higher-order and weak/set identification. Equation (11) implies that the behaviour of \( B_{n,LS} \) is determined by the behaviour of \( \Sigma_n \). This implies a similar relation for their eigenvalues. In turn, determining the rate for \( \lambda_{\min}(B_{n,LS}) \) is equivalent to solving for \( \lambda_{\max}(\Sigma_n) \). Under the sup-norm, the diameter of the set \( \{ \theta, \|\bar{g}_n(\theta)\|_{W_n} \leq \kappa_n \} \) is a determinant in the behaviour of \( \lambda_{\min}(B_{n,\infty}) \). Here, \( \lambda_{\max}(\Sigma_n) \) is analog of the diameter of this set, as measured by the quasi-posterior distribution.

For the exponential kernel, an additional condition is required where the moments must not grow too fast when \( \theta \) is away from \( \Theta_0 \). The posterior may not concentrate only on \( \Theta_0 \) if this assumption does not hold giving non-negligible weight to other regions of \( \Theta \).

**Sketch of the proof:** Since \( A_{n,LS} \) is the intercept of a least-squares estimator, it has a closed form:

\[ A_{n,LS} = \int_\Theta \bar{g}_n(\theta)\hat{\pi}_n(\theta)d\theta - B_{n,LS}\bar{\theta}_n. \]

Substituting this into the least-squares objective:

\[ \int_\Theta \|B_{n,LS}(\theta - \theta_0) - [\bar{g}_n(\theta) - \int_\Theta \bar{g}_n(\theta)\hat{\pi}_n(\theta)d\theta]|^2\hat{\pi}_n(\theta)d\theta \leq 4 \int \|\bar{g}_n(\theta)\|^2\hat{\pi}_n(\theta)d\theta = O_p(\tilde{\kappa}_n^2). \]

By the reverse triangular inequality, this implies:

\[ \int \|B_{n,LS}(\theta - \bar{\theta}_n)\|^2\hat{\pi}_n(\theta)d\theta \leq O_p(\tilde{\kappa}_n^2), \]

where the term on the left-hand side simplifies to

\[ \int \text{trace}(B_{n,LS}[\theta - \bar{\theta}_n][\theta - \bar{\theta}_n]'B_{n,LS}'\hat{\pi}_n(\theta)d\theta = \text{trace}(B_{n,LS}\Sigma_nB_{n,LS}'), \]

which implies the desired results.

**Theorem 7. (Behaviour of the Least-Squares Approximation under Higher-Order Local Identification)**

Suppose that the model is higher-order locally identified at an order \( r \geq 2 \) and that Assumptions 1 and 2 hold, then the least-squares approximation satisfies:

\[ |\lambda_{\min}(B_{n,LS})| = O_p(\tilde{\kappa}_n^{1-1/r}), \]

23
where $\tilde{\kappa}_n = \kappa_n$ if $K$ is a kernel with compact support and $\tilde{\kappa}_n = \kappa_n \log(n)^{1/a}$ if $K$ is an exponential kernel. Also, for all $v_j \in \text{Span}(P_j)$, $j \in \{1, \ldots, r\}$:

$$B_{n,LS}v_j = O_p(\tilde{\kappa}_n^{1-1/j}),$$

where $P_j$ are the projection matrices in Definition 5.

Theorem 7 is the first application of Lemma 1; it relies on derivations for $P_j\Sigma_n P_j'$. Under semi-strong identification using a compact kernel, the posterior is asymptotically equivalent to

$$\hat{K}_n(\theta) \simeq K\left(\theta - \hat{\theta}_n\right)^T\partial_\theta g_n(\hat{\theta}_n)\partial_\theta g_n(\hat{\theta}_n)\left(\theta - \hat{\theta}_n\right)/\kappa_n.$$

As a result the posterior concentrates at a $\kappa_n$ rate around $\hat{\theta}_n$ with the compact kernel. Under higher-order identification, $\|g_n(\theta)\|W_n/\kappa_n \simeq \sum_{j=1}^r \|P_j(\theta - \theta_0)/\kappa_n^{1/j}\|^j$ so that the posterior concentrates at a rate $\kappa_n^{1/j}$ around $\hat{\theta}_n$ along the span of $P_j$. These rates translate directly into rates for the posterior variance $\Sigma_n$ in both cases.

Proposition 1. (Behaviour of the Least-Squares Approximation under Weak Identification)

Suppose that there exists two $\theta_0 \neq \theta_1 \in \Theta_0$ such that for some $0 < \varepsilon < \|\theta_0 - \theta_1\|$, $\exists \eta > 0$:

$$\lim_{n \to \infty} \min_{\|\theta - \theta_0\|_2 \leq \varepsilon/3} \pi_n(\theta)d\theta, \min_{\|\theta - \theta_1\|_2 \leq \varepsilon/3} \pi_n(\theta)d\theta \geq \eta > 0,$$

then the quasi-posterior variance satisfies:

$$\lambda_{\text{max}}(\Sigma_n) \geq \eta \varepsilon^2/[36d_\theta] + o_p(1)$$

and, under the conditions of Lemma 7:

$$|\lambda_{\text{min}}(B_{n,LS})| = O_p(\tilde{\kappa}_n).$$

Proposition 1 simply states that when there are two different $\theta_0, \theta_1$ to which the quasi-posterior gives weight asymptotically, then $\Sigma_n$ is bounded below in some direction. By Lemma 7 this implies that $B_{n,LS}$ becomes singular as in Theorem 4. The following theorem provides primitive topological conditions that ensure the posterior mass does not concentrate around a sole element of $\Theta_0$.

Theorem 8. (Topology of the Weakly Identified Set $\Theta_0$ and quasi-Posterior Concentration)

Suppose that the conditions in Lemma 7 hold and that one of the following is satisfied:

i. $\Theta_0$ has non-empty interior,
ii. $\Theta_0$ is finite, i.e. $\Theta_0 = \bigcup_{j=0}^{k-1} \{\theta_j\}$ for some finite $k \geq 2$ and

a. $\exists \epsilon > 0$ and $\eta(\epsilon) > 0$ such that:

$$\inf_{\theta \in \Theta, d(\theta, \Theta_0) \geq \epsilon} \|g_n(\theta)\|_W \geq \eta(\epsilon), \forall n \geq 1,$$

b. $\exists \underline{C} > 0, \overline{C} > 0$ and some finite $r \geq 1$ such that

$$C_d(\theta, \Theta_0)^r \leq \|g_n(\theta)\|_W \leq \overline{C}_d(\theta, \Theta_0)^r, \forall n \geq 1, \forall \theta \in \Theta, d(\theta, \Theta_0) \leq \epsilon,$$

for $\epsilon$ defined in ii.a. above.

iii. $\Theta_0$ is a finite union of lower-dimensional manifolds, $\Theta_0 = \bigcup_{j=0}^{k-1} S_j$ for some finite $k \geq 1$, where $S_j$ are bounded sets with $d(S_j, S_j') > 0, j \neq j'$ such that:

a. for each $j \in \{0, \ldots, k\}$, $\exists k_j \in \{1, \ldots, d_\theta\}, \exists U_j \subset \mathbb{R}^{d_\theta - k_j}$ a connected and bounded subset of $\mathbb{R}^{d_\theta - k_j}$ with non-empty interior and, $\exists \varphi_j$, an invertible, continuously differentiable mapping from the open neighbourhood $\mathcal{N}(U_j) \times \mathcal{N}(\{0\}) \subseteq \mathbb{R}^{d_\theta}$ to the open neighbourhood $\mathcal{N}(S_j)$ such that $\vartheta \in U_j \times \{0\}$ if, and only if, $\varphi_j(\vartheta) \in S_j$ and $\exists \lambda_j, \overline{\lambda}_j$ such that $\forall \vartheta \in \varphi_j^{-1}(\mathcal{N}(S_j))$:

$$0 < \lambda_j \leq |\lambda_{\min}(\partial_\vartheta \varphi_j(\vartheta))| \leq |\lambda_{\max}(\partial_\vartheta \varphi_j(\vartheta))| \leq \overline{\lambda}_j < +\infty,$$

b. $\exists \eta > 0$ such that:

$$\inf_{\theta \notin \bigcup_{j=0}^{k-1} \mathcal{N}(S_j)} \|g_n(\theta)\|_W \geq \eta, \forall n \geq 1,$$

c. $\exists \underline{C}, \overline{C} > 0$ such that:

$$\underline{C}_d(\theta, \Theta_0) \leq \|g_n(\theta)\|_W \leq \overline{C}_d(\theta, \Theta_0), \forall n \geq 1, \forall \theta \in \bigcup_{j=0}^{k-1} \mathcal{N}(S_j),$$
then the assumptions and the results of Proposition 1 hold.

Theorem 8 considers three possibilities: i. $\Theta_0$ has non-empty interior and thus contains open sets with non-zero Lebesgue measure, ii. $\Theta_0$ is a finite union of singletons (zero dimensional Manifolds) and, iii. $\Theta_0$ is a finite union of lower-dimensional manifolds.

Case i. is immediate. Case ii. requires that $g_n$ behaves similarly around the each point in $\Theta_0$. This could be weakened slightly to require only two points to be associated with a $r$-th order polynomial behaviour, while other points could be characterized by different polynomial behaviour $j \leq r$ or $j < r$. If the inequality is strict, by an argument similar to
case iii., the two points with largest polynomial order would dominate the posterior so that the other points would not satisfy the assumption in Proposition 1.

Case iii. states that $\Theta_0$ is a union of lower-dimensional manifolds. Manifolds have non-empty interior in a lower-dimension space, so within each $S_j$ there are two disjoint open sets with non-zero Lebesgue measure in $\mathbb{R}^{d_\theta-k_j}$. Some primitives for condition iii. a. include the constant rank theorem\textsuperscript{20}, which implies the existence of local reparameterizations, and the partition of unity, which ensures that a finite number of these local reparameterizations can be "glued" together to create a global re-parameterization $\varphi_j$ (see e.g. Lee, 2012)\textsuperscript{21}

The eigenvalue condition on $\varphi_j$ ensures that a change of variable argument can be used to construct explicit bounds on the integrals in Proposition 1. Conditions iii. b. and c. ensure that $\Theta_0$ is well separated by $g_n$ from the rest of the parameter space and control the local behaviour of $g_n$ around $\Theta_0$.

Note that these manifolds may have different dimensions. An implication of the proof of Theorem 8 is that for two small disjoint open neighborhoods $N(S_j), N(S_{j'})$ which do not overlap with any other manifold,

$$\frac{\int_{N(S_{j'})} \hat{\pi}_n(\theta)d\theta}{\int_{N(S_j)} \hat{\pi}_n(\theta)d\theta} \xrightarrow{P} 0, \text{ if } k_j > k_{j'}.$$ 

This means that the posterior is dominated by the manifold(s) with the largest dimension $k^* = \max_j k_j$, i.e. the highest degree of identification failure. Lower dimensional manifolds, with $k_j < k^*$, will have measure zero in the limit. Previous results have established that the posterior concentrates on the identified set, i.e. $\int_{N(\Theta_0)} \hat{\pi}_n(\theta)d\theta \xrightarrow{P} 1$ for any open neighborhood of $\Theta_0$ (see e.g. Moon & Schorfheide, 2012). While the posterior only gives weight to regions covering $\Theta_0$, the present result suggests that some regions within $\Theta_0$ may have zero posterior mass in the limit. A practical implication is that when using MCMC to estimate $\Theta_0$, the Markov-Chain might get stuck on the larger dimensional manifold(s) which account for nearly all of the posterior mass. Further investigation of this phenomenon goes beyond the scope of this paper and is left to future research.

Appendix C.3 illustrates the three types of topological requirements for Theorem 8 and

\textsuperscript{20}The constant rank theorem is a generalization of the implicit function theorem.

\textsuperscript{21}Note that existence of a global reparameterization does not necessarily imply that it is analytically tractable nor globally smooth. Condition iii. a. is stronger than these theorems since we also need to extend each $\varphi_j$ to a neighborhood of $S_j$. Since the proof relies on a change of variable argument it may be possible to relax the global smoothness condition and consider a finite number of smooth local maps "glued" together if the resulting map is non-smooth on a set of measure zero in the appropriate dimension and measure. This is not considered in the present paper.
provides an example where the conditions for Proposition 1 are not met. The construction shows a highly fluctuating function where the posterior concentrates around a single point even though the identified set consists of infinitely many disjoint singletons.

**Corollary 1.** *(Weak Identification, Global Re-Parametrizations and Posterior Concentration)* Suppose that there exists a global re-parametrization \( \theta = \varphi(\beta, \gamma) \) where \( (\beta, \gamma) \in B \times \Gamma \subseteq \mathbb{R}^{d_\beta} \times \mathbb{R}^{d_\gamma} \) such that:

i. \( \varphi : (B \times \Gamma) \to \Theta \) is continuously differentiable and invertible on \( \Theta \) and \( \exists \lambda, \overline{\lambda} \) such that:

\[
0 < \lambda \leq |\lambda_{\min}(\partial_{\beta, \gamma}\varphi(\beta, \gamma))| \leq |\lambda_{\max}(\partial_{\beta, \gamma}\varphi(\beta, \gamma))| \leq \overline{\lambda} < +\infty,
\]

ii. \( \gamma \) is point identified, i.e. \( \Theta_0 = \varphi(B_0 \times \{\gamma_0\}) \), \( B_0 \) is bounded with non-empty interior and, \( \exists \varepsilon > 0, \eta > 0 \) such that:

\[
\inf_{d(\beta, B_0) + \|\gamma - \gamma_0\| \geq \varepsilon} \|g_n \circ \varphi(\beta, \gamma)\| \geq \eta, \forall n \geq 1,
\]

and, \( \exists C > 0, \overline{C} \) such that \( \forall (\beta, \gamma) \) with \( (d(\beta, B_0) + \|\gamma - \gamma_0\|) \leq \varepsilon \):

\[
C \left[ d(\beta, B_0) + \|\gamma - \gamma_0\| \right] \leq \|g_n \circ \varphi(\beta, \gamma)\| \leq \overline{C} \left[ d(\beta, B_0) + \|\gamma - \gamma_0\| \right], \forall n \geq 1,
\]

then the assumptions of Theorem 8 are satisfied and \( \lambda_{\min}(B_{n,LS}) = O_p(\tilde{\kappa}_n) \) where \( \tilde{\kappa}_n = \kappa_n \) for the compact kernel and \( \tilde{\kappa}_n = \kappa_n \log(n)^{1/a} \) for the exponential kernel.

Corrolary 1 re-states Theorem 8 iii. in the more familiar settings where \( \theta \) can be globally and smoothly mapped into a point identified coefficient \( \gamma \) and a weakly/set identified coefficient \( \beta \).

### 4 Detecting Identification Failure and Two-Step Subvector Inference

This section builds on the asymptotic properties of the linear approximations derived above to construct a two-step subvector inference procedure for potentially weakly or higher-order identified models. As discussed in the introduction, the first step amounts to determining which parameters need to be fixed and the second performs robust inference given this information. The procedure is concerned with hypotheses of the form:

\[
H_0 : R\theta = c \text{ vs. } H_1 : R\theta \neq c,
\]
for a given restriction matrix \( R \in \mathbb{R}^{m \times d} \) with \( 1 \leq m \leq d \) and \( c \in \mathbb{R}^m \).

Weak and higher-order identification will be detected using different criteria, so the two are considered in separate subsections. If a combination of both weak and higher-order identification is a concern, it should be noted that one could in principle pre-test for weak identification, determine which coefficients need to be fixed to restore point identification and then check for higher-order identification issues on the remaining "free" parameters.

In both cases, a pre-determined nested sequential search is used to determine which parameters to fix. In practice, it amounts to looking at a sequence of restriction matrices \( R_\ell, \ell = 1, 2, \ldots \) until a given criteria is met. The definition below describes the sequence of restriction matrices considered here.

**Definition 8.** (Nested Sequence of Restrictions) Let \( R_1 = R \) be the restriction matrix used to test the null hypothesis (1). The pre-determined set of restriction matrices \( (R_\ell)_{1 \leq \ell \leq \mathcal{L}} \), is given by \( R_\ell = (R_{\ell-1}', \tilde{R}_\ell')' \), \( 2 \leq \ell \leq \mathcal{L} \), where \( \tilde{R}_\ell \) is a sequence of \( \mathcal{L} - 1 \) matrices such that \( 1 \leq m = \text{rank}(R_1) < \text{rank}(R_2) < \cdots < \text{rank}(R_\mathcal{L}) = d \).

The appeal of using this type of search in the first-step is that it involves at most \( \mathcal{L} \leq d \) pre-tests. This will simplify the asymptotic analysis significantly. For a given restriction matrix, the criteria used for the search is shown to determine - with probability going to 1 - whether "free" parameters remain in the span of the identification failure. Hence, at each step the search continues - with probability going to 1 - so long as "free" parameters are in this span. Note that the search’s length \( \mathcal{L} \) is finite and, by construction, \( R_\mathcal{L} \) fixes all coefficients. Hence, there exists a \( \ell^* \) such that for \( \ell > \ell^* \), all "free" parameters lie outside this span. Using a family-wise error rate argument: with probability going to 1, the search will end at an \( \hat{\ell}_n \geq \ell^* \) thereby fixing the span of the identification failure.

Once the algorithm has picked a \( \hat{\ell}_n \), confidence sets for \( R_\theta \) can be constructed by projection inference. First, compute a \( 1 - \alpha \) confidence set for \( R_{\hat{\ell}_n} \theta \):

\[
CS_{1-\alpha} = \{ c \in \mathbb{R}^{\text{rank}(R_{\hat{\ell}_n})}, R_{\hat{\ell}_n} \theta = c \text{ and } S_n(\hat{\theta}_{n,c}) \leq c_{1-\alpha} \}, \quad \hat{\theta}_{n,c} = \arg\min_{R_{\hat{\ell}_n} \theta = c} \| \bar{g}_n(\theta) \| W_n.
\]

The critical value \( c_{1-\alpha} \) depends on the choice of the test statistic. For instance, for the Anderson-Rubin test, one would use the \( 1 - \alpha \) quantile of a \( \chi^2 \) distribution with \( (\text{dim}(g) - [d_\theta - \text{rank}(R_{\hat{\ell}_n})]) \) degrees of freedom. For the K-statistic, one would use the \( 1 - \alpha \) quantile of a \( \chi^2 \) distribution with \( \text{rank}(R_{\hat{\ell}_n}) \) degrees of freedom. Then, take all the values in the first \( m \)-rows of each element in \( CS_{1-\alpha} \). This is the projected \( 1 - \alpha \) confidence set for \( R_\theta \).

Progress towards uniform inference would require explicit bounds on the probability of the family-wise error rate of selecting too few restrictions. The proofs of Theorem 4 and
Proposition 1 reveals that, under weak or set identification, the distribution of the smallest eigenvalue of the quasi-Jacobian $B_{n,LS/\infty}$ depends (among other things) on the diameter of the weakly identified set, $\sup_{\theta_0, \theta_1 \in \Theta} \|\theta_0 - \theta_1\|$, as well as the tail probability of the empirical process, $P(\sup_{\theta \in \Theta} \|G_n(\theta)\|_W > M)$. The latter could be bounded using empirical process methods (van der Vaart & Wellner, 1996) or sub-Gaussian inequalities. The former seems more challenging to handle given that the weakly identified set has to be estimated. A rigorous investigation is left to future research.

Another appeal of the approach described below is that the quasi-Jacobian $B_{n,LS/\infty}$ only needs to be computed once. This can be important when the moments $\bar{g}_n$ are costly to evaluate. With that in mind, more powerful procedures might be possible if one were to consider computing $B_{n,LS/\infty,\ell}$, the quasi-Jacobian of the moments computed with the additional restriction $R_\ell \theta = c_\ell$. The user would have to compute $\mathcal{L}$ linear approximations, which is more demanding.

### 4.1 Weak or set identification

The first set of results deals with weakly and set identified models. A general Algorithm is introduced and its asymptotic properties are given. Subsection 4.1.2 provides a simple rule-of-thumb for choosing the cutoff for the eigenvalues of $B_{n,LS/\infty}$ in the just-identified case. Another rule-of-thumb for over-identified models is presented in Appendix C.1.1.

#### 4.1.1 Algorithm and two-step inference

Algorithm 1 combines two pieces of information: the number of eigenvalues below the threshold for the full matrix $B_{n,LS/\infty}$ and the span of the “free” parameters $P_{R_\ell}^\perp$. The first quantity conservatively estimates the rank of the span of the identification failure $V$. Fixing fewer coefficients may not suffice to resolve the identification problem. The second quantity checks if the restriction $R_\ell$ helps with the identification problem. While the criteria suggest too few coefficients have been fixed, the algorithm will continue its search for a large enough set of restrictions.

**Theorem 9.** (Two-Step Weak Identification Robust Subvector Inference) For each $\ell = 1, \ldots, \mathcal{L}$, suppose that $c_{\ell,0}$ is such that there exists $\theta_{0,c}$ with $E(\bar{g}_n(\theta_{0,c})) = 0, R_\ell \theta_{0,\ell} = c_{\ell,0}$ for all $\ell \in \{1, \ldots, \mathcal{L}\}$. Let

$$\hat{\theta}_{n,\ell,c} = \arg\min_{R_\ell \theta = c_{\ell,0}} \|\bar{g}_n(\theta)\|_{W_n},$$
Algorithm 1 Fixing the Span of the Identification Failure

compute $B_{n,LS/\infty}$ and $\lambda_{\min}(B_{n,LS/\infty})$

if $\lambda_{\min}(B_{n,LS/\infty}) > \Lambda_n$ then
    treat all $d_\theta$ parameters as point identified
else
    set $\ell = 1$
    compute $\hat{d}_V = \#\{j \in \{1, \ldots, d_\theta\}, \lambda_j(B_{n,LS/\infty} \leq \Lambda_n)\}$
    while $(\text{rank}(R_\ell) < \hat{d}_V)$ or $\left(\lambda_{\text{rank}(P_{R_\ell'}, \perp)}(B_{n,LS/\infty} P_{R_\ell'}) \leq \Lambda_n\right)$ do
        $\ell = \ell + 1$
    end while
    set $\hat{\ell}_n = \ell$
    treat $R_{\hat{\ell}_n} \theta$ as weakly identified, the remaining $d_\theta - \text{rank}(R_{\hat{\ell}_n})$ parameters as point identified
end if

be the constrained estimator of $\theta_{0,c}$ with $R_\ell$ as in Definition 8. Let $S_{n,\ell}$ be a test statistic for $H_0 : R_\ell \theta_{0,c} - c_{\ell,0} = 0$ computed at $\hat{\theta}_{n,\ell,c}$ and $c_{1-\alpha,\ell}$ the corresponding critical value. Suppose the assumptions for Lemma D4 hold as well as one of the following:

1. (semi-strong identification) the model satisfies the assumptions of Theorem 1, 2, 5 or 6, and:
   \[ \mathbb{P}(S_{n,1} \leq c_{1-\alpha,1}) = 1 - \alpha + o(1), \]
2. (weak identification) the model satisfies the assumptions of Lemma D6 hold. Let $\ell^*$ be the smallest $\ell \in \{1, \ldots, \mathcal{L}\}$ such that $\text{rank}(P_{R_{\ell^*}}, P_V) = \text{rank}(P_V)$, where $V$ is the span of the identification failure, suppose that:
   \[ \inf_{\ell \in \{\ell^*, \ldots, \mathcal{L}\}} \mathbb{P}(S_{n,\ell} \leq c_{1-\alpha,\ell}) = 1 - \alpha + o(1). \]

Let $\hat{\ell}_n$ be the $\ell \in \{1, \ldots, \mathcal{L}\}$ selected by Algorithm 1 then:

1. (semi-strong identification) with probability going to 1, $\hat{\ell}_n = 1$ so that $R_{\hat{\ell}_n} = R_1$ and:
   \[ \mathbb{P}(S_{n,\hat{\ell}_n} \leq c_{1-\alpha,\hat{\ell}_n}) = \mathbb{P}(S_{n,1} \leq c_{1-\alpha,1}) = 1 - \alpha + o(1). \]
2. (weak identification) with probability going to 1, $\hat{\ell}_n \geq \ell^*$ and:
   \[ \mathbb{P}(S_{n,\hat{\ell}_n} \leq c_{1-\alpha,\hat{\ell}_n}) \geq \inf_{\ell = \ell^*, \ldots, \mathcal{L}} \mathbb{P}(S_{n,\ell} \leq c_{1-\alpha,\ell}) = 1 - \alpha + o(1). \]
Theorem 9 allows for a large class of identification-robust test statistics in the second step. The sole requirement is that the statistics yield valid inferences for the full vector $R_{\ell_0}\theta$ for each $\ell \geq \ell^*$. In this paper, projection inference is then used to construct a confidence set for $R_{\ell_0}\theta$. Other approaches to testing with nuisance parameters include Chaudhuri & Zivot (2011), Elliott et al. (2015) and McCloskey (2017).

Proposition C2 in Appendix C.2.2 shows that the requirement for Theorem 9 will hold when using the S-statistic and the (semi)-strongly identified parameters are estimated. This result could be similarly extended to the K and CQLR statistics. An important concern is that projection inference may yield conservative inferences. This is discussed below.

Remark 2. (Complete Identification Failure of the Nuisance Parameters) Let $\theta = (\alpha, \beta)$, suppose that $\bar{g}_n(\alpha, \beta)$ and $\hat{V}_n(\alpha, \beta)$ do not depend on $\beta$ when $\alpha = \alpha_0$ and $E(\bar{g}_n(\alpha_0, \beta)) = 0$. If the model is just-identified $\dim(g) = d_\alpha + d_\beta$ and $\inf_{\alpha, \beta} \|\bar{g}_n(\alpha, \beta)\|_{\hat{V}_n^{-1}} = 0$ and Assumption 3 holds, then the projected S statistic of Stock & Wright (2000) satisfies:

$$S_n(\alpha_0) = \inf_{\beta} n \|\bar{g}_n(\alpha_0, \beta)\|_{\hat{V}_n^{-1}}^2 = n \|\bar{g}_n(\alpha_0, \beta_0)\|_{\hat{V}_n^{-1}}^2 \overset{d}{\to} \chi^2_{\dim(g)}.$$  (12)

This implies that projection inference has exact asymptotic coverage:

$$\lim_{n \to \infty} P(S_n(\alpha_0) \leq q_{\chi^2_{\dim(g)}}(1 - \alpha)) = 1 - \alpha,$$  (13)

whereas the test is asymptotically conservative when $\beta$ is strongly identified:

$$\lim_{n \to \infty} P(S_n(\alpha_0) \leq q_{\chi^2_{\dim(g)}}(1 - \alpha)) = P(\chi^2_{\dim(g)} - d_\beta \leq q_{\chi^2_{\dim(g)}}(1 - \alpha)) > 1 - \alpha.$$  (14)

Remark 2 does not appear to have been discussed in the literature although it may be already known. A simple proof is given in the Appendix. It shows that when the moments and their variance do not depend on the nuisance parameters, which will be referred to as complete identification failure, then projection inference provides exact asymptotic coverage. This is interesting because much of the literature mentions that projection inference can be conservative. However, when the model is very close to complete identification failure, the least-favorable critical value for the S-statistic is the one used for projection inference which has a simple closed-form expression.

4.1.2 A data-driven rule-of-thumb

The following provides a data-driven approach to find a cutoff $\lambda_n$ for Algorithm 1. The main idea is to consider (semi)-strongly identified models and local asymptotics where the
Jacobian is increasingly flat. As in linear OLS when $X'X/n$ is close to singular, because of near multicollinearity, or in IV when $Z'X/n$ is close to singular, because of near irrelevant instruments, the randomness in the sample Jacobian affects the distribution of $\hat{\theta}_n$. Higher-order Nagar expansions allow to approximate the resulting size-distortion and to find a cutoff on the signal to noise ratio where size distortion is greater than some pre-determined threshold. This is similar to e.g. Stock & Yogo (2005). This approach is convenient but not uniform, although one would expect it to perform reasonably well in settings where these local asymptotics approximate the identification failure well enough. A non-local approach is also considered in Appendix C.1.2.

The following relates the eigenvalues of $B_{n,LS}/\infty$ with the size distortion of a test on scalar hypotheses of the form $H_0 : v\theta = c$, for some $v \in \mathbb{R}^{d_v}/\{0\}$ and $c \in \mathbb{R}$, in the just-identified case. The over-identified case is discussed in the Appendix. Consider the asymptotic experiment:

\[ \bar{g}_n(\theta) = A_{n,LS} + B_{n,LS}\theta, \]

where $A_{n,LS} + B_{n,LS}\theta_0 = Z_1$, $B_{n,LS} - \bar{B}_{n,LS} = Z_2$, $(Z_1', \text{vec}(Z_2)')'$ is Gaussian and $\bar{B}_{n,LS}$ is non-stochastic and invertible. $\mathbb{E}(Z_1Z_1') = V_1/n$, $\mathbb{E}(Z_1Z_2) = V_{12}/n$. Furthermore, assume that $n \times \lambda_{\min}(\bar{B}_{n,LS}\bar{B}_{n,LS}) \to +\infty$, so that the model is linear and semi-strongly identified. Using the Woodbury identity, it can be shown that:

\[ \hat{\theta}_{n,LS} - \theta_0 = -\bar{B}_{n,LS}^{-1}Z_1 + \bar{B}_{n,LS}^{-2}Z_2Z_1 - \bar{B}_{n,LS}^{-3}(I + Z_2\bar{B}_{n,LS}^{-1})^{-1}Z_2^2Z_1. \]

As a result, the following expansions hold for $v_{j,n} \in \mathbb{C}^{d_v}$ the complex eigenvector of $\bar{B}_{n,LS}$ associated the complex eigenvalue $\lambda_{j,n} \in \mathbb{C}$:

\[
\mathbb{E}(v_{j,n}'[\hat{\theta}_{n,LS} - \theta_0]) = v_{j,n}'\bar{B}_{n,LS}^{-2}V_{21}/n + O\left(\frac{1}{n^2 \times |\lambda_{j,n}|^2}\right),
\]
\[
\mathbb{E}(|v_{j,n}'[\hat{\theta}_{n,LS} - \theta_0]|^2) = v_{j,n}'\bar{B}_{n,LS}^{-1}V_{1}\bar{B}_{n,LS}^{-1}'v_{j,n}/n + O\left(\frac{1}{n^2 \times |\lambda_{j,n}|^2}\right),
\]

where $\bar{v}_{j,n}$ is the complex conjugate of $v_{j,n}$. The first term approximates the higher-order bias and the second the asymptotic variance. The squared bias to variance ratio of $v_{j,n}'(\hat{\theta}_{n,LS} - \theta_0)$ can be approximated by:

\[
\frac{|\text{bias}|^2}{|\text{variance}|} = \frac{1}{n \times |\lambda_{j,n}|^2} v_{j,n}'V_{21}V_{12}\bar{v}_{j,n} + o\left(\frac{1}{n \times |\lambda_{j,n}|^2}\right).
\]

Using Nagar semi-strong asymptotics, as in Stock & Yogo (2005) 22 the size distortion $\gamma$ for a Wald test on $H_0 : v_{j,n}(\theta - \theta_0) = 0$ at the $1 - \alpha$ confidence level can be approximated by

\[ \gamma \approx \frac{1}{n \times |\lambda_{j,n}|^2} v_{j,n}'V_{21}V_{12}\bar{v}_{j,n} + o\left(\frac{1}{n \times |\lambda_{j,n}|^2}\right). \]

\[ ^{22}\text{Note that under weak identification the remainder may not be negligible.} \]
(see e.g. Rothenberg [1984]):

\[ \gamma \simeq 1 - \alpha - \mathbb{P}(w_n^* \leq c_{1-\alpha}), \]

where \( w_n^* \) follows a non-central \( \chi^2 \) distribution with non-centrality parameter

\[ \frac{1}{\sqrt{n} \times |\lambda_{j,n}|} \sqrt{\frac{\nu'_{j,n} V_{21} V_{12} \nu_{j,n}}{\nu'_{j,n} V_{11} \nu_{j,n}}}, \]

and \( c_{1-\alpha} \) is the \( 1 - \alpha \) quantile of a central \( \chi^2 \) distribution. Note that \( \gamma \) is increasing in the non-centrality parameter. Hence, imposing a maximum level of size distortion \( \gamma \leq \bar{\gamma}_n \) can be achieved with the restriction:

\[ |\lambda_{\min}(\tilde{B}_{n,LS})|^2 \geq \frac{1}{n \times c(\bar{\gamma}_n)^2} \max_{\|v\|=1} \frac{v' V_{21} V_{12} v}{v' V_1 v}, \]

where \( c(\bar{\gamma}_n) \) solves the equation \( \bar{\gamma}_n = 1 - \alpha - \mathbb{P}(\bar{w}_n^* \leq c_{1-\alpha}) \), \( \bar{w}_n^* \) follows a non-central \( \chi^2 \) distribution with non-centrality parameter \( c(\bar{\gamma}_n) \). A closed-form, potentially conservative but user-friendly, upper-bound for the maximum on the non-centrality parameter can be derived from a ratio of the largest eigenvalue of \( V_{21} V_{12} \) to the smallest eigenvalue of \( V_1 \). A data-driven cutoff for \( \lambda_{\min}(B_{n,LS/\infty}) \) is then given by:

\[ \Delta_n^2 = \frac{1}{n \times c(\bar{\gamma}_n)^2} \frac{\lambda_{\max}(V_{21} V_{12})}{\lambda_{\min}(V_1)}. \tag{15} \]

In practice, the quantities \( V_1 \) and \( V_{21} \) need to be approximated to make the rule-of-thumb feasible. Lemma C2 suggests an approach to approximate these quantities: for now, suppose \( \theta_0 \) is known, then \( V_1 \) and \( V_{21} \) can be approximated by computing the variance-covariance matrix of

\[ \frac{1}{n} \sum_{i=1}^{n} \text{vec} \left( \int X(\theta) X(\theta)' \hat{\pi}_n(\theta) d\theta \right)^{-1} \int X(\theta) g_i(\theta)' \hat{\pi}_n(\theta) d\theta, \quad X(\theta) = (1, \theta)', \]

while assuming \( \Sigma_n, \tilde{\theta}_n \) and \( \hat{\pi}_n \) are non-stochastic. Since \( Z_1, Z_2 \) are linear transformations of this sample mean the \( \tilde{V}_1 \) and \( \tilde{V}_{21} \) can be derived from the sample variance-covariance matrix for independent observations \( i \) or the HAC estimator for time-series data. Since \( \theta_0 \) is unknown in practice, it is possible to take the least-favorable \( \theta \) with \( \|\tilde{g}_n(\theta)\| w_n \leq \kappa_n \). Under (semi)-strong asymptotics \( \tilde{\theta}_n \) is a consistent estimator of \( \theta_0 \) so that substituting \( \theta_0 \) for \( \tilde{\theta}_n \) should yield a valid rule-of-thumb in that case.

\[ ^{23} \text{This is shown in the proofs of Theorems 5 and 6.} \]
4.2 Higher-order identification

The second set of results deals with higher-order identified models. It is assumed throughout that weak and set identifications are not a concern here. The rule-of-thumb, which will be presented in Subsection 4.2.2, is more involved than the one for weak identification because one has to check whether the residual curvature in the moments is negligible. The results rely on projection inference as in the weak/set identification case.

4.2.1 Algorithm and two-step inference

The main intuition for this section is that the remainder in the first-order expansion is non-negligible under higher-order identification and has the same order of magnitude as the variance. This implies that:

$$\sqrt{n} \times \| R_n(\theta) \| \asymp (\sqrt{n} \times \kappa_n)$$

for some of the $\theta \in \Theta$ such that $\| g_n(\theta) \|_W \leq \kappa_n$, which diverges to $+\infty$ in the directions of the first-order identification failure if $\sqrt{n}\kappa_n \to +\infty$, where $R_n(\theta) = g_n(\theta - g_n(\theta^0) - \partial_\theta g_n(\theta^0)(\theta - \theta^0)$ is the remainder in the first-order Taylor expansion. Whereas when the model is first-order identified:

$$\sqrt{n} \times \| R_n(\theta) \| \asymp (\sqrt{n} \times \kappa_n^2)$$

for all $\theta \in \Theta$ such that $\| g_n(\theta) \|_W \leq \kappa_n$, the remainder in the first-order expansion is negligible if $\sqrt{n}\kappa_n^2 \to 0$. This difference between the two regimes suggests that scaling an estimate of $R_n(\cdot)$ by $\sqrt{n}$ should allow to gauge the importance of the remainder is indeed small. Nagar asymptotics allow to approximate the size distortion attributable to the higher-order terms.

Using this idea, Algorithm 2 below relies on a criterion described in more detail in subsection 4.2.2. It computes the amount of size distortion, under (semi)-strong Nagar asymptotics, implied by the residual curvature in the moments $g_n(\cdot)$. This value separates (semi)-strongly from higher-order identified models under mild conditions as shown in Appendix D.2. The degree of size distortion is then compared with $\bar{\gamma}_n$, a user-chosen sequence of tolerance for size distortion. The user can choose either $\bar{\gamma}_n \downarrow 0$ or $\bar{\gamma}_n = \gamma > 0$ small but fixed. Note that in the Monte-Carlo simulations, the rule-of-thumb was computed for $W =$ identity matrix and performed well. Also, the criterion $\bar{h}^2$ in Algorithm 2 can be quickly bounded above by a more user-friendly quantity provided in equation (16) at the end of subsection 4.2.2.
Algorithm 2 Fixing the Span of the Higher-Order Identification Failure

compute $B_n$ and $\hat{R}_n(\cdot)$ which approximate $\partial_\theta g_n(\theta_0)$ and the remainder $R_n$, respectively approximate $V_1$ the asymptotic variance of $\sqrt{n} \times \bar{g}_n(\theta_0)$

set $\ell = 0$

if $B_n$ is singular then
    set $\bar{h} = +\infty$
else
    compute
    \[
    \bar{h}^2 = \max_{v \in \mathbb{R}^{d\theta}, ||v||=1} \left( \max_{\theta \in \Theta, \|\bar{g}_n(\theta)\|_W \leq \kappa^2_n} n \times \frac{\hat{R}_n(\theta)' B'_W v v' B_W \hat{R}_n(\theta)}{v' B_W V_1 B'_W v} \right)
    \]
    where
    \[
    B_W = - \left[ B'_n W_n(\bar{\theta}_n) B_n \right]^{-1} B'_n W_n(\bar{\theta}_n)
    \]
    compute
    \[
    \gamma_1 = |1 - \alpha - \mathbb{P}(w^*_n \leq c_{1-\alpha})|
    \]
    where $w^*_n$ follows a non-central $\chi^2_1$ distribution with non-centrality parameter $\bar{h}$ and $c_{1-\alpha}$ is the $1 - \alpha$ quantile of a central $\chi^2_1$ distribution
end if

while $\gamma_\ell < \bar{\gamma}_n$ and $\ell < L$ do
    set $\ell = \ell + 1$
    if $B_{n,\ell} = (B'_{n,\ell}, R'_{\ell})'$ is singular then
        set $\bar{h} = +\infty$
    else
        compute
        \[
        \bar{h}^2 = \max_{v \in \mathbb{R}^{d\theta}, ||v||=1} \left( \max_{\theta \in \Theta, \|\bar{g}_n(\theta)\|_W \leq \kappa^2_n} n \times \frac{\hat{R}_n(\theta)' B'_{W,\ell} v v' B_W \hat{R}_n(\theta)}{v' B_{W,\ell} V_1 B'_{W,\ell} v} \right)
        \]
        where
        \[
        B_{W,\ell} = - \left[ B'_{n,\ell} W_n(\bar{\theta}_n) B_{n,\ell} \right]^{-1} B'_{n,\ell} W_n(\bar{\theta}_n)
        \]
        compute
        \[
        \gamma_\ell = |1 - \alpha - \mathbb{P}(w^*_n \leq c_{1-\alpha})|
        \]
    end if
end while

set $\hat{\ell}_n = \ell$

if $\hat{\ell}_n > 1$ or $\gamma_1 \geq \bar{\gamma}_n$ then
    treat $R_{\hat{\ell}_n} \theta$ as higher-order identified and the remaining $d_\theta - \text{rank}(R_{\hat{\ell}_n})$ parameters as first-order identified
else
    treat the full vector $\theta$ as first-order identified
end if
Theorem 10. (Two-Step Higher-Order Identification Robust Subvector Inference) For each \( \ell = 1, \ldots, \mathcal{L} \), suppose that \( c_{\ell,0} \) is such that \( R_\ell \theta_0 = c_\ell \) with \( \mathbb{E}(\tilde{g}_n(\theta_0)) = 0 \), for all \( \ell \in \{1, \ldots, \mathcal{L}\} \). Let
\[
\hat{\theta}_{n,\ell,c} = \text{argmin}_{R_\ell \theta = c_\ell,0} \| \tilde{g}_n(\theta) \| W_n,
\]
be the constrained estimator of \( \theta_0 \) with \( R_\ell \) as in Definition 8. Let \( S_{n,\ell} \) be a test statistic for \( H_0 : R_\ell \theta_0 - c_{\ell,0} = 0 \) computed at \( \hat{\theta}_{n,\ell,c} \) and \( c_{1-\alpha,\ell} \) the corresponding critical value.

Suppose one of the following holds:

1. (semi-strong identification) the model satisfies the assumptions of Lemma D8
\[
\sqrt{n} \alpha_n^2 / \lambda_{\min}(\partial g_n(\theta_0)' \partial g_n(\theta_0)) = o(\bar{\gamma}_n),
\]
where \( \bar{\gamma}_n \) is the level of tolerance in Algorithm 2, and:
\[
P(S_{n,1} \leq c_{1-\alpha,1}) = 1 - \alpha + o(1),
\]

2. (higher-order identification) the model satisfies the assumptions of Lemma D7. Let \( \ell^* \) be the smallest \( \ell \in \{1, \ldots, \mathcal{L}\} \) such that \( \text{rank}(P_{R_\ell^*} V_r) = \text{rank}(P_r) \), where \( V_r = \text{Span}(P_2, \ldots, P_r) \) is the span of the first-order identification failure, suppose that:
\[
\inf_{\ell \in \{\ell^*, \ldots, \mathcal{L}\}} P(S_{n,\ell} \leq c_{1-\alpha,\ell}) = 1 - \alpha + o(1).
\]

Let \( \hat{\ell}_n \) be the \( \ell \in \{1, \ldots, \mathcal{L}\} \) selected by Algorithm 2, then:

1. (semi-strong identification) with probability going to 1, \( \hat{\ell}_n = 1 \) so that \( R_{\hat{\ell}_n} = R_1 \) and:
\[
P(S_{n,\hat{\ell}_n} \leq c_{1-\alpha,\hat{\ell}_n}) = P(S_{n,1} \leq c_{1-\alpha,1}) = 1 - \alpha + o(1).
\]

2. (higher-order identification) with probability going to 1, \( \hat{\ell}_n \geq \ell^* \) and:
\[
P(S_{n,\hat{\ell}_n} \leq c_{1-\alpha,\hat{\ell}_n}) \geq \inf_{\ell = \ell^*, \ldots, \mathcal{L}} P(S_{n,\ell} \leq c_{1-\alpha,\ell}) = 1 - \alpha + o(1).
\]

Theorem 10 combines the previous lemmas to show that \( \hat{\ell}_n \geq \ell^* \) with probability going to 1 so that the span of the local identification failure is fixed. Combining projection inference with identification robust statistics \( S_{n,\ell} \) yields valid asymptotic coverage. Dovonon et al. (2019) study the properties of these tests under second-order identification.
4.2.2 A data-driven rule-of-thumb

The following provides a simple approach to approximate the size distortion due to the non-linearity in the objective function for tests on scalar hypotheses of the form $H_0 : v \theta_0 = c$, for some $v \in \mathbb{R}^{d_v}/\{0\}$ and $c \in \mathbb{R}$ in both just and over-identified models using semi-strong Nagar asymptotics. Consider the following asymptotic experiment:

$$\bar{g}_n(\theta) = A_n + B_n(\theta - \theta_0) + R_n(\theta - \theta_0)$$

where $\sqrt{n}A_n = Z_1 \sim \mathcal{N}(0, V_1)$, $B_n$ and $R_n$ are non-stochastic. Assume that $n \times \lambda_{\min}(B_n' B_n) \to +\infty$ and for any $v \in \mathbb{R}^{d_v}/\{0\}$, $v R_n(\theta - \theta_0) = o(\|v B_n(\theta - \theta_0)\|)$, $\|v R_n(\theta - \theta_0)\| \leq O(\|\theta - \theta_0\|^2)$. For a positive definite and non-stochastic weighting matrix $W$, the minimizer $\hat{\theta}_n$ of $\|\bar{g}_n\|_W$ solves:

$$\hat{\theta}_n - \theta_0 = -[B'_n W B_n]^{-1} B'_n W [A_n + R_n(\hat{\theta}_n - \theta_0)]$$

$$= B_W A_n + B_W R_n(B_W A_n) + o_p(r_n)$$

where $B_W = -[B'W B]^{-1} B'W$ and $r_n$ satisfies $B_W R_n(B_W A_n) = O_p(r_n)$. Let $\check{R}_n = \mathbb{E}[R_n(B_W A_n)]$. For $v \in \mathbb{R}^{d_v}/\{0\}$, the Wald statistic $w_n$ for testing $v' \theta_0 - c = 0$ is

$$w_n = n \times \left( v' [\hat{\theta}_n - \theta_0] \right)' (B_W V_1 B'_W)^{-1} \left( v' [\hat{\theta}_n - \theta_0] \right).$$

Using Nagar asymptotics for $w_n$ (again, see e.g. Rothenberg 1984) yields:

$$\mathbb{P}(w_n \leq c_{1-\alpha}) = \mathbb{P}(w^*_n \leq c_{1-\alpha}) + o(r_n)$$

where $w^*_n$ follows a non-central $\chi^2_1$ distribution with non-centrality parameter:

$$\left[ n \times \check{R}_n B'_W v (v' B_W V_1 B'_W v)^{-1} v' B_W \check{R}_n \right]^{1/2}.$$ 

A feasible upper-bound for the non-centrality parameter can be computed as:

$$\sup_{\|v\|=1, \theta \in \Theta, \|\bar{g}_n(\theta)\|_{w_n} \leq \kappa_n} \left[ n \times \check{R}_n(\theta)' B'_W v (v' B_W V_1 B'_W v)^{-1} v' B_W \check{R}_n(\theta) \right]^{1/2}$$

where $\check{R}_n$ approximates the remainder term $R_n$. Plug-in estimates include $\check{R}_n(\theta) = \check{g}_n(\theta) - A_{n,LS/\infty} - B_{n,LS/\infty} \theta$ and $\check{R}_n(\theta) = \check{g}_n(\theta) - \bar{g}_n(\theta) - \partial \bar{g}_n(\theta)$. Since $\hat{\theta}_n$ is consistent under (semi)-strong and higher-order identification, $V_1$ can be consistently estimated using the sample variance-covariance matrix of $\bar{g}_n$ evaluated at $\check{\theta}_n$. For time-series data, a HAC estimator should be used. In Algorithm 2, $B_{W,\ell}$ is used instead of $B_W$ when constraints are
enforced to ensure that the non-centrality parameter does not involve a singular matrix in the denominator. This allows to remove $B_{W, \ell}$ from the optimization and directly compute:

$$\sup_{\theta \in \Theta, \|g_n(\theta)\|_{W_n} + \|R_\ell \theta - c_\ell\|_2 \leq \kappa_n^2} \frac{\|\hat{R}_n(\theta)\|_\infty^2}{\lambda_{\min}(V_1)}.$$  \hspace{1cm} (16)

This is a more user-friendly (although potentially more conservative) upper bound for the non-centrality parameter. This quantity was used in the Monte-Carlo simulations in Appendix G.3. The other quantity used in the simulations relies on $\|B_W \hat{R}_n(\theta)\|_\infty^2$ and $\lambda_{\min}(B_W V_1 B_W')$. Both performed well in the simulations for the example considered.

5 Monte-Carlo Simulations

This section provides Monte-Carlo evidence for the theoretical results in Sections 3 and 4. Example 1 and 2 (in Appendix G.2) are used to illustrate the finite sample properties of $\lambda_{\min}(B_{n,LS})$ and the two-step inference procedure. Only the least-squares approximation is considered in the below, some numerical experiments suggest that the difference between $B_{n,LS}$ and $B_{n,\infty}$ is negligible. To illustrate the properties of the methods under higher-order identification another simple non-linear least-squares example is presented in Appendix G.3 where one of the coefficients is either first or second-order identified depending on a nuisance parameter. Note that even though the models considered in the simulations are very stylized, they are representative of specific issues that could arise in structural estimation: important non-linearities in the parameters that could lead to global and/or local identification failures (NLS examples) and variations in the data that are not sufficiently large in finite samples to pin down the coefficients (MA example). Monte-Carlo simulations were conducted in R and C++ though Rcpp. Some results were also replicated in Julia.

5.1 Example 1. Non-Linear Least Squares

The first example uses the non-linear data generating process:

$$y_i = \theta_{1,n} x_{i,1} + \theta_{1,n} \theta_{2} x_{i,2} + e_i,$$

with $x_{i,1}, x_{i,2}, e_i \overset{iid}{\sim} \mathcal{N}(0, 1)$. When $\theta_{1,n} = 0$, $\theta_2$ is not identified which leads to the so-called Davies problem when testing for $\theta_{1} = 0$ (Davies, 1977, 1987). When $\theta_{1,n} \asymp n^{-1/2}$, the model
Figure 1: Distribution of $\lambda_{\text{min}}(B_{n,LS})$ and sample size $n$

Note: Model $y_i = \theta_{1,n} x_{i,1} + \theta_{1,n} \theta_2 x_{i,2} + e_i$, $\theta_{1,n} = 2 \times n^{-1/2}$, $100 \leq n \leq 5,000$, $B = 500$ Monte-Carlo replications and $\kappa_n = \sqrt{2 \log(\log(n))} n^{-1/2}$.

Legend: Black lines - boxplot of the distribution of $\lambda_{\text{min}}(B_{n,LS})$ for each $n$; Blue crosses - fitted rate from regressing the Monte-Carlo $\lambda_{\text{min}}(B_{n,LS})$ draws on $\kappa_n$ with OLS without an intercept.

is weakly identified as discussed in Section 2. The estimating moments are given by:

$$\bar{g}_n(\theta) = \frac{1}{n} \sum_{i=1}^{n} (y_i - \theta_{1,n} x_{i,1} - \theta_1 \theta_2 x_{i,2}) \begin{pmatrix} x_{i,1} \\ x_{i,2} \end{pmatrix}.$$ 

The grid used to compute the integral in the least-squares approximation consists of 10,000 Sobol points. Figure 1 shows the distribution of $\lambda_{\text{min}}(B_{n,LS})$ for sample sizes $100 \leq n \leq 5,000$. The distribution is compared to the rate derived in Section 3. Overall, the finite sample results are in line with the theory. The top panel in Figure 2 shows the coverage (y-axis) for several test procedures on $H_0 : \theta_1 = \theta_{1,0}$ where $\theta_{1,0} = c \times n^{-1/2}$ (x-axis). This illustrates Remark 2. Indeed, the projected Anderson-Rubin test statistic for $\beta_{1,0} = 0$ is:

$$AR_n(0) = \inf_{\theta_2} n \times \bar{g}_n(0, \theta_2)' \hat{V}_n(0, \theta_2)^{-1} \bar{g}_n(0, \theta_2) = n \times \bar{g}_n(0, 0)' \hat{V}_n(0, 0)^{-1} \bar{g}_n(0, 0),$$

because neither the moments nor their variances depend on $\theta_2$ when $\theta_1 = 0$. Hence, projection inference has exact coverage when $c = 0$, as illustrated in the figure. The bottom panel in Figure 2 shows similar results when using a Wald statistic instead of a QLR statistic. The test

\[24\] The R package randtoolbox was used to create the grid.
Note: Model $y_i = \theta_{1,n}x_{i,1} + \theta_{1,n}\theta_2 x_{i,2} + e_i$, $\theta_{1,n} = c \times n^{-1/2}$, $n = 1,000$, $B = 5,000$ Monte-Carlo replications and $\kappa_n = \sqrt{2\log(\log(n))}n^{-1/2}$.

Legend: Anderson-Rubin (solid/dot) - projection-based confidence interval; Standard (dashed/cross) - QLR (top panel) and Wald (bottom panel)-based confidence interval; Rule-of-thumb (dotted/triangle) - two-step procedure with $\lambda_n = $ data-driven rule-of-thumb; $\sqrt{\log(n)}$ (dashed/square) - two-step procedure with $\lambda_n = \sqrt{\log(n)}$. 

40
also switches to Wald inferences when no identification failure is detected. Size distortion is much larger in this case for the standard test while the two-step procedures seem to perform reasonably well. Power comparisons are also reported in Appendix G.1.

6 Empirical Application: US Euler Equation

The main application considers the US Euler equation:

\[
\tilde{g}_n(\theta) = \frac{1}{n} \sum_{t=1}^{n} \left( \delta \left( \frac{C_t}{C_{t-1}} \right)^{-\gamma} R_t - 1 \right) Z_t,
\]

where \( C_t \) is US consumption data, \( R_t \) the risk-free rate and \( Z_t = (1, C_{t-1}/C_{t-2}, R_{t-1}) \). \( \delta \) is the coefficient of time-preference and \( \gamma \) the coefficient of relative risk-aversion. The data is taken from Stock & Wright (2000). After taking lags, the sample size is \( n = 103 \). The weighting matrix \( W_n = \hat{V}_n^{-1} \) is computed by continuous updating with the HAC estimator of the R sandwich package. The bounds used for the \( \theta = (\delta, \gamma) \) grid\(^{25}\) are \([0.7, 1.2] \times [0, 20]\) to match earlier applications.\(^{26}\) Before going into the results, Figure 3 shows the region selected by the compact kernel. From the figure, it is clear that at least one of the coefficients is not well identified. The estimated quasi-Jacobian matrix is, rounded to the third decimal:

\[
B_{n,LS}' = \begin{pmatrix}
0.664 & 0.680 & 0.675 \\
-0.002 & -0.002 & -0.001
\end{pmatrix}.
\]

The first column corresponds to coefficients relating to \( \delta \) and the second to coefficients for \( \gamma \). Going further, the singular value decomposition of the quasi-Jacobian matrix is:

\[
U_n = \begin{pmatrix}
-1.0 & 0.003 \\
0.003 & 1.0
\end{pmatrix},
D_n = \text{diag}(1.166, 0.001),
V_n' = \begin{pmatrix}
-0.570 & -0.583 & -0.579 \\
-0.342 & -0.472 & 0.813
\end{pmatrix},
\]

where \( B_{n,LS} = U_n D_n V_n' \). Note that \( \sqrt{n} \times \text{diag}(D_n) = (11.834, 0.006) \). The second eigenvalue is very small relative to the sample size. The first eigenvalue is not so small so that we can expect one of the coefficients to be identified. The singular value decomposition can be interpreted as in factor analysis: \( U_n \) suggests that \( \delta \) is (semi)-strongly identified\(^{27}\) and

\(^{25}\)The grid is constructed using 20,000 points from the Sobol sequence.

\(^{26}\)The results were replicated with \( \delta \in [0.7, 1.0] \) in Appendix H.1.

\(^{27}\)Higher-order identification is excluded here because the model is linear when \( \gamma \) is fixed.
Figure 3: US Euler Equation - \( \hat{\Theta}_n = \{ \theta \in \Theta, \| \tilde{g}_n(\theta) \|_{W_n} - \inf_{\theta \in \Theta} \| \tilde{g}_n(\theta) \|_{W_n} \leq \kappa_n \} \)

Note: region \( \hat{\Theta}_n \) computed for \( \kappa_n = \max(\sqrt{q_{0.99}(\chi^2_3)}, \sqrt{2 \log(\log[n])} n^{-1/2}) \) where \( q_{0.99} \) is the 99\% quantile of a \( \chi^2_3 \) distribution. \( W_n = \hat{V}_n^{-1} \).

\( \gamma \) is weakly or set identified. The matrix \( V_n \) indicates that all moments contribute to the identification of \( \delta \).

As reported in previous replications, the confidence sets are very sensitive to tuning parameters used in the computation of the HAC variance-covariance estimator \( \hat{V}_n \). The estimated matrix \( \hat{V}_n \) is actually found to be severely ill-conditioned.\(^{28}\) As shown in Figure H12 in Appendix H.1, the moments are extremely redundant over most of the range of \((\delta, \gamma) \in [0, 1.2] \times [0, 20] \). This near-singularity\(^{29}\) implies that singularity and identification robust tests should be implemented (Andrews & Guggenberger, 2019). Since the matrix \( \hat{V}_n \) is near rank one over most of the parameter space \( \Theta \), singularity robust inference amounts to dropping two instrument and using the remaining one for inference. The intercept, \( Z_t = 1 \), is kept and an AR statistic is inverted with \( \chi^2_1 \) critical values. This yields the following two robust 95\% confidence intervals:

\[
CI_{95\%}(\delta) = [0.87, 1.1] \quad CI_{95\%}(\gamma) = [0, 20].
\]

\(^{28}\)The ratio of the largest eigenvalue to the smallest eigenvalue is typically between 10,000 and 15,000 over the grid of \( \theta \) considered. The second eigenvalue is also very small.

\(^{29}\)Here near-singularity refers to the variance-covariance matrix of the moments \( \tilde{g}_n \) as in Andrews & Guggenberger (2019) rather than the Jacobian.
7 Conclusion

This paper proposes an approach to detect potential identification failure and conduct two-step robust subvector inference. It generalizes the use of the first stage F-statistic and rank tests in linear IV models to non-linear moment condition models. The computation is massively parallel which can be attractive in problems where \( \bar{g}_n \) is costly to compute. The recommended inference procedure is similar to the type I approach of \cite{Andrews&Ceng2012} but without assuming knowledge of the identification structure. A rule-of-thumb is given to choose the cutoff for the pre-test in the first stage. Monte-Carlo simulations show that the methodology provides satisfying results. Two empirical applications illustrate the approach in practice. An important direction for future research would be to extend the results to uniform inferences and other M-estimators.

Appendix A  Proofs for the Results of Section 3

A.1 Proofs for the sup-norm approximation

Proof of Theorem 1. Take $\varepsilon > 0$ from Definition 3, we have $\|g_n(\theta)\|_W \geq \eta(\varepsilon)$ for $\|\theta - \theta_0\| > \varepsilon$ and $\|g_n(\theta)\|_W \geq C_\|\theta - \theta_0\|$ for $\|\theta - \theta_0\| \leq \varepsilon$. Also, by the triangular and reverse triangular inequalities:

\[
\|g_n(\theta)\|_W - \lambda \times \|G_n(\theta)/\sqrt{n}\| \leq \|\bar{g}_n(\theta)\|_W \leq \|g_n(\theta)\|_W + \lambda \times \|G_n(\theta)/\sqrt{n}\|.
\]

Furthermore, uniformly in $\theta \in \Theta$: $\|\bar{g}_n(\theta)\|_{W_n} = \|\bar{g}_n(\theta)\|_{W + W_n - W} = \|\bar{g}_n(\theta)\|_{W \times [1 + o_p(1)]} = \|\bar{g}_n(\theta)\|_{W \times [1 + o_p(1)]}$ using the uniform convergence of $W_n$ in Assumption 2. As a result, for $\|\theta - \theta_0\| > \varepsilon$:

\[
\left[\frac{\eta(\varepsilon) / \kappa_n - \lambda \times \sup_{\theta \in \Theta} \|G_n(\theta)\|}{\sqrt{n} \kappa_n}\right] / [1 + o_p(1)] \leq \inf_{\theta, \|\theta - \theta_0\| \geq \varepsilon} \|\bar{g}_n(\theta)\|_{W_n} / \kappa_n.
\]

Assumptions 1 and 2 imply the term on the left-hand side goes to $+\infty$ as $n \to \infty$ so that:

\[
P\left(\sup_{\theta, \|\theta - \theta_0\| \geq \varepsilon} K(\|\bar{g}_n(\theta)\|_{W_n} / \kappa_n) = 0\right) \to 1.
\]

This allows us to focus on $\theta$ such that $\|\theta - \theta_0\| \leq \varepsilon$, for which:

\[
C_\|\theta - \theta_0\| - \lambda \times \|G_n(\theta)/\sqrt{n}\| \leq \|g_n(\theta)\|_W - \lambda \times \|G_n(\theta)/\sqrt{n}\| \leq \|\bar{g}_n(\theta)\|_W.
\]

Using similar arguments as above:

\[
P\left(\sup_{\theta, \|\theta - \theta_0\| \geq 2\kappa_n / C} K(\|\bar{g}_n(\theta)\|_{W_n} / \kappa_n) = 0\right) \to 1.
\]

This allows us to further restrict the analysis to $\|\theta - \theta_0\| \leq 2\kappa_n / C$. Let $\theta = \theta_0 + h\kappa_n$, Assumption 2 implies that uniformly in $\theta = \theta_0 + h\kappa_n$ with $\|h\| \leq 2 / C$:

\[
\|A + B\theta - \bar{g}_n(\theta)\| \times K(\|\bar{g}_n(\theta)\|_{W_n} / \kappa_n)
\]

\[
= \|A - B\theta_0 + Bh\kappa_n - \bar{g}_n(\theta_0) - \partial_\theta g_n(\theta_0)h\kappa_n + o_p(n^{-1/2}) + O(\kappa_n^2)\| \times K(\|\partial_\theta g_n(\theta_0)h\|_{W} + o_p(1))
\]

Assumption 1 implies that $\kappa_n^2 = o(n^{-1/2})$. By minimization, we have: $A_{n,\infty} + B_{n,\infty}\theta_0 - \bar{g}_n(\theta_0) = o_p(n^{-1/2})$ and $B_{n,\infty} - \partial_\theta g(\theta_0) = o_p(n^{-1/2})\kappa_n^{-1}$. Indeed, this sequence implies that the objective is $o_p(n^{-1/2})$ whereas for other sequences the objective would be greater than a $o_p(n^{-1/2})$ contradicting the minimization. This concludes the proof. \[\square\]
Proof of Theorem \[ \theta \] As in the proof of Theorem \[ \theta \] by compactness of \( K \), we have:

\[
\sup_{\theta \in \Theta; \|\theta - \theta_0\| \geq \varepsilon} K(\|\hat{g}_n(\theta)\|_{W_n}) = 0
\]

with probability going to 1. This allows us to focus on \( \theta \) such that \( \|\theta - \theta_0\| \leq \varepsilon \). We can re-parameterize \( \theta \) as \( \theta = \theta_0 + (\partial_{\theta}g_n(\theta_0)'\partial_{\theta}g_n(\theta_0))^{-1/2} h \kappa_n \) for \( h \in \mathbb{R}^{d_\theta} \). Using Definition 4 ii:

\[
C\|\partial_{\theta}g_n(\theta_0) (\partial_{\theta}g_n(\theta_0)'\partial_{\theta}g_n(\theta_0))^{-1/2} h\| \geq \|g_n(\theta)\|_{W} / \kappa_n \geq C\|\partial_{\theta}g_n(\theta_0) (\partial_{\theta}g_n(\theta_0)'\partial_{\theta}g_n(\theta_0))^{-1/2} h\|
\]

By definition of the Frobenius norm, the norm on the left and right-hand-side is equal to:

\[
\text{trace} \left( (\partial_{\theta}g_n(\theta_0) (\partial_{\theta}g_n(\theta_0)'\partial_{\theta}g_n(\theta_0))^{-1/2} hh' (\partial_{\theta}g_n(\theta_0)'\partial_{\theta}g_n(\theta_0))^{-1/2} \partial_{\theta}g_n(\theta_0)) \right)^{1/2} = \text{trace}(hh')^{1/2} = \|h\|.
\]

Then, uniformly in \( h \) such that

\[
\| (\partial_{\theta}g_n(\theta_0)'\partial_{\theta}g_n(\theta_0))^{-1/2} h \kappa_n \| \leq \varepsilon,
\]

we have:

\[
\|\hat{g}_n(\theta)\|_{W} / \kappa_n \geq C\|h\| - \frac{\sup_{\theta \in \Theta} \|G_n(\theta)\|}{\sqrt{n} \kappa_n} = C\|h\| - o_p(1).
\]

This implies that for \( \|h\| \geq 3/C \), we have:

\[
\|\hat{g}_n(\theta)\|_{W_n} / \kappa_n \geq \|\hat{g}_n(\theta)\|_{W} / \kappa_n + o_p(1) \geq 3 - o_p(1) \geq 2,
\]

with probability going to 1; as a result:

\[
\sup_{\|h\| \geq 3/C} K\left(\|\hat{g}_n\left(\theta_0 + (\partial_{\theta}g_n(\theta_0)'\partial_{\theta}g_n(\theta_0))^{-1/2} h \kappa_n\right)\|_{W_n} / \kappa_n\right) = 0,
\]

also with probability going to 1. Similarly, for \( \|h\| \leq 1/[2C] \), we have:

\[
\|\hat{g}_n\left(\theta_0 + (\partial_{\theta}g_n(\theta_0)'\partial_{\theta}g_n(\theta_0))^{-1/2} h \kappa_n\right)\|_{W_n} / \kappa_n \\
\leq \left(\|g_n\left(\theta_0 + (\partial_{\theta}g_n(\theta_0)'\partial_{\theta}g_n(\theta_0))^{-1/2} h \kappa_n\right)\|_{W} \times [1 + o_p(1)] + \frac{\sup_{\theta \in \Theta} \|G_n(\theta)\|}{\sqrt{n} \kappa_n}\right) / \kappa_n \\
\leq C \times \|h\| \times [1 + o_p(1)] + o_p(1) \leq 1/2 + o_p(1) \leq 3/4,
\]

with probability going to 1. This implies that:

\[
\inf_{\|h\| \leq 1/[2C]} K\left(\|\hat{g}_n\left(\theta_0 + (\partial_{\theta}g_n(\theta_0)'\partial_{\theta}g_n(\theta_0))^{-1/2} h \kappa_n\right)\|_{W_n} / \kappa_n\right) \geq \inf_{x \in [0,3/4]} K(x)
\]

51
which is strictly positive by assumption. For any pair \((A, B)\) we can write, with probability going to 1:
\[
\sup_{\theta \in \Theta} \| \tilde{g}_n(\theta) - A - B\theta \| \times \tilde{K}_n(\theta)
= \sup_{\|h\| \leq 3/|\Theta|} \| \tilde{g}_n(\theta) - A - B\theta - B (\partial_\theta g_n(\theta_0)')\partial_\theta g_n(\theta_0))^{-1/2} h\kappa_n \| \times \tilde{K}_n(\theta)
\geq \sup_{\|h\| \leq 1/2 |\Theta|} \| \tilde{g}_n(\theta) - A - B\theta - B (\partial_\theta g_n(\theta_0)')\partial_\theta g_n(\theta_0))^{-1/2} h\kappa_n \| \times \inf_{x \in (0, 1/4)} K(x)
\]
Note that for \(\|h\|\) bounded, we have \(\theta - \theta_0 = o(1)\) and:
\[
\tilde{g}_n(\theta) - \tilde{g}_n(\theta_0) - \partial_\theta g_n(\theta_0) (\partial_\theta g_n(\theta_0)')\partial_\theta g_n(\theta_0))^{-1/2} h\kappa_n
= o_p(n^{-1/2}) + O_p \left( \| \partial_\theta g_n(\theta_0) (\partial_\theta g_n(\theta_0)')\partial_\theta g_n(\theta_0))^{-1/2} h\kappa_n \|^2 \right).
\]
By construction, we also have:
\[
O_p \left( \| \partial_\theta g_n(\theta_0) (\partial_\theta g_n(\theta_0)')\partial_\theta g_n(\theta_0))^{-1/2} h\kappa_n \|^2 \right) = O_p (\kappa_n^2) = o_p(n^{-1/2}).
\]
Altogether, as in the proof of Theorem 1 if \(A, B\) are different from:
\[
A_{n, \infty} = \tilde{g}_n(\theta_0) - B_{n, \infty} \theta_0 + o_p(n^{-1/2})
B_{n, \infty} H_n = \partial_\theta \tilde{g}_n(\theta_0) H_n + o_p \left( n^{-1/2} \kappa_n^{-1} \right)
\]
by more than a \(o_p(n^{-1/2})\) and a \(o_p(n^{-1/2} \kappa_n^{-1})\) term respectively, then the sup over \(\theta \in \Theta\) is greater than a \(o_p(n^{-1/2})\) which is suboptimal compared to \(A_{n, \infty}, B_{n, \infty}\). This concludes the proof.

**Proof of Theorem 5** Pick \(v_j \in \text{Span}(P_j)\) with \(\|v_j\| = 1\). Consider \(h \in \mathbb{R}\) and \(\theta_{j, n} = \theta_0 + (\kappa_n^{-1} h)v_j\). Using Definition 5 we have:
\[
\| g_n(\theta_{j, n}) / \kappa_n \| W \geq C_j |h|.
\]
Using an argument similar to the proof of Theorem 4 this implies that for \(|h| \leq 1/[2 \max_j C_j]\), we have for \(0 < \varepsilon < \|K\|_\infty\):
\[
P (K(\| g_n(\theta_{j, n}) / \kappa_n \| W_n) \geq \varepsilon) \rightarrow 1
\]
\footnote{This is because \(\kappa_n^2\) goes to zero faster than \(\lambda_{\min} (\partial_\theta g_n(\theta_0)')\partial_\theta g_n(\theta_0)).\}
as \( n \to \infty \). As before, this statement holds uniformly over \( \theta_{j,n} = \theta_0 + (\kappa_n^{1/j} h) v_j \) with \(|h| \leq 1/[2 \max_j C_j]\). We also have, using similar arguments to the proof of Theorem 4:

\[
\|A_{n,\infty} + B_{n,\infty} \theta_0\| = O_p(\kappa_n)
\]

\[
\|A_{n,\infty} + B_{n,\infty} \theta_{j,n}\| = O_p(\kappa_n).
\]

Noting that \( \|\theta_{j,n} - \theta_0\| = |h| \kappa_n^{-1/j} \), the above equalities yield for \( 0 < |h| \leq 1/[2 \max_j C_j] \):

\[
\|B_{n,\infty}(\theta_{j,n} - \theta_0)\| = O_p(\kappa_n)
\]

\[
\Rightarrow \|B_{n,\infty} v_j\| = O_p(\kappa_n) \times \kappa_n^{-1/j}|h|.
\]

This implies \( \|B_{n,\infty} v_j\| = O_p(\kappa_n^{1-1/j}) \). In turn this implies, as in Theorem 4, that \( |\lambda_{\min}(B_{n,\infty})| = O_p(\kappa_n^{1-1/r}) \) which concludes the proof.

**Proof of Theorem 4.** First note that for any \( \theta \in \Theta \), the conditions on the weight matrix \( W \) in Definition 1 and the compactness of the kernel \( K \):

\[
\|\tilde{g}_n(\theta)\| \times \hat{K}_n(\theta) = \|\tilde{g}_n(\theta)\| \times K(\|\tilde{g}_n(\theta)\|_{W_n}/\kappa_n)
\]

\[
\leq \|\tilde{g}_n(\theta)\|_{W_n} \times K(\|\tilde{g}_n(\theta)\|_{W_n}/\kappa_n)/\lambda
\]

\[
\leq \kappa_n \|K\|_{\infty}/\lambda
\]

\[
= O(\kappa_n).
\]

By minimization of the sup-norm criterion:

\[
\sup_{\theta \in \Theta} \left( \|A_{n,\infty} + B_{n,\infty} \theta - \tilde{g}_n(\theta)\| \times \hat{K}_n(\theta) \right) \leq \sup_{\theta \in \Theta} \left( \|\tilde{g}_n(\theta)\| \times \hat{K}_n(\theta) \right) \leq O(\kappa_n).
\]

Pick any two \( \theta_0, \theta_1 \in \Theta_0 \). We have, by definition of \( \Theta_0 \) and Assumption 2 for \( j \in \{0, 1\} \):

\[
K(\|\tilde{g}_n(\theta_j)\|_{W_n}/\kappa_n) = K(\|g_n(\theta_j)/\kappa_n + G_n(\theta_j)n^{-1/2}/\kappa_n\|_{W_n}) = K(\lambda_0(1)) = K(0) + o_p(1).
\]

The last equality follows from the Lipschitz-continuity of \( K \). This implies that \( K(\|\tilde{g}_n(\theta_0)\|_{W_n}/\kappa_n) \) is strictly positive with probability going to 1. Note that Assumption 2 implies that this result is uniform in \( \theta \in \Theta_0 \). Since \( K > 0 \) and continuous on \((-1, 1)\), there exists \( K > 0 \) and \( \varepsilon > 0 \) such that \( |x| \leq \varepsilon \Rightarrow K(x) \geq K \) so that:

\[
P(\inf_{\theta \in \Theta_0} K(\|\tilde{g}_n(\theta)\|_{W_n}/\kappa_n) \geq K)
\]

\[
\geq P(\sup_{\theta \in \Theta_0} \|\tilde{g}_n(\theta)\|_{W_n}/\kappa_n \leq \varepsilon)
\]

\[
\geq P \left( \sup_{\theta \in \Theta_0} \sqrt{n} \|g_n(\theta)\| + \sup_{\theta \in \Theta} \|G_n(\theta)\| \leq \sqrt{n} \kappa_n \varepsilon / \lambda \right) \rightarrow 1,
\]
as \( n \to \infty \). This relies on the assumptions that \( \sup_{\theta \in \Theta_0} \sqrt{n}\|g_n(\theta_0)\|_W \) is finite and \( \sup_{\theta \in \Theta} \|G_n(\theta)\| = O_p(1) \) while \( \sqrt{n}\kappa_n \to +\infty \) by assumption and \( 0 < \lambda \leq \lambda_{\min}(W_n) \leq \lambda_{\max}(W_n) \leq \bar{\lambda} < +\infty \). Now, by the reverse triangular inequality, we have:

\[
\sup_{\theta \in \Theta} \|A_{n,\infty} + B_{n,\infty}\theta - \bar{g}_n(\theta)\| \times K(\|\bar{g}_n(\theta)\|_{W_n/\kappa_n}) \\
\geq (\|A_{n,\infty} + B_{n,\infty}\theta_0\| - \|\bar{g}_n(\theta_0)\|) \times [K(0) + o_p(1)].
\]

Since the term on the left-hand side is a \( O(\kappa_n) \) and \( \|\bar{g}_n(\theta_0)\| \geq \|\bar{g}_n(\theta_0)\|_{W_n/\bar{\lambda}} = O_p(\kappa_n) \), we have:

\[
0 \leq \|A_{n,\infty} + B_{n,\infty}\theta_0\| \leq \frac{O_p(\kappa_n)}{K(0) + o_p(1)} = O_p(\kappa_n).
\]

This implies that \( A_{n,\infty} = -B_{n,\infty}\theta_0 \) up to a \( O_p(\kappa_n) \) term. Now evaluating the expression at \( \theta = \theta_1 \):

\[
\|A_{n,\infty} + B_{n,\infty}\theta_1\| = \|O_p(\kappa_n) + B_{n,\infty}(\theta_1 - \theta_0)\| \\
\geq \|B_{n,\infty}(\theta_1 - \theta_0)\| - O_p(\kappa_n).
\]

Together with the inequalities above, this implies:

\[
0 \leq \|B_{n,\infty}(\theta_1 - \theta_0)\| \leq O_p(\kappa_n) + \frac{O_p(\kappa_n)}{K(0) + o_p(1)} = O_p(\kappa_n).
\]

By definition of \( \lambda_{\min}(B_{n,\infty}) \), we have:

\[
0 \leq |\lambda_{\min}(B_{n,\infty})|^2 \|\theta_1 - \theta_0\|^2 \leq \|(\theta_1 - \theta_0)'B_{n,\infty}'B_{n,\infty}(\theta_1 - \theta_0)\| \leq O_p(\kappa_n^2).
\]

This concludes the first part of the proof. Let \( V = \text{Span} \{\theta_0 - \theta_1, \theta_0, \theta_1 \in \Theta_0\} \). Take \((\theta_{1,j} - \theta_{0,j})_{j=1,...,r}\), a basis of this span with \((\theta_{1,j}, \theta_{0,j}) \in \Theta_0^2 \) for all \( j \), then for any \( v \in V \) there exists \((a_1, \ldots, a_r)\) such that \( v = \sum_{j=1}^r a_j(\theta_{1,j} - \theta_{0,j}) \). Since the derivations above were uniform in \((\theta_0, \theta_1) \in \Theta_0^2 \), we have:

\[
0 \leq \|B_{n,\infty}v\| \leq \sum_{j=1}^r |a_j| \times \|B_{n,\infty}(\theta_{1,j} - \theta_{0,j})\| = O_p(\kappa_n),
\]

which concludes the proof. \( \square \)

### A.2 Proofs for the least-squares approximation

**Proof of Theorem 5.** The proof is divided into several steps.

**Step 1. Proof of the results concerning \( A_{n,\text{LS}} \):**

54
Note that the least-squares formula implies:

\[ A_{n,LS} = \int \bar{g}_n(\theta) \hat{\pi}_n(\theta) d\theta - B_{n,LS} \int \theta \hat{\pi}_n(\theta) d\theta \]

\[ = \int [\bar{g}_n(\theta) - \bar{g}_n(\hat{\theta}_n)] \hat{\pi}_n(\theta) d\theta - B_{n,LS} \int [\theta - \hat{\theta}_n] \hat{\pi}_n(\theta) d\theta + \bar{g}_n(\hat{\theta}_n) - B_{n,LS} \hat{\theta}_n. \]

The first part of the proof amounts to showing that:

\[ \int [\bar{g}_n(\theta) - \bar{g}_n(\hat{\theta}_n)] \hat{\pi}_n(\theta) d\theta = o_p(n^{-1/2}) \]

\[ \int [\theta - \hat{\theta}_n] \hat{\pi}_n(\theta) d\theta = o_p(n^{-1/2}) \]

for both the compact and the exponential kernels.

**Step 1.a. Compact Kernel K:**

First, consider the kernel \( K \) with compact support. Let \( \hat{W}_n = W_n(\hat{\theta}_n) \). Together, Definition 3 and Assumption 2 ii. imply:

\[ \mathbb{P} \left( \inf_{\theta, \|\theta - \theta_0\| \geq 3\kappa_n / \sqrt{C}} K \left( \|\bar{g}_n(\theta)\|_{W_n / \kappa_n} - \|\bar{g}_n(\hat{\theta}_n)\|_{\hat{W}_n / \kappa_n} \right) > 0 \right) \]

\[ \leq \mathbb{P} \left( \inf_{\theta, \|\theta - \theta_0\| \geq 3\kappa_n / \sqrt{C}} \|\bar{g}_n(\theta)\|_{W_n / \kappa_n} - \|\bar{g}_n(\hat{\theta}_n)\|_{\hat{W}_n / \kappa_n} \leq 2 \right) \]

\[ \leq \mathbb{P} \left( \inf_{\theta, \|\theta - \theta_0\| \geq 3\kappa_n / \sqrt{C}} \|g_n(\theta)\|_{W \times [1 + o_p(1)] / \kappa_n} - \chi \times \sup_{\theta \in \Theta} \|G_n(\theta)\| / n\kappa_n - O_p(n^{-1/2}\kappa_n^{-1}) \leq 2 \right) \]

\[ = \mathbb{P} \left( \inf_{\theta, \|\theta - \theta_0\| \geq 3\kappa_n / \sqrt{C}} \|g_n(\theta)\|_{W / \kappa_n} - 2 \leq O_p(n^{-1/2}\kappa_n^{-1}) \right) \]

\[ \leq \mathbb{P} \left( 1 \leq O_p(n^{-1/2}\kappa_n^{-1}) \right) \to 0 \]

as \( n \to \infty \) since \( \sqrt{n\kappa_n} \to +\infty \) so that \( (n^{-1/2}\kappa_n^{-1}) = o(1) \). Hence with probability going to 1:

\[ \int [\bar{g}_n(\theta) - \bar{g}_n(\hat{\theta}_n)] \hat{\pi}_n(\theta) d\theta = \int \left[ \bar{g}_n(\theta) - \bar{g}_n(\hat{\theta}_n) \right] \hat{\pi}_n(\theta) d\theta. \]

Assumption 2 further implies that:

\[ \int [\bar{g}_n(\theta) - \bar{g}_n(\hat{\theta}_n)] \hat{\pi}_n(\theta) d\theta = \int_{\|\theta - \theta_0\| \leq 3\kappa_n / \sqrt{C}} [\bar{g}_n(\theta) - \bar{g}_n(\hat{\theta}_n)] \hat{\pi}_n(\theta) d\theta \]

\[ = \int_{\|\theta - \theta_0\| \leq 3\kappa_n / \sqrt{C}} [g_n(\theta) - g_n(\hat{\theta}_n)] \hat{\pi}_n(\theta) d\theta + o_p(n^{-1/2}) \]

\[ = \int_{\|\theta - \theta_0\| \leq 3\kappa_n / \sqrt{C}} \partial_\theta g_n(\hat{\theta}_n) \hat{\theta}_n \hat{\pi}_n(\theta) d\theta + o_p(n^{-1/2}) + O_p(\kappa_n^2) \]

\[ = \partial_\theta g_n(\hat{\theta}_n) \int_{\|\theta - \theta_0\| \leq 3\kappa_n / \sqrt{C}} \hat{\theta}_n \hat{\pi}_n(\theta) d\theta + o_p(n^{-1/2}) + O_p(\kappa_n^2). \]
The last equality implies that if \( \int_{\|\theta - \theta_0\| \leq 3\kappa_n/C} \left[ \theta - \hat{\theta}_n \right] \pi_n(\theta) d\theta = o_p(n^{-1/2}) \) then the first result holds. To prove this, note that:

\[
\{ \theta, \|\theta - \theta_0\| \leq 3\kappa_n/C \} = \{ \hat{\theta}_n + h\kappa_n, \|\hat{\theta}_n - \theta_0 + h\kappa_n\| \leq 3\kappa_n/C \}
\]

so that the integral becomes:

\[
\int_{\|\theta - \theta_0\| \leq 3\kappa_n/C} \left[ \theta - \hat{\theta}_n \right] \pi_n(\theta) d\theta = \int_{\|\hat{\theta}_n - \theta_0 + h\kappa_n\| \leq 3\kappa_n/C} \kappa_n h \hat{\pi}_n(\hat{\theta}_n + h\kappa_n) \kappa^g_n dh.
\]

Since \( \hat{\theta}_n - \theta_0 = O_p(n^{-1/2}) = o_p(\kappa_n) \) under the stated assumptions, with probability going to 1: \( \|\theta - \theta_0\| \leq 3\kappa_n/C \) implies \( \|h\| \leq 4/C \). Using this and Assumptions 1 and 2, the terms inside the kernel can be expanded into:

\[
\bar{g}_n(\hat{\theta}_n + \kappa_n h) / \kappa_n = \bar{g}_n(\hat{\theta}_n) / \kappa_n + \partial_0 g_n(\hat{\theta}_n) h + o_p(n^{-1/2}) + O_p(\|h\|^2 \kappa_n)
\]

\[
= \partial_0 g_n(\hat{\theta}_n) h + O_p(n^{-1/2} \kappa_n^{-1}) + o_p(n^{-1/2}) + O_p(\|h\|^2 \kappa_n^2)
\]

uniformly in \( h \). Using the assumptions on \( W_n \) and \( W, \|W_n(\hat{\theta}_n + h\kappa_n) - W_n(\hat{\theta}_n)\| = \|W(\hat{\theta}_n + h\kappa_n) - W(\hat{\theta}_n)\| + o_p(1) = o_p(1) \). To simplify notation, consider \( \bar{W}_n = W_n(\hat{\theta}_n) \). This implies that:

\[
\|\bar{g}_n(\theta)\|_{\bar{W}_n} = \|\bar{g}_n(\theta)\|_{\bar{W}_n + W_n - \bar{W}_n} = \|\bar{g}_n(\theta)\|_{\bar{W}_n \times [1 + o_p(1)]} = \|\bar{g}_n(\theta)\|_{\bar{W}_n} \times (1 + o_p(1)).
\]

Since \( K \) is Lipschitz-continuous:

\[
\left| K \left( \|\bar{g}_n(\theta)\|_{\bar{W}_n} - \|\bar{g}_n(\hat{\theta}_n)\|_{\bar{W}_n} / \kappa_n \right) - K \left( \|\partial g_n(\hat{\theta}_n) h\|_{\bar{W}_n} \right) \right| \\
\leq C_K \left| \|\bar{g}_n(\theta)\|_{\bar{W}_n} [1 + o_p(1)] - \|\bar{g}_n(\hat{\theta}_n)\|_{\bar{W}_n} / \kappa_n - \|\partial g_n(\hat{\theta}_n) h\|_{\bar{W}_n} \right| \\
= C_K \left| \|\bar{g}_n(\theta)\|_{\bar{W}_n} - \|\bar{g}_n(\hat{\theta}_n)\|_{\bar{W}_n} / \kappa_n - \|\partial g_n(\hat{\theta}_n) h\|_{\bar{W}_n} \right| \times [1 + o_p(1)] \\
\leq C_K \left( \|\bar{g}_n(\theta) - \bar{g}_n(\hat{\theta}_n)\| / \kappa_n - \|\partial g_n(\hat{\theta}_n) h\|_{\bar{W}_n} \right) \times [1 + o_p(1)] \\
\leq \bar{X} \times C_K(\|O_p(\kappa_n \|h\|^2) + o_p(n^{-1/2} \kappa_n^{-1})\| \times [1 + o_p(1)]) = O_p(\kappa_n \|h\|^2) + o_p(n^{-1/2} \kappa_n^{-1}).
\]

Using the results above, with probability going to 1:

\[
\int_{\|\hat{\theta}_n - \theta_0 + h\kappa_n\| \leq 3\kappa_n/C} h K \left( \|\bar{g}_n(\hat{\theta}_n + h\kappa_n)\|_{\bar{W}_n} - \|\bar{g}_n(\hat{\theta}_n)\|_{\bar{W}_n} \right) dh \\
= \int_{\|h\| \leq 4/C} h K \left( \|\partial g_n(\hat{\theta}_n) h\|_{\bar{W}_n} \right) + o_p(n^{-1/2} \kappa_n^{-1}) + O_p(\|h\|^2 \kappa_n) \right) \right) dh \\
= 0 + o_p(n^{-1/2} \kappa_n^{-1}) + O_p(\kappa_n).
\]
The last equality arises because $K \left( \| \partial g_n(\hat{\theta}_n)h \|_{\tilde{W}_n} \right)$ is symmetric in $h$. Putting everything together, with probability going to 1:

$$
\int_\Theta [\theta - \hat{\theta}_n]^2 \tilde{\pi}_n(\theta)d\theta = \frac{\int_{\|h\| \leq 4/C} h[K \left( \| \partial g_n(\hat{\theta}_n)h \|_{W_n} \right) + o_p(n^{-1/2}\kappa_n^{-1}) + O_p(\kappa_n)]d\theta}{\int_{\|h\| \leq 4/C} [K \left( \| \partial g_n(\hat{\theta}_n)h \|_{W_n} \right) + o_p(n^{-1/2}\kappa_n^{-1}) + O_p(\kappa_n)]d\theta}
$$

$$
= \frac{\kappa_n}{\int_{\|h\| \leq 4/C} [K \left( \| \partial g_n(\hat{\theta}_n)h \|_{W_n} \right) + o_p(n^{-1/2}\kappa_n^{-1}) + O_p(\kappa_n)]d\theta + o_p(1)}
$$

$$
= o_p(n^{-1/2}) + o_p(\kappa_n^2) = o_p(n^{-1/2}).
$$

This concludes the first part of the proof for the compact kernel.

**Step 1.b. Exponential Kernel $K$:**

First, consider $\|\theta - \theta_0\| \geq \kappa_n \left\{ [2d_\theta \log(n)]/C_2 \right\}^{1/a} / C$; then as in the proof for the compact kernel:

$$
\|\tilde{g}_n(\theta)\|_{W_n} / \kappa_n \geq \left\{ [2d_\theta \log(n)]/[C_2 + O_p(n^{-1/2})] \right\}^{1/a} - O_p(n^{-1/2}\kappa_n^{-1}).
$$

This implies that:

$$
\tilde{K}_n(\theta) \leq C_1 \exp \left( -2d_\theta \log(n) + O_p(n^{-1/2}\kappa_n^{-1}) \right) = o_p(n^{-2d_\theta}).
$$

Hence the integral becomes:

$$
\int [\tilde{g}_n(\theta) - \tilde{g}_n(\hat{\theta}_n)]\tilde{\pi}_n(\theta)d\theta = \int [\tilde{g}_n(\theta) - \tilde{g}_n(\hat{\theta}_n)]\tilde{\pi}_n(\theta)d\theta + o_p(n^{-2d_\theta}).
$$

As for the compact kernel, Assumption 2 further implies that:

$$
\int [\tilde{g}_n(\theta) - \tilde{g}_n(\hat{\theta}_n)]\tilde{\pi}_n(\theta)d\theta = \partial_\theta g_n(\hat{\theta}_n) \int [\theta - \hat{\theta}_n]\tilde{\pi}_n(\theta)d\theta + o_p(n^{-1/2}).
$$

As in the proof for the compact kernel, the following holds:

$$
\|\tilde{g}_n(\theta)\|_{W_n} / \kappa_n - \|\tilde{g}_n(\hat{\theta}_n)\|_{\tilde{W}_n} / \kappa_n - \|\partial_\theta g_n(\hat{\theta}_n)h\|_{\tilde{W}_n} = O_p(\kappa_n \|h\|) + o_p(n^{-1/2}\kappa_n^{-1}).
$$

Since the kernel is exponential, this implies that the kernel satisfies for $\theta = \hat{\theta}_n + h\kappa_n$, $\|h\| \leq 2C_K \log(n)^{1/a}$

$$
\tilde{K}_n(\theta) = K \left( \| \partial g_n(\hat{\theta}_n)h \|_{\tilde{W}_n} + O_p(\kappa_n \|h\|^2) + o_p(n^{-1/2}\kappa_n^{-1}) \right)
$$

$$
= K \left( \| \partial g_n(\hat{\theta}_n)h \|_{\tilde{W}_n} \right) \times \left[ 1 + O_p(\kappa_n \|h\|^2) + o_p(n^{-1/2}\kappa_n^{-1}) \right].
$$

57
This implies, as in the proof for the compact kernel, that:

\[ \int_{\|h\| \leq 2C_K \log(n)^{1/a}} hK_n(\hat{\theta}_n + \kappa_n h)dh \]

\[ = \int_{\|h\| \leq 2C_K \log(n)^{1/a}} hK(\| \partial_\theta g_n(\hat{\theta}_n)h \|_{\hat{W}_n}) \times [1 + O_p(\kappa_n \|h\|^2) + o_p(n^{-1/2} \kappa_n^{-1})]dh \]

\[ \leq 0 + \int_{\|h\| \leq 2C_K \log(n)^{1/a}} \left[ \|h\| + \|h\|^3 \right] K(\| \partial_\theta g_n(\hat{\theta}_n)h \|_{\hat{W}_n})dh \times [1 + O_p(\kappa_n) + o_p(n^{-1/2} \kappa_n^{-1})] \]

\[ \leq 0 + \int_{h \in \mathbb{R}^d} \left[ \|h\| + \|h\|^3 \right] K(\| \partial_\theta g_n(\hat{\theta}_n)h \|_{\hat{W}_n})dh \times [1 + O_p(\kappa_n) + o_p(n^{-1/2} \kappa_n^{-1})]. \]

The last integral is finite if \( \partial_\theta g_n(\hat{\theta}_n) \) is non-singular which is true with probability going to 1 under strong identification. Putting everything together:

\[ \int_{\hat{\Theta}} [\theta - \hat{\theta}_n] \pi_n(\theta)d\theta \]

\[ = \kappa_n \int_{\|h\| \leq 2C_K \log(n)^{1/a}} hK \left( \| \partial_\theta g_n(\hat{\theta}_n)h \|_{\hat{W}_n} \right) \times \left[ 1 + o_p(n^{-1/2} \kappa_n^{-1}) + O_p(\kappa_n \|h\|^2) \right] \kappa_n^{da} dh \]

\[ = \kappa_n \frac{o_p(n^{-1/2} \kappa_n^{-1}) + O_p(\kappa_n)}{\int_{\|h\| \leq 2C_K \log(n)^{1/a}} K \left( \| \partial_\theta g_n(\hat{\theta}_n)h \|_{\hat{W}_n} \right) dh + o_p(1)} + o_p(n^{-1/2}) \]

\[ = o_p(n^{-1/2}) + O_p(\kappa_n^2) \]

\[ = o_p(n^{-1/2}). \]

This concludes the first part of the proof for the exponential kernel.

**Step 2. Proof of the results concerning \( B_{n,LS} \):**

The least-squares formula implies:

\[ B'_{n,LS} = \left( \int (\theta - \bar{\theta}_n) (\theta - \bar{\theta}_n)' \pi_n(\theta)d\theta \right)^{-1} \int (\theta - \bar{\theta}_n) \left( g_n(\theta) - \int g_n(\theta) \pi_n(\theta)d\theta \right)' \pi_n(\theta)d\theta \]

where \( \bar{\theta}_n = \int \theta \pi_n(\theta)d\theta \). Recall from step 1 that \( \bar{\theta}_n = \hat{\theta}_n + o_p(n^{-1/2}) \)

**Step 2.a. Compact Kernel \( K \):**

As in step 1.a., consider the change of variable \( \theta = \hat{\theta}_n + \kappa_n h \). With probability going to 1:

\[ \int (\theta - \bar{\theta}_n) (\theta - \bar{\theta}_n)' \pi_n(\theta)d\theta \]

\[ = \int_{\|h\| \leq 4C \log(n)^{1/a}} \left[ \kappa_n^2 hh' + o_p(\kappa_n n^{-1/2}) \right] \kappa_n^{da} \pi_n(\hat{\theta}_n + \kappa_n h)dh. \]
From step 1.a., we also have:

\[ \int \bar{g}_n(\bar{\theta}) \hat{\pi}_n(\bar{\theta}) d\bar{\theta} = \bar{g}_n(\hat{\theta}_n) + o_p(n^{1/2}). \]

Together with the change of variable described above, it implies:

\[ \int (\theta - \bar{\theta}_n) \left( \bar{g}_n(\theta) - \int \bar{g}_n(\bar{\theta}) \hat{\pi}_n(\bar{\theta}) d\bar{\theta} \right) \hat{\pi}_n(\theta) d\theta 
= \int_{\|h\| \leq 4/\mathcal{C}} \left( \kappa_n h + o_p(n^{-1/2}) \right) \left( \bar{g}_n(\hat{\theta}_n + \kappa_n h) - \bar{g}_n(\hat{\theta}_n) \right) \hat{\pi}_n(\hat{\theta}_n + \kappa_n h) dh 
= \int_{\|h\| \leq 4/\mathcal{C}} \left( \kappa_n h + o_p(n^{-1/2}) \right) \left( \kappa_n \partial_{\theta} \bar{g}_n(\hat{\theta}_n) h + o_p(n^{-1/2}) \right) \hat{\pi}_n(\hat{\theta}_n + \kappa_n h) dh 
= \left( \int_{\|h\| \leq 4/\mathcal{C}} \left( \kappa_n^2 h h' + o_p(\kappa_n n^{-1/2}) \right) \kappa_n^{\partial_{\theta}} \hat{\pi}_n(\hat{\theta}_n + \kappa_n h) dh \right) \left[ \partial_{\theta} \bar{g}_n(\hat{\theta}_n) + o_p(n^{-1/2} \kappa_n^{-1}) \right]. \]

Putting everything together implies \( B'_{n,LS} = \partial_{\theta} \bar{g}_n(\hat{\theta}_n) + o_p(n^{-1/2} \kappa_n^{-1}) \).

**Step 2.b. Exponential Kernel \( K \):**

The proof is very similar to the case of the compact kernel, consider the re-parameterization \( \theta = \bar{\theta}_n + \kappa_n h \):

\[ \int (\theta - \bar{\theta}_n) (\theta - \bar{\theta}_n)' \hat{\pi}_n(\theta) d\theta 
= \int_{\|h\| \leq C_K \log(n)^{1/a}} \left[ \kappa_n^2 h h' + o_p(\kappa_n n^{-1/2}) \right] \kappa_n^{\partial_{\theta}} \hat{\pi}_n(\hat{\theta}_n + \kappa_n h) dh + o_p(n^{-2\partial_{\theta}}). \]

From step 1.b., we also have:

\[ \int \bar{g}_n(\bar{\theta}) \hat{\pi}_n(\bar{\theta}) d\bar{\theta} = \bar{g}_n(\hat{\theta}_n) + o_p(n^{1/2}). \]

As in step 2.a, it implies:

\[ \int (\theta - \bar{\theta}_n) \left( \bar{g}_n(\theta) - \int \bar{g}_n(\bar{\theta}) \hat{\pi}_n(\bar{\theta}) d\bar{\theta} \right) \hat{\pi}_n(\theta) d\theta 
= \left( \int_{\|h\| \leq 2C_K \log(n)^{1/a}} \left( \kappa_n^2 h h' + o_p(\kappa_n n^{-1/2}) \right) \kappa_n^{\partial_{\theta}} \hat{\pi}_n(\hat{\theta}_n + \kappa_n h) dh \right) \left[ \partial_{\theta} \bar{g}_n(\hat{\theta}_n) + o_p(n^{-1/2} \kappa_n^{-1}) \right] 
+ o_p(n^{-\partial_{\theta}}). \]

Putting everything together implies \( B'_{n,LS} = \partial_{\theta} \bar{g}_n(\hat{\theta}_n) + o_p(n^{-1/2} \kappa_n^{-1}) \).
Final Step, showing that: \( \hat{\theta}_{n,LS} = \hat{\theta} + o_p(n^{-1/2}) \)

From step 1, we have \( A_{n,LS} = \bar{g}_n(\hat{\theta}_n) - B_{n,LS} \hat{\theta}_n + o_p(n^{-1/2}) \) which implies that:

\[
\hat{\theta}_{n,LS} - \hat{\theta}_n = \left( B'_{n,LS} \hat{W}_n B_{n,LS} \right)^{-1} B'_{n,LS} \hat{W}_n \bar{g}_n(\hat{\theta}_n) + o_p(n^{-1/2}).
\]

The proof that \( \hat{\theta}_{n,LS} = \hat{\theta} + o_p(n^{-1/2}) \) is very similar to the derivations of the asymptotic distribution of the J-test:

\[
\bar{g}_n(\hat{\theta}_n) = \bar{g}_n(\theta_0) + \partial_\theta g_n(\theta_0)[\hat{\theta}_n - \theta_0] + o_p(n^{-1/2})
\]

\[
= \bar{g}_n(\theta_0) - \partial_\theta g_n(\theta_0) \left( \partial_\theta g_n(\hat{\theta}_n)' \hat{W}_n \partial_\theta g_n(\hat{\theta}_n) \right)^{-1} \partial_\theta g_n(\hat{\theta}_n)' \hat{W}_n \bar{g}_n(\theta_0) + o_p(n^{-1/2})
\]

\[
= \left( I - \left( B'_{n,LS} \hat{W}_n B_{n,LS} \right)^{-1} B'_{n,LS} \hat{W}_n \right) \bar{g}_n(\theta_0) + o_p(n^{-1/2}).
\]

Note that it is important to use the same weights \( \hat{W}_n \) for both \( \hat{\theta}_n \) and \( \hat{\theta}_{n,LS} \). The matrix preceding \( \bar{g}_n(\theta_0) \) is orthogonal to the matrix preceding \( \bar{g}_n(\hat{\theta}_n) \) in the previous expansion which implies the desired result. This concludes the proof. \( \square \)

Proof of Theorem \[5 \]

The proof is divided into several steps.

Step 1. Proof of the results concerning \( A_{n,LS} \):

As for Theorem \[5 \], the least-squares formula implies:

\[
A_{n,LS} = \int \bar{g}_n(\theta) \hat{\pi}_n(\theta) d\theta - B_{n,LS} \int \theta \hat{\pi}_n(\theta) d\theta.
\]

And again, the first part of the proof amounts to showing that:

\[
\int [\bar{g}_n(\theta) - \bar{g}_n(\theta_0)] \hat{\pi}_n(\theta) d\theta = o_p(n^{-1/2})
\]

\[
\int [\theta - \hat{\theta}_n] \hat{\pi}_n(\theta) d\theta = o_p(n^{-1/2})
\]

for both the compact and the exponential kernels.

Step 1.a. Compact Kernel \( K \):

For \( \|\theta - \theta_0\| \geq \varepsilon > 0 \), we have, as in the proof of Theorem \[5 \], \( \hat{\pi}_n(\theta) \leq O_p(n^{-d}) \) for any \( d \geq 1 \). Then for \( \|\theta - \theta_0\| \leq \varepsilon \), as in the proof with the sup-norm, we have after the following re-parametrization \( \theta = \hat{\theta}_n + H_n \varepsilon \): \( H_n = (\partial_\theta g_n(\theta_0)' \partial_\theta g_n(\theta_0))^{-1/2} \):

\[
\sup_{h \in \mathbb{R}^d, \|h\| \geq 4/\varepsilon} K \left( \|\bar{g}_n(\theta)\|_{\hat{W}_n} - \|\bar{g}_n(\hat{\theta}_n)\|_{\hat{W}_n} \right) = 0
\]

60
with probability going to 1. \( \theta - \hat{\theta}_n = H_n h \kappa_n = o_p(1) \) implies that with probability going to 1:

\[
\int_{\Theta} [\tilde{g}_n(\theta) - \tilde{g}_n(\hat{\theta}_n)] \hat{\pi}_n(\theta) d\theta = \int_{\theta, \|h\| \leq 4/C} [\tilde{g}_n(\theta) - \tilde{g}_n(\hat{\theta}_n)] \hat{\pi}_n(\theta) d\theta
\]

\[
= \int_{\theta, \|h\| \leq 3/C} \partial_h g_n(\theta_0)[\theta - \theta_0] \hat{\pi}_n(\theta) d\theta + o_p(n^{-1/2}) + O_p(\kappa_n^2)
\]

where the expansion of \( \tilde{g}_n(\theta) \) is derived the same way as in the proof of Theorem 2. Showing that \( \hat{\theta}_n - \tilde{\theta}_n = o_p(n^{-1/2}) \) relies on expanding the terms inside the kernel:

\[
\tilde{g}_n(\theta) = \tilde{g}_n(\hat{\theta}_n) + \partial_h g_n(\hat{\theta}_n) H_n h \kappa_n + o_p(n^{-1/2}) + O_p(\kappa_n^2)
\]

\[
= \tilde{g}_n(\hat{\theta}_n) + \partial_h g_n(\theta_0) H_n h \kappa_n + o_p(n^{-1/2}) + O_p(\kappa_n^2)
\]

where the last equality is due to Definition iv. Since the kernel \( K \) is Lipschitz-continuous:

\[
\left| K \left( \|\partial_h g_n(\hat{\theta}_n) H_n h\|_{\hat{W}_n} \right) - K \left( \|\tilde{g}_n(\theta_0)\|_{W_n}/\kappa_n - \|\tilde{g}_n(\hat{\theta}_n)\|_{\hat{W}_n}/\kappa_n \right) \right| = o_p(n^{-1/2} \kappa_n^{-1}) + O_p(\kappa_n).
\]

As in the proof of Theorem 5, this implies that: \( \hat{\theta}_n - \tilde{\theta}_n = o_p(n^{-1/2}) + O_p(\kappa_n^2) = o_p(n^{-1/2}) \).

**Step 1.b. Exponential Kernel K:****

For \( \|\theta - \theta_0\| \geq \varepsilon > 0 \), we have, as in the proof of Theorem 3: \( \hat{\pi}_n(\theta) \leq O_p(n^{-d}) \) for any \( d \geq 1 \). Again, consider the re-parameterization \( \theta = \hat{\theta}_n + H_n h \kappa_n, H_n = (\partial_h g_n(\hat{\theta}_n)' \partial_h g_n(\theta_0))^{-1/2} \); using a similar strategy to Theorem 5, for \( \|h\| \geq [d_0 \log(n)/C_2]^{1/\alpha}/C \) we have:

\[
\hat{K}_n(\theta) \leq C_1 \exp(-d_0 \log(n) + o_p(1)) = O_p(n^{-d_0}).
\]

Assumption 1 also implies that \( \hat{\kappa}_n = \kappa_n \log(n)^{1/\alpha} = o(1) \) so that the stochastic equicontinuity result applies in balls centered around \( \hat{\theta}_n \) with radius proportional to \( \hat{\kappa}_n \):

\[
\tilde{g}_n(\theta) = \tilde{g}_n(\hat{\theta}_n) + \partial_h g_n(\hat{\theta}_n) H_n h \kappa_n + o_p(n^{-1/2}) + O_p(\|\partial_h g_n(\hat{\theta}_n) H_n h \kappa_n\|^2)
\]

Since, up to a fixed constant, we have \( \|h\| \leq \log(n)^{1/\alpha} \), the last term is a \( O_p(\hat{\kappa}_n^2) = o_p(n^{-1/2}) \).

As in the case of the compact kernel:

\[
K \left( \|\tilde{g}_n(\theta)\|_{W_n}/\kappa_n - \|\tilde{g}_n(\hat{\theta}_n)\|_{\hat{W}_n}/\kappa_n \right)
\]

\[
= K \left( \|\partial_h g_n(\hat{\theta}_n) H_n h\|_{\hat{W}_n} \right) \times \left[ 1 + o_p(n^{-1/2} \kappa_n^{-1}) + O_p(\kappa_n \|h\|^2) \right].
\]

61
Note that $\partial_\theta g_n(\hat{\theta}_n)H_n = \partial_\theta g_n(\theta_0)H_n + o_p(1)$; since the first $d_\theta$ eigenvalues of $\partial_\theta g_n(\theta_0)H_n$ are bounded below by construction (this is the role of $H_n$), with probability going to 1, $\partial_\theta g_n(\hat{\theta}_n)H_n$ is also non-singular. This implies that:

$$\bar{\theta}_n$$

$$= \hat{\theta}_n + \kappa_n \frac{\int_{\|h\| \leq C_K \log(n)^{1/\alpha}} h \kappa_n^{-\alpha} K(\|\partial_\theta g_n(\hat{\theta}_n)H_nh\|_{\hat{W}_n}) \times \left[ 1 + o_p(n^{-1/2}\kappa_n^{-1}) + O_p(\kappa_n\|h\|^2) \right] dh}{\int_{\|h\| \leq C_K \log(n)^{1/\alpha}} K(\|\partial_\theta g_n(\hat{\theta}_n)H_nh\|_{\hat{W}_n}) \times \left[ 1 + o_p(n^{-1/2}\kappa_n^{-1}) + O_p(\kappa_n\|h\|^2) \right] dh + o_p(n^{-1/2})} + o_p(n^{-1/2})$$

$$= \hat{\theta}_n + o_p(n^{-1/2}) + O_p(\kappa_n^2) + o_p(1)$$

Step 2. Proof of the results concerning $B_{n,LS}$:

The least-squares formula implies that:

$$B_{n,LS} = \left( \int [\theta - \bar{\theta}_n][\theta - \bar{\theta}_n]' \pi_n(\theta) d\theta \right)^{-1} \int [\theta - \bar{\theta}_n][\bar{g}_n(\theta) - \int \bar{g}_n(\hat{\theta}) \hat{\pi}_n(\hat{\theta}) d\hat{\theta}]' \hat{\pi}_n(\theta) d\theta.$$ 

Using the change of variable: $\theta = \hat{\theta}_n + H_n h \kappa_n$, the first term can be re-written as:

$$\int [\theta - \bar{\theta}_n][\theta - \bar{\theta}_n]' \pi_n(\theta) d\theta$$

$$= \int_{\|h\| \leq 4/C} [H_n h \kappa_n + o_p(n^{-1/2})][H_n h \kappa_n + o_p(n^{-1/2})]' \kappa_n^{-\alpha} \pi_n(\hat{\theta}_n + H_n \kappa_n h) dh$$

$$\int_{\|h\| \leq 4/C} [\kappa_n^2 H_n h' h' H_n + o_p(\kappa_n^{-1} n^{-1/2})] \kappa_n^{-\alpha} \pi_n(\hat{\theta}_n + H_n \kappa_n h) dh.$$ 

Note that $O(n^{1/2}) \geq H_n \geq o_p(1)$ so that the $o_p(\kappa_n^{-1} n^{-1/2})$ term is negligible compared to $\kappa_n^2 H_n h' h' H_n$. The second term can be expanded as:

$$\int [\theta - \bar{\theta}_n][\bar{g}_n(\theta) - \int \bar{g}_n(\hat{\theta}) \hat{\pi}_n(\hat{\theta}) d\hat{\theta}]' \hat{\pi}_n(\theta) d\theta$$

$$= \int_{\|h\| \leq 4/C} [H_n h \kappa_n + o_p(n^{-1/2})][\partial_\theta g_n(\hat{\theta}_n)H_n h \kappa_n + o_p(n^{-1/2})]' \kappa_n^{-\alpha} \pi_n(\hat{\theta}_n + H_n \kappa_n h) dh$$

$$= \int_{\|h\| \leq 4/C} \left( [\kappa_n^2 H_n h' h' \partial_\theta g_n(\hat{\theta}_n)'] + [H_n o_p(\kappa_n n^{-1/2})] \right) \kappa_n^{-\alpha} \pi_n(\hat{\theta}_n + H_n \kappa_n h) dh.$$ 

Together these imply that:

$$H_n B_{n,LS}' = H_n \partial_\theta g_n(\hat{\theta}_n)' + o_p(n^{-1/2}\kappa_n^{-1}).$$
Note that \( H_n \partial_{\theta} g_n(\hat{\theta}_n)' = O_p(1) \) so that the \( o_p(n^{-1/2}k_n^{-1}) \) term is negligible relative to \( H_n \partial_{\theta} g_n(\hat{\theta}_n)' \).

**Final Step, showing that:** \( \sqrt{n}H_n^{-1/2} \left( \hat{\theta}_n - \theta_{n,LS} \right) = o_p(1) \):

Since \( \hat{\theta}_n \) is consistent under the stated assumptions, the problem can be re-parameterized using \( \theta_n = \theta_0 + H_n h n^{-1/2} \):

\[
\frac{n}{\| \tilde{g}_n(\theta_n) \|_{W_n}} = (G_n(\theta_0) + \partial_{\theta} g_n(\theta_0)H_n h + o_p(1))' [\tilde{W}_n + o_p(1)] (G_n(\theta_0) + \partial_{\theta} g_n(\theta_0)H_n h + o_p(1)).
\]

Then the Argmax Theorem (van der Vaart & Wellner 1996) implies that the minimizer \( \hat{h}_n \) satisfies:

\[
\hat{h}_n = \left( H_n \partial_{\theta} g_n(\theta_0)' \tilde{W}_n \partial_{\theta} g_n(\theta_0)H_n \right)^{-1} H_n \partial_{\theta} g_n(\theta_0)' \tilde{W}_n [G_n(\theta_0) + o_p(1)].
\]

and so the estimator \( \hat{\theta}_n = \theta_0 + H_n \hat{h}_n n^{-1/2} \) satisfies:

\[
\sqrt{n}H_n^{-1}(\hat{\theta}_n - \theta_0) = \left( H_n \partial_{\theta} g_n(\theta_0)' \tilde{W}_n \partial_{\theta} g_n(\theta_0)H_n \right)^{-1} H_n \partial_{\theta} g_n(\theta_0)' \tilde{W}_n G_n(\theta_0) + o_p(1).
\]

The estimator computed from the least-squares representation can be written as:

\[
\hat{\theta}_{n,LS} = -\left( B'_{n,LS} \tilde{W}_n B_{n,LS} \right)^{-1} B'_{n,LS} \tilde{W}_n A_n
\]

\[
= \hat{\theta}_n - \left( B'_{n,LS} \tilde{W}_n B_{n,LS} \right)^{-1} B'_{n,LS} \tilde{W}_n [\tilde{g}_n(\hat{\theta}_n) + o_p(n^{-1/2})]
\]

which implies that the difference with the optimal GMM estimator can be written as:

\[
\sqrt{n}H_n^{-1}(\hat{\theta}_n - \hat{\theta}_{n,LS})
\]

\[
= \sqrt{n}H_n^{-1} \left( B'_{n,LS} \tilde{W}_n B_{n,LS} \right)^{-1} B'_{n,LS} \tilde{W}_n [\tilde{g}_n(\hat{\theta}_n) + o_p(n^{-1/2})]
\]

\[
= \sqrt{n} \left( H_n \partial_{\theta} g_n(\theta_0)' \tilde{W}_n \partial_{\theta} g_n(\theta_0)H_n \right)^{-1} H_n \partial_{\theta} g_n(\theta_0)' \tilde{W}_n [\tilde{g}_n(\hat{\theta}_n) + o_p(n^{-1/2})](1 + o_p(1)).
\]

Then, the term \( \tilde{g}_n(\hat{\theta}_n) \) can be expanded into:

\[
\tilde{g}_n(\hat{\theta}_n) = \tilde{g}_n(\theta_0) + \partial_{\theta} g_n(\theta_0)(\hat{\theta}_n - \theta_0) + o_p(n^{-1/2})
\]

\[
= \left( I - \partial_{\theta} g_n(\theta_0)H_n \left( H_n \partial_{\theta} g_n(\theta_0)' \tilde{W}_n \partial_{\theta} g_n(\theta_0)H_n \right)^{-1} H_n \partial_{\theta} g_n(\theta_0)' \tilde{W}_n + o_p(1) \right) \tilde{g}_n(\theta_0)
\]

\[+ o_p(n^{-1/2}).
\]

Since the term before \( \tilde{g}_n(\theta) \) is a projection matrix argument orthogonal to \( H_n \partial_{\theta} g_n(\theta_0)' = O(1) \):

\[
H_n \partial_{\theta} g_n(\theta_0)' \tilde{W}_n \tilde{g}_n(\hat{\theta}_n) = o_p(n^{-1/2})
\]

which implies \( \sqrt{n}H_n^{-1}(\hat{\theta}_n - \hat{\theta}_{n,LS}) = o_p(1) \) and concludes the proof. \( \square \)

63
Proof of Lemma 1: From the least-squares formula, we know that:

\[ A_{n,LS} = \int \tilde{g}_n(\theta)\tilde{\pi}_n(\theta)d\theta - B_{n,LS}\tilde{\theta}_n. \]

Substituting into the least-squares objective implies that \( B_{n,LS} \) is the minimizer of:

\[ \int \left\| B_{n,LS}(\theta - \tilde{\theta}_n) - \left[ \tilde{g}_n(\theta) - \int \tilde{g}_n(\tilde{\theta})\tilde{\pi}_n(\tilde{\theta})d\tilde{\theta} \right] \right\|^2 \tilde{\pi}_n(\theta)d\theta. \]

The proof proceed in 3 steps:

1. Proving that \( \int \|g_n(\theta)\|^2\tilde{\pi}_n(\theta)d\theta \leq O_p(\kappa_n^2) \) for both the compact and the exponential kernel.

2. Proving that \( \int \left\| B_{n,LS}(\theta - \tilde{\theta}_n) \right\|^2\tilde{\pi}_n(\theta)d\theta \leq O_p(\kappa_n^2). \)

3. Deducing the results from steps 1 and 2.

Step 1. Proving that \( \int \|g_n(\theta)\|^2\tilde{\pi}_n(\theta)d\theta \leq O_p(\kappa_n^2): \)

Step 1.a. Compact Kernel \( K \):

For the compact kernel, it is immediate that:

\[ \|\tilde{g}_n(\tilde{\theta})\|^2\tilde{\pi}_n(\tilde{\theta}) \leq O(\kappa_n^2)\tilde{\pi}_n(\tilde{\theta}). \]

This follows from \( \tilde{\pi}_n(\tilde{\theta}) = 0 \) when \( \|\tilde{g}_n(\tilde{\theta})\|_{W_n} \geq \kappa_n \) and \( \Delta\|\tilde{g}_n(\tilde{\theta})\| \leq \|\tilde{g}_n(\tilde{\theta})\|_{W_n} \) where \( \Delta > 0 \) is a lower bound on the smallest eigenvalue of \( W_n. \)

Step 1.b. Exponential Kernel \( K \):

For the exponential kernel, pick \( d \geq 1 \) and consider a \( \theta \) such that \( \|g_n(\theta)\|_{W_n} \geq \kappa_n \times [d/C_2]^{1/a} \), then:

\[ \hat{K}_n(\theta) \leq C_1 \exp\left(-d[\kappa_n/\kappa_n]^a\right) = C_1 \exp\left(-d\log(n)\right) = C_1 n^{-d}, \]

this implies for these values of \( \theta \) that \( \|\hat{g}_n(\theta)\|^2\times\hat{K}_n(\theta) \leq \bar{\lambda} \times \sup_{\theta \in \Theta} \|g_n(\theta)\|_{W_n} + O_p(n^{-1/2}) \]^2 \times C_1 n^{-d} = O_p(n^{-d}). \) Now pick any \( \theta_0 \in \Theta_0 \), the Hölder-type condition implies that for any \( \theta \) such that \( \|\theta - \theta_0\| \leq \kappa_n^{1/c} \), we have \( \|g_n(\theta)\|_{W_n} \leq \bar{\lambda}\kappa_n \), which implies for the sample moments:

\[ \|\tilde{g}_n(\theta)\|_{W_n} \leq \bar{\lambda}\kappa_n + O_p(n^{-1/2}) \leq (1 + \bar{\lambda})\kappa_n, \]

with probability going to 1. For the exponential kernel, it implies that \( \hat{K}_n(\theta) \geq C_1 \exp\left(-C_2[1 + \bar{\lambda}]^a\right) \) with probability going to 1. This implies that, with probability going to 1:

\[ \int_{\|\theta - \theta_0\| \leq \kappa_n^{1/c}} \hat{K}_n(\theta)d\theta \geq \kappa_n^{d/b/c} \frac{\pi^{d/b/2}}{\Gamma(d/b/2 + 1)} C_1 \exp\left(-C_2[1 + \bar{\lambda}]^a\right). \]
Together with the first bound, this implies that:

\[
\int_{\theta, \|g_n(\theta)\|_{\infty} \geq \bar{\kappa}_n \times [d/C_2]^{1/a}} \hat{\pi}_n(\theta) d\theta \leq \kappa^{d_0/n} n^{-d} \frac{n^{d_0/2}}{\Gamma(d_0/2 + 1)} \exp \left(-C_2[1 + C]^a\right).
\]

For \(d\) large enough, \(\kappa^{d_0/n} n^{-d} \leq O_p(\bar{\kappa}_n^2)\). Putting everything together, we get:

\[
\int_{\theta} \|g_n(\theta)\|^2 \hat{\pi}_n(\theta) d\theta 
\leq \lambda^{-2} \int_{\theta} \|g_n(\theta)\|^2 W_n \hat{\pi}_n(\theta) d\theta 
= \lambda^{-2} \left[ \int_{\theta, \|g_n(\theta)\|_{\infty} \leq \bar{\kappa}_n [d/C_2]^{1/a}} \|g_n(\theta)\|^2 W_n \hat{\pi}_n(\theta) d\theta + \int_{\theta, \|g_n(\theta)\|_{\infty} > \bar{\kappa}_n [d/C_2]^{1/a}} \|g_n(\theta)\|^2 W_n \hat{\pi}_n(\theta) d\theta \right] 
\leq \lambda^{-2} \left[ \bar{\kappa}_n^2 [d/C_2]^{2/a} + O_p(\bar{\kappa}_n^2) \right] = O_p(\bar{\kappa}_n^2).
\]

**Step 2. Proving that** \(\int \left\|B_{n,LS}(\theta - \bar{\theta}_n)\right\|^2 \hat{\pi}_n(\theta) d\theta \leq O_p(\bar{\kappa}_n^2)\):

From step 1., we have:

\[
\int \left\|g_n(\theta) - \int g_n(\theta) \hat{\pi}_n(\theta) d\theta \right\|^2 \hat{\pi}_n(\theta) d\theta \leq 4 \int \|g_n(\theta)\|^2 \hat{\pi}_n(\theta) d\theta \leq O_p(\bar{\kappa}_n^2).
\]

Since \(B_{n,LS}\) minimizes the least-squares criterion:

\[
\int \left\|B_{n,LS}(\theta - \bar{\theta}_n) - \left[ g_n(\theta) - \int g_n(\theta) \hat{\pi}_n(\theta) d\theta \right] \right\|^2 \hat{\pi}_n(\theta) d\theta 
\leq \int \left\|g_n(\theta) - \int g_n(\theta) \hat{\pi}_n(\theta) d\theta \right\|^2 \hat{\pi}_n(\theta) d\theta 
\leq O_p(\bar{\kappa}_n^2).
\]

By the reverse triangle inequality:

\[
\int \left\|B_{n,LS}(\theta - \bar{\theta}_n)\right\|^2 \hat{\pi}_n(\theta) d\theta 
\leq \int \left\|B_{n,LS}(\theta - \bar{\theta}_n) - \left[ g_n(\theta) - \int g_n(\theta) \hat{\pi}_n(\theta) d\theta \right] \right\|^2 \hat{\pi}_n(\theta) d\theta 
+ \int \left\|g_n(\theta) - \int g_n(\theta) \hat{\pi}_n(\theta) d\theta \right\|^2 \hat{\pi}_n(\theta) d\theta 
\leq O_p(\bar{\kappa}_n^2)
\]

**Step 3. Deducing the results of Lemma 1**

By definition of the Frobenius norm:

\[
\int \text{trace} \left( B_{n,LS}(\theta - \bar{\theta}_n)(\theta - \bar{\theta}_n)' B_{n,LS}' \right) \hat{\pi}_n(\theta) d\theta \leq O_p(\bar{\kappa}_n^2).
\]
By linearity of the trace and integral operators:

\[
\text{trace} \left( B_{n,LS} \Sigma_n B'_{n,LS} \right) = \text{trace} \left( B_{n,LS} \left[ \int (\theta - \hat{\theta}_n)(\theta - \hat{\theta}_n)' \hat{\pi}_n(\theta) d\theta \right] B'_{n,LS} \right) \leq O_p(\tilde{\kappa}_n^2).
\]

In turn, this implies that \( \text{trace} \left( B'_{n,LS} B_{n,LS} \Sigma_n \right) \leq O_p(\tilde{\kappa}_n^2) \). Since \( \Sigma_n \) and \( B'_{n,LS} B_{n,LS} \) are Hermitian (self-adjoint), Problem III.6.14, in Bhatia (1997) implies that:

\[
0 \leq \lambda_j(B'_{n,LS} B_{n,LS}) \lambda_{d_n+1-j} (\Sigma_n) \leq \text{trace} \left( B'_{n,LS} B_{n,LS} \Sigma_n \right) = O_p(\tilde{\kappa}_n^2)
\]

which, in turn, implies the desired results.

Let \( v_{j,n} \) be an eigenvector of \( \Sigma_n \), then \( \Sigma_n^{1/2} v_{j,n} = \sqrt{\lambda_{j,n}} v_{j,n} \). Furthermore, \( \| B_{n,LS} \Sigma_n^{1/2} \| = O_p(\tilde{\kappa}_n) \). Together these imply:

\[
0 \leq \sqrt{\lambda_{j,n}} \| B_{n,LS} v_{j,n} \| = \| B_{n,LS} \Sigma_n^{1/2} \| = O_p(\tilde{\kappa}_n).
\]

Since \( \sqrt{\lambda_{j,n}} = O_p(r_{j,n}) \) this implies the final result and concludes the proof. \( \square \)

**Proof of Theorem 7.** According to Lemma 1, the asymptotic behaviour of \( B_{n,LS} \) is related to the asymptotic behaviour of the posterior variance \( \Sigma_n \). Proving the desired result amounts to showing that the posterior variance \( \Sigma_n \) induced by \( \hat{\pi}_n \) satisfies \( P_j \Sigma_n P'_j = O_p(\tilde{\kappa}_n^{2/j}) \) for each \( j = 1, \ldots, r \). Before we proceed, note that:

\[
\Sigma_n = \int_{\Theta} (\theta - \hat{\theta}_n)(\theta - \hat{\theta}_n)' \hat{\pi}_n(\theta) d\theta
\]

\[
= (\hat{\theta}_n - \hat{\theta}_n)(\hat{\theta}_n - \hat{\theta}_n)' + \int_{\Theta} (\theta - \hat{\theta}_n)(\theta - \hat{\theta}_n)' \hat{\pi}_n(\theta) d\theta.
\]

So that showing the results amounts to showing that the posterior mean is such that: \( P_j(\hat{\theta}_n - \hat{\theta}_n) = O_p(\tilde{\kappa}_n^{1/j}) \) and that the posterior concentrates around \( \hat{\theta}_n \) at a \( \tilde{\kappa}_n^{1/j} \) rate in each direction \( P_j \). This is shown separately for the compact and exponential kernels.

We also need to derive the rate for \( \hat{\theta}_n - \theta_0 \). First, \( \hat{\theta}_n \) is consistent under the stated assumptions using Theorem 2.1 in Newey & McFadden (1994). Second, we can re-write \( \theta = \theta_0 + \sum_{j=1}^r n^{-1/2j} P_j h \), with \( h \in \mathbb{R}^{d_h} \), and using the assumption that \( \sup_{\theta \in \Theta} \| G_n(\theta) \|_W = O_p(1) \):

\[
\left[ \sum_{j=1}^r C_j \| P_j h \|^2 + O_p(1) \right]^{1/2} \geq [1 + o_p(1)] n \times \| g_n(\theta_0) + \sum_{j=1}^r n^{-1/2j} P_j h \|_W^2 \geq 0.
\]

The result invoked from Bhatia (1997) is a consequence of Lidskii’s theorems and states that if \( A, B \) are Hermitian then \( \langle \lambda^1(A), \lambda^1(B) \rangle \leq \text{trace}(AB) \) where \( \lambda^1, \lambda^1 \) are the eigenvalues in decreasing and increasing order, respectively. Furthermore, if the matrices are positive semi-definite, then the eigenvalues of each matrix are positive so that the result implies \( 0 \leq \lambda_j(A) \lambda_{d_n+1-j}(B) \leq \text{trace}(AB) \) which implies the desired result.

---

\( \text{The result invoked from Bhatia (1997) is a consequence of Lidskii’s theorems and states that if } A, B \text{ are Hermitian then } \langle \lambda^1(A), \lambda^1(B) \rangle \leq \text{trace}(AB) \text{ where } \lambda^1, \lambda^1 \text{ are the eigenvalues in decreasing and increasing order, respectively. Furthermore, if the matrices are positive semi-definite, then the eigenvalues of each matrix are positive so that the result implies } 0 \leq \lambda_j(A) \lambda_{d_n+1-j}(B) \leq \text{trace}(AB) \text{ which implies the desired result.} \)
which implies that the minimizer $\hat{h}_n$ of $\|g_n(\theta_0 + \sum_{j=1}^r n^{-1/2} P_j h)\|^2_{W_n}$ is a $O_p(1)$. This in turn implies that $P_j(\hat{\theta}_n - \theta_0) = O_p(n^{-\frac{1}{2j}})$ for each $j \in \{1, \ldots, r\}$.

**Step 1.a. Results for the Compact Kernel $K$:**

Using the same approach as above, we can re-write $\theta = \hat{\theta}_n + \sum_{j=1}^r \kappa_n^{1/j} P_j h$ with $h \in \mathbb{R}^d$ and:

$$\|g_n(\theta)/\kappa_n\|_{W_n} \geq \left[ \sum_{j=1}^r C_j \|P_j(\hat{\theta}_n - \theta_0)\kappa_n^{-1/j} + P_j h\|^j - O_p(n^{-1/2}\kappa_n^{-1}) \right] \left[ 1 + o_p(1) \right]$$

$$= \left[ \sum_{j=1}^r C_j \|O_p(n^{-1/2}\kappa_n^{-1})^{1/j} + P_j h\|^j - O_p(n^{-1/2}\kappa_n^{-1}) \right] \left[ 1 + o_p(1) \right]$$

$$= \left[ \sum_{j=1}^r C_j \|o_p(1) + P_j h\|^j - o_p(1) \right] \left[ 1 + o_p(1) \right]$$

$$= \sum_{j=1}^r C_j \|P_j h\|^j - o_p(1) \geq 2,$$

with probability going to 1 when $\sum_{j=1}^r \|P_j h\|^j \geq 2/C$ where $C = \min_{j=1, \ldots, r} C_j > 0$ \[32\]. Then we have, with probability going to 1:

$$\sup_{h, \sum_{j=1}^r \|P_j h\|^j \geq 2/C} \hat{K}_n(\hat{\theta}_n + \sum_{j=1}^r \kappa_n^{1/j} P_j h) = 0.$$

This, in turn implies that, with probability going to 1:

$$\tilde{\theta}_n = \int_{\Theta} \theta \hat{\pi}_n(\theta) \, d\theta = \hat{\theta}_n + \sum_{j=1}^r \kappa_n^{1/j} P_j \int_{h, \sum_{j=1}^r \|P_j h\|^j \leq 2/C} h \hat{\pi}_n(\hat{\theta}_n + \sum_{j=1}^r \kappa_n^{1/j} P_j h) \, dh.$$  

Since the integral is taken over a bounded set, we have:

$$\|\int_{h, \sum_{j=1}^r \|P_j h\|^j \leq 2/C} h \hat{\pi}_n(\hat{\theta}_n + \sum_{j=1}^r \kappa_n^{1/j} P_j h) \, dh\| \leq \sup_{h, \sum_{j=1}^r \|P_j h\|^j \leq 2/C} \|h\| \times + \infty.$$  

This implies that, with probability going to 1:

$$P_j(\tilde{\theta}_n - \hat{\theta}_n) = \kappa_n^{1/j} O_p(1).$$

Since $\tilde{\theta}_n - \hat{\theta}_n = \sum_{j=1}^r P_j(\hat{\theta}_n - \hat{\theta}_n)$, we have $(\tilde{\theta}_n - \hat{\theta}_n)(\tilde{\theta}_n - \hat{\theta}_n)' = \sum_{j=1}^r \kappa_n^{2/j} O_p(1) P_j'$. Pre and post-multiplying this equation by $P_j$ implies:

$$P_j(\tilde{\theta}_n - \hat{\theta}_n)(\tilde{\theta}_n - \hat{\theta}_n)'P_j = \kappa_n^{2/j} O_p(1).$$

\[32\] If the minimum is zero, one can take the minimum over the non-zero elements instead.
With probability going to 1, we also have:

\[
\int_{\Theta} (\theta - \hat{\theta}_n)(\theta - \hat{\theta}_n)' \hat{\pi}_n(\theta) d\theta = \sum_{j=1}^{r} \kappa_n^{2/j} P_j \left( \int_{h, \sum_{j=1}^{r} \|P_j h\| \leq 2/C} hh' \hat{\pi}_n(\hat{\theta}_n + \sum_{j=1}^{r} \kappa_n^{1/j} P_j h) dh \right) P_j'
\]

and, using the same argument as above:

\[
\| \int_{h, \sum_{j=1}^{r} \|P_j h\| \leq 2/C} hh' \hat{\pi}_n(\hat{\theta}_n + \sum_{j=1}^{r} \kappa_n^{1/j} P_j h) dh \| \leq \sup_{h, \sum_{j=1}^{r} \|P_j h\| \leq 2/C} \| hh' \| < +\infty.
\]

This implies that with probability going to 1, we have:

\[
\int_{\Theta} (\theta - \hat{\theta}_n)(\theta - \hat{\theta}_n)' \hat{\pi}_n(\theta) d\theta = \sum_{j=1}^{r} \kappa_n^{2/j} P_j O_p(1) P_j'.
\]

Putting everything together, we have \( \Sigma_n = \sum_{j=1}^{r} \kappa_n^{2/j} P_j O_p(1) P'_j \) so that for any \( v_j \in \text{Span}(P_j) \), \( v_j \Sigma_n v_j' = O_p(\kappa_n^{2/j}) \) which by Lemma [1] implies \( |\lambda_{\min}(B_{n,LS})| = O_p(\kappa_n^{1-1/r}) \) and \( B_{n,LS} v_j = O_p(\kappa_n^{1-1/j}) \) for any \( v_j \in \text{Span}(P_j) \).

**Step 1.b. Results for the Exponential Kernel \( K \):**

For the exponential kernel, consider the re-parametrization \( \theta = \hat{\theta}_n + \sum_{j=1}^{r} \tilde{\kappa}_n^{1/j} P_j h \). This implies that, uniformly in \( h \):

\[
\| \tilde{g}_n(\hat{\theta}_n + \sum_{j=1}^{r} \tilde{\kappa}_n^{1/j} P_j h)/\kappa_n \|_{W_n} \geq \left[ \sum_{j=1}^{r} C_j \|P_j h\|^j \log(n)^{1/a} - o_p(1) \right] / [1 + o_p(1)].
\]

Using the monotonicity of the exponential kernel, this implies:

\[
\hat{K}_n(\hat{\theta}_n + \sum_{j=1}^{r} \tilde{\kappa}_n^{1/j} P_j h) \leq C_1 \exp \left( -C_2 \left[ \sum_{j=1}^{r} C_j \|P_j h\|^j \log(n) - o_p(1) \right] \right) = O_p(n^{-4})
\]

uniformly in \( h \) such that \( \sum_{j=1}^{r} C_j \|P_j h\|^j \geq 4/C_2 \). Using the same approach as for the compact kernel, we have:

\[
\hat{\theta}_n = \hat{\theta}_n + \sum_{j=1}^{r} \tilde{\kappa}_n^{1/j} P_j \left[ \int_{h, \sum_{j=1}^{r} \|P_j h\| \geq 4/(C_2) h \hat{\pi}_n(\hat{\theta}_n + \sum_{j=1}^{r} \tilde{\kappa}_n^{1/j} P_j h) dh \right] + O_p(n^{-4}).
\]

Since \( n^{-4} = o(\kappa_n) = o(\tilde{\kappa}_n) \), this implies that \( P_j(\hat{\theta}_n - \hat{\theta}_n) = O_p(\kappa_n^{1/j}) \). Similarly:

\[
\int_{\Theta} (\theta - \hat{\theta}_n)(\theta - \hat{\theta}_n)' \hat{\pi}_n(\theta) d\theta = \sum_{j=1}^{r} \kappa_n^{2/j} P_j O_p(1) P_j' + O_p(n^{-4}).
\]
Putting everything together, we have $\Sigma_n = \sum_{j=1}^r \tilde{\kappa}_n^{2/j} P_j O_p(1) P_j' \sum r_j = 1 \tilde{\kappa}_n^2/j \sum P_j O_p(1)$ so that for any $v \in \text{Span}(P_r)$, $v \Sigma_n v' = O_p(\tilde{\kappa}_n^{2/j})$ which by Lemma \ref{lemma} implies $|\lambda_{\min}(B_{n,LS})| = O_p(\tilde{\kappa}_n^{1-1/j})$ and $B_{n,LS} v_j = O_p(\tilde{\kappa}_n^{1-1/j})$ for any $v_j \in \text{Span}(P_j)$.

This concludes the proof.

\begin{proof}[Proof of Proposition \ref{prop}]
Let $\hat{\Pi}_n$ be the probability function associated with $\hat{\pi}_n$

$$\hat{\Pi}_n (\|\theta - \hat{\theta}_n\| > \varepsilon/6) \geq \min \left( \int_{\|\theta - \hat{\theta}_n\| \leq \varepsilon/3} \hat{\pi}_n(\theta) d\theta, \int_{\|\theta - \hat{\theta}_n\| \leq \varepsilon/3} \hat{\pi}_n(\theta) d\theta \right) \geq \eta + o_p(1)$$

since $\hat{\theta}_n$ has always a distance of at least $\varepsilon/6$ from either one of these two $\varepsilon/3$ balls. Applying Chebyshev’s inequality over the distribution $\hat{\pi}_n$ implies:

$$\hat{\Pi}_n (\|\theta - \hat{\theta}_n\| > \varepsilon/6) = \hat{\Pi}_n (\|\theta - \hat{\theta}_n\|^2 > \varepsilon^2/36) \leq \frac{36}{\varepsilon^2} \times \text{trace}(\Sigma_n).$$

Putting everything together, we get:

$$\frac{\eta \varepsilon^2}{36} + o_p(1) \leq \text{trace}(\Sigma_n) \leq d_\theta \lambda_{\max}(\Sigma_n).$$

Given that $\eta \varepsilon^2/[36d_\theta] + o_p(1) > 0$ with probability going to 1, Lemma \ref{lemma} implies that:

$$\lambda_{\min}(B'_{n,LS} B_{n,LS}) = O_p(\tilde{\kappa}_n^2)$$

which concludes the proof.

\end{proof}

\begin{proof}[Proof of Theorem \ref{thm}]
Each case described in the Theorem will be treated separately.

\textbf{Case i. $\Theta_0$ has non-empty interior:}

By assumption, there exists $\varepsilon > 0$ and $\theta_0 \in \Theta_0$ such that $B_{5\varepsilon/3}(\theta_0) \subseteq \Theta_0$. In this open ball $B_{5\varepsilon/3}(\theta_0)$, we can find two points $\theta_1, \theta_2$ such that $\|\theta_1 - \theta_2\| = \varepsilon$ and $B_{\varepsilon/3}(\theta_1) \subseteq \Theta_0$, $B_{\varepsilon/3}(\theta_2) \subseteq \Theta_0$. Then, by definition of the weakly identified set and Assumptions \ref{assumption2} \ref{assumption1}, $\sup_{\theta \in B_{\varepsilon/3}(\theta_1)} \|\hat{g}_n(\theta)\|_w / \kappa_n = o_p(1)$. Since for either compact or exponential kernel, we have $K$ continuous:

$$\sup_{\theta \in B_{\varepsilon/3}(\theta_1)} \hat{K}_n(\theta) = \sup_{\theta \in B_{\varepsilon/3}(\theta_1)} K(\|\hat{g}_n(\theta)\|_w / \kappa_n - \|\hat{g}_n(\hat{\theta}_n)\|_w / \kappa_n)$$

$$= K(O_p(n^{-1/2} \kappa_n^{-1}))$$

$$= K(0) + o_p(1).$$
Note that \( K(0) > 0 \) by assumption. Now the integral of interest can be bounded using:

\[
\frac{\text{vol}(B_{\varepsilon/3}(\theta_1))K(0) + o_p(1)}{\text{vol}(\Theta)} \leq \frac{\int_{\theta \in B_{\varepsilon/3}(\theta_1)} \hat{K}_n(\theta) d\theta}{\int_{\theta \in \Theta} \hat{K}_n(\theta) d\theta} = \frac{\int_{\theta \in B_{\varepsilon/3}(\theta_1)} \hat{K}_n(\theta) d\theta}{\int_{\theta \in B_{\varepsilon/3}(\theta_1)} \hat{K}_n(\theta) d\theta + \int_{\theta \in B_{\varepsilon/3}(\theta_2)} \hat{K}_n(\theta) d\theta} = \frac{1}{2} + o_p(1)
\]

where \( \text{vol}(B_{\varepsilon/3}(\theta_1)) \) is the volume of the ball: \( \int_{B_{\varepsilon/3}(\theta_1)} d\theta \). This implies that the assumption in Proposition 1 is satisfied for this choice of \( \varepsilon \) and for \( \eta = \frac{\text{vol}(B_{\varepsilon/3}(\theta_1))K(0)}{\text{vol}(\Theta)\|K\|_\infty} > 0 \).

**Case ii. \( \Theta_0 \) finite:**

Pick \( \varepsilon = \min_{\theta_1, \theta_2 \in \Theta_0, \theta_1 \neq \theta_2} \| \theta_1 - \theta_2 \| \). Uniformly in \( \theta \not\in \bigcup_{j=0}^k B_{\varepsilon/3}(\theta_j) \):

\[
\| \bar{g}_n(\theta) \|_W \geq \left[ \eta(\varepsilon/3) - \sup_{\theta \in \Theta} \frac{\| \mathcal{G}_n(\theta) \|}{\lambda \sqrt{n}} \right] \left[ 1 + o_p(1) \right] = \eta(\varepsilon/3) - O_p(n^{-1/2}).
\]

**Case ii.a. Compact Kernel:**

Assumption 1 implies that for the compact kernel \( \sup_{\theta \in \bigcup_{j=0}^k B_{\varepsilon/3}(\theta_j)} \hat{K}_n(\theta) = 0 \) with probability going to 1 and for any \( j \in \{0, \ldots, k\} \), \( \theta \in B_{\varepsilon/3}(\theta_j) \):

\[
C\|\theta - \theta_j\|_r / \kappa_n - o_p(1) \leq \| \bar{g}_n(\theta) \|_W / \kappa_n \leq C\|\theta - \theta_j\|_r / \kappa_n + o_p(1).
\]

Using the re-parameterization \( \theta = \theta_j + h \kappa_n^{1/r} \): \( C\|h\|_r - o_p(1) \leq \| \bar{g}_n(\theta) \|_W / \kappa_n \leq C\|h\|_r + o_p(1) \) so that \( \hat{K}_n(\theta) = 0 \) with probability going to 1 uniformly in \( \|h\|_r \geq 2/C \) and \( \hat{K}_n(\theta) \geq \inf_{x \in [0,3/4]} K(x) + o_p(1) \) uniformly in \( \|h\|_r \leq 1/[2C] \). This implies that, with probability going to 1:

\[
0 < \kappa_n^{d/b/r} \left( \inf_{x \in [0,3/4]} K(x) + o_p(1) \right) \int_{\|h\|_r \leq 1/[2C]} dh \leq \int_{B_{\varepsilon/3}(\theta_j)} \hat{K}_n(\theta) d\theta \leq \kappa_n^{d/b/r} \|K\|_\infty \int_{\|h\|_r \leq 1/[2C]} dh < +\infty.
\]

This implies that with probability going to 1:

\[
\int_{B_{\varepsilon/3}(\theta_j)} \hat{\pi}_n(\theta) d\theta \geq \frac{\inf_{x \in [0,3/4]} K(x)}{\|K\|_\infty} \frac{\text{vol}(B_{1/[2C]^{1/r}}(0))}{\text{vol}(B_{[2/C]^{1/r}}(0))} + o_p(1) > 0
\]

for any \( j \in \{0, \ldots, k\} \) and with probability going to 1, which provides the desired result.
Case ii.b. Exponential Kernel:

For the exponential kernel, we have:

$$\sup_{\theta \in \mathcal{B}_{\varepsilon/3}(\theta_j)} \hat{K}_n(\theta) \leq C_1 \exp \left[ -C_2 [\theta / 3]^{a \kappa_n^{-a}} + o_p(1) \right]$$

which is a $o_p(\kappa_n^d)$ for any $d \geq 1$.\footnote{This is because $\log(\kappa_n) = o(\kappa_n^{-a})$ for any $a > 0$.} Using the re-parameterization $\theta = \theta_j + h\tilde{\kappa}_n^{-1/r}$, where $\tilde{\kappa}_n = \kappa_n \log(n)^{1/a}$ is defined in Assumption 1, we have uniformly in $h$:

$$C \log(n)^{1/a} \|h\|^{r} - o_p(1) \leq \|\tilde{g}_n(\theta)\|_{W/\kappa_n} \leq C \log(n)^{1/a} \|h\|^{r} + o_p(1).$$

In turn, this implies that for $\|h\|^{ra} > d/[C_2 C^a] > 0$:

$$\hat{K}_n(\theta) \leq C_1 \exp \left[ -C_2 C^a \|h\|^{ra} \log(n) + o_p(1) \right] = o_p(n^{-d})$$

for any $d \geq 1$. The integral of interest can now be bounded above and below for $n \geq 2$:

$$\kappa_n^{d/a} C_1 \int_{\|h\|^{ra} \leq d/a r \log(n)/[C_2 C^a]} \exp \left[ -C_2 C^a \|h\|^{ra} + o_p(1) \right] dh + o_p(n^{-d/a/r})$$

$$\leq \int_{\mathcal{B}_{\varepsilon/3}(\theta_j)} \hat{K}_n(\theta) d\theta$$

$$\leq \kappa_n^{d/a} C_1 \int_{\|h\|^{ra} \leq d/a r \log(n)/[C_2 C^a]} \exp \left[ -C_2 C^a \|h\|^{ra} + o_p(1) \right] dh + o_p(n^{-d/a/r}).$$

Now note that:

$$\int_{\|h\|^{ra} \leq d/a r \log(n)/[C_2 C^a]} \exp \left[ -C_2 C^a \|h\|^{ra} + o_p(1) \right] dh$$

$$\geq \int_{\|h\|^{ra} \geq d/a r \log(2)/[C_2 C^a]} \exp \left[ -C_2 C^a \|h\|^{ra} + o_p(1) \right] dh > 0$$

$$\int_{\|h\|^{ra} \leq d/a r \log(n)/[C_2 C^a]} \exp \left[ -C_2 C^a \|h\|^{ra} + o_p(1) \right] dh$$

$$\leq \int_{\mathbb{R}^d} \exp \left[ -C_2 C^a \|h\|^{ra} + o_p(1) \right] dh < +\infty.$$
Since the first term is strictly positive, this provides the desired result.

**Case iii.** \( \Theta_0 = \bigcup_{j=1}^k S_j \):

Let \( \theta \notin \bigcup_{j=1}^k \mathcal{N}(S_j) \), then condition iii.c. implies that \( \|\bar{g}_n(\theta)\|_{W_n}/\kappa_n \geq \eta/\kappa_n - o_p(1) \to +\infty \)

uniformly in \( \theta \). This implies that, as in the proofs of Theorem 1 and 5 for instance, we have with probability going to 1:

\[
\sup_{\theta \notin \bigcup_{j=1}^k \mathcal{N}(S_j)} K\left( \|\bar{g}_n(\theta)\|_{W_n}/\kappa_n - \|\tilde{g}_n(\hat{\theta}_n)\|_{W_n}/\kappa_n \right) = \sup_{\theta \notin \bigcup_{j=1}^k \mathcal{N}(S_j)} K\left( \|\bar{g}_n(\theta)\|_{W_n}/\kappa_n - o_p(1) \right) = 0
\]

for the compact kernel. For the exponential kernel, we have for any \( d \geq 1 \):

\[
\sup_{\theta \notin \bigcup_{j=1}^k \mathcal{N}(S_j)} K\left( \|\bar{g}_n(\theta)\|_{W_n}/\kappa_n - \|\tilde{g}_n(\hat{\theta}_n)\|_{W_n}/\kappa_n \right) \leq C_1 \exp \left( -C_2 \left[ \eta^a/\kappa_n - o_p(1) \right] \right) \leq o_p(n^{-d}).
\]

Then assumption iii.c. implies that for any \( \theta \) such that \( d(\theta, \Theta_0) \geq 2\kappa_n/C \), we have:

\[
\|\bar{g}_n(\theta)\|_{W_n}/\kappa_n \geq 2 - o_p(1)
\]

which is greater than 3/2 with probability going to 1 so that for the compact kernel \( \hat{K}_n(\theta) = 0 \) with probability going to 1 uniformly in \( \theta \) with \( d(\theta, \Theta_0) \geq 2\kappa_n/C \). Similarly, for any \( \theta \) such that \( d(\theta, \Theta_0) \geq [d^{1/a}2C^{-1}C_2^{-1/a}]\kappa_n \log(n)^{1/a} \), we have:

\[
\hat{K}_n(\theta) \leq C_1 \exp \left( -[d^{a} \log(n) - o_p(1)] \right) \leq o_p(n^{-d})
\]

for the exponential kernel. In both cases, we have with probability going to 1:

\[
\hat{K}_n(\theta) \leq o_p(n^{-d_0})
\]

uniformly in \( \theta \) such that \( d(\theta, \Theta_0) \geq C_K \tilde{\kappa}_n \), where the constant \( C_K \) corresponds to the bounds described above for the compact and exponential kernels. \( \tilde{\kappa}_n = \kappa_n \) for the compact kernel and \( \tilde{\kappa}_n = \kappa_n \log(n)^{1/a} \) for the exponential kernel.

Furthermore, for the compact kernel, \( d(\theta, \Theta_0) \leq \kappa_n/[2C] \) implies that:

\[
\|\bar{g}_n(\theta)\|_{W_n}/\kappa_n \leq 1/2 + o_p(1)
\]

so that, uniformly in \( \theta \) such that \( d(\theta, \Theta_0) \leq \kappa_n/[2C] \), we have with probability going to 1:

\[
\hat{K}_n(\theta) \geq \inf_{x \in [0, 2/3]} K(x) > 0.
\]

Similarly, for \( d(\theta, \Theta_0) \leq \kappa_n \log(n)^{1/a}/[2C] \), we have for the exponential kernel:

\[
\hat{K}_n(\theta) \geq C_1 \exp \left( -C_2 \log(n) \right) \times [1 + o_p(1)].
\]
This implies the following two inequalities:

\[
\int_{\theta, d(\theta, S_j) \leq \kappa_n/\|2C\|} \hat{K}_n(\theta) d\theta \leq \int_{\mathcal{N}(S_j)} \hat{K}_n(\theta) d\theta \leq \int_{\theta, d(\theta, S_j) \leq C\kappa_n} \hat{K}_n(\theta) d\theta + o_p(n^{-d_\theta}).
\]

The next step is to find a lower bound for the term on the left-hand side and an upper-bound for the term on the right-hand side using the change of variable \(\varphi_j\). Before applying the change of variable, it is necessary to map the \(\kappa_n\) neighborhoods in the integrals with neighborhoods in the space induced by the change of variable.

Condition iii.a. requires that \(U_j\) has non-empty interior and is bounded so that there exists \(0 < \varepsilon_1 \leq \varepsilon_2 < \infty\) and \(\nu_j \in S_j\) such that:

\[
B_{\varepsilon_1}(\nu_j) \subseteq U_j \subseteq B_{\varepsilon_2}(\nu_j) \Rightarrow B_{\varepsilon_1}(\nu_j) \times \{0\} \subseteq U_j \times \{0\} = \varphi_j^{-1}(S_j) \subseteq B_{\varepsilon_2}(\nu_j) \times \{0\}.
\]

Note that for any \(\vartheta_1, \vartheta_2 \in \mathcal{N}(U_j) \times \mathcal{N}(\{0\})\) and \(\vartheta_j \in U_j \times \{0\}\), we have by the mean-value theorem:

\[
\|\varphi_j(\vartheta_1) - \varphi_j(\vartheta_2)\| = \|\partial_\vartheta \varphi_j(\tilde{\vartheta})(\vartheta_1 - \vartheta_2)\| \leq |\lambda_{\max}(\partial_\vartheta \varphi_j(\tilde{\vartheta}))| \times \|\vartheta_1 - \vartheta_2\| \leq \lambda_j \times \|\vartheta_1 - \vartheta_2\|
\]

This implies that \(B_{C\kappa_n}(S_j) \subseteq \varphi_j\left(B_{C\kappa_n/\bar{S}_j}(U_j) \times B_{C\kappa_n/\bar{S}_j}(\{0\})\right)\) so that:

\[
\int_{\theta, d(\theta, S_j) \leq C\kappa_n} \hat{K}_n(\theta) d\theta \leq \int_{\theta=\varphi_j^{-1}(\theta), d(\theta, U_j \times \{0\}) \leq C\kappa_n} \hat{K}_n(\theta) d\theta
\]

\[
\leq \int_{\theta=\varphi_j^{-1}(\theta), \vartheta_j \in B_{\varepsilon_2}(\nu_j) \times B_{C\kappa_n/\bar{S}_j}} \hat{K}_n(\theta) d\theta.
\]

The mean-value theorem can also be used to derive a lower bound:

\[
\|\varphi_j(\vartheta_1) - \varphi_j(\vartheta_2)\| = \|\partial_\vartheta \varphi_j(\tilde{\vartheta})(\vartheta_1 - \vartheta_2)\| \geq \lambda_{\min}(\partial_\vartheta \varphi_j(\tilde{\vartheta})) \times \|\vartheta_1 - \vartheta_2\| \geq \lambda_j \times \|\vartheta_1 - \vartheta_2\|
\]

By definition of \(\varepsilon_1\), for \(n\) large enough

\[
\varphi_j\left(B_{\varepsilon_1/2}(\nu_j) \times B_{C\kappa_n/\bar{S}_j}(\{0\})\right) \subseteq \varphi_j\left(B_{\varepsilon_1}(\theta_j) \times B_{C\kappa_n/\bar{S}_j}(\{0\})\right) \subseteq B_{C\kappa_n}(S_j).
\]

This results in another inequality:

\[
\int_{\theta=\varphi_j^{-1}(\theta), \vartheta_j \in B_{\varepsilon_1/2}(\nu_j) \times B_{\kappa_n/\|2\mathcal{C}\bar{S}_j\|}} \hat{K}_n(\theta) d\theta \leq \int_{\theta, d(\theta, S_j) \leq \kappa_n/\|2\mathcal{C}\|} \hat{K}_n(\theta) d\theta.
\]

Now that the neighborhoods are defined, consider the change of variable: \(\varphi_j(\vartheta) = \theta\), then the integral becomes:

\[
\int_{\vartheta \in B_{\varepsilon_1/2} \times B_{\kappa_n/\|2\mathcal{C}\bar{S}_j\|}} |\det(\partial_\vartheta \varphi_j(\vartheta))| \hat{K}_n \circ \varphi_j(\vartheta) d\vartheta.
\]

73
Condition iii.a. implies that uniformly in \( \vartheta \in \varphi_j(\mathcal{N}(S_j)) \), the determinant of the Jacobian transformation is bounded above and below:

\[
0 < \frac{\Delta_j \alpha}{d_j} \leq |\det(\partial_\vartheta \varphi_j(\vartheta))| \leq \frac{\pi^d}{\alpha_j} < +\infty.
\]

Combining this together with the bounds on \( \tilde{K}_n \) implies the following lower bound; for the compact kernel, with probability going to 1:

\[
\frac{\Delta_j \alpha}{d_j} \times \left( \inf_{x \in [0,2/3]} K(x) \right) \int_{B_{\varepsilon_1/2} \times B_{\kappa_n/\varepsilon_j}(\{0\})} d\vartheta \leq \int_{\vartheta \in B_{\varepsilon_1/2} \times B_{\kappa_n/\varepsilon_j}(\{0\})} |\det(\partial_\vartheta \varphi_j(\vartheta))| \tilde{K}_n \circ \varphi_j(\vartheta) d\vartheta.
\]

The formula for the integral of a \( d \)-dimensional ball provides a closed form expression for the integral on the left-hand side:

\[
\int_{B_{\varepsilon_1/2} \times B_{\kappa_n/(2\varepsilon_j)}(\{0\})} d\vartheta = \pi^{d_j/2} \frac{\Gamma(k_j/2)\Gamma(\varepsilon_1/2)}{\Gamma(\varepsilon_1/2 + k_j/2)} [\varepsilon_1/2]^d - k_j [\kappa_n/(2\varepsilon_j)]^{k_j}
\]

where \( \Gamma \) is Euler’s gamma function. Similarly, for the exponential kernel:

\[
\frac{\Delta_j \alpha}{d_j} C_1 \exp(-C_2 \log(n)) [1 + o_p(1)] \int_{B_{\varepsilon_1/2} \times B_{\kappa_n/\varepsilon_j}(\{0\})} d\vartheta \leq \int_{\vartheta \in B_{\varepsilon_1/2} \times B_{\kappa_n/\varepsilon_j}(\{0\})} |\det(\partial_\vartheta \varphi_j(\vartheta))| \tilde{K}_n \circ \varphi_j(\vartheta) d\vartheta.
\]

Similarly, a change of variable can be applied to the upper-bound:

\[
\int_{\vartheta = \varphi_j(\vartheta), \vartheta \in B_{2\varepsilon_2}(\nu_j) \times B_{C_K/\mathcal{L}_j}(\tilde{\kappa}_n)} \tilde{K}_n(\vartheta) d\vartheta = \int_{\vartheta \in B_{2\varepsilon_2}(\nu_j) \times B_{C_K/\mathcal{L}_j}(\tilde{\kappa}_n)} |\det(\partial_\vartheta \varphi_j(\vartheta))| \tilde{K}_n \circ \varphi_j(\vartheta) d\vartheta
\]

\[
\leq \frac{\pi^d_k}{\alpha_j} \times \|K\|_\infty \times \int_{\vartheta \in B_{2\varepsilon_2}(\nu_j) \times B_{C_K/\mathcal{L}_j}(\tilde{\kappa}_n)} d\vartheta.
\]

The integral on the right-hand side can also be computed using the formula for the volume of a \( d \)-dimensional ball:

\[
\int_{\vartheta \in B_{2\varepsilon_2}(\nu_j) \times B_{C_K/\mathcal{L}_j}(\tilde{\kappa}_n)} d\vartheta = \pi^d_\alpha \frac{\Gamma([d_\alpha - k_j]/2 + 1)\Gamma(k_j/2 + 1)}{\Gamma(k_j/2 + 1)\Gamma([d_\alpha - k_j]/2 + 1)} [2\varepsilon_2]^{d_\alpha - k_j} [\kappa_n C_K/\mathcal{L}_j]^{k_j}.
\]

Putting everything together and given that \( n^{-d_\alpha} = o(\tilde{\kappa}_n^{-k_j}) \), we have with probability going to 1:

\[
\int_{\mathcal{N}(S_j)} \tilde{K}_n(\vartheta) d\vartheta \asymp \tilde{\kappa}_n^{k_j}
\]
for each set $S_j$ covering $\Theta_0$. This implies that:

$$\int_{\mathcal{N}(S_j)} \hat{\pi}_n(\theta) d\theta \simeq \nu_{\min \ell}^{k_j}$$

which goes to 0 for all $j$ with $k_j > k = \min \ell k_\ell$. Asymptotically, the sets $S_j$ with the largest degree of identification failure $k_j$ will dominate the posterior distribution.

To get the desired result, pick $j$ such that $k_j = k$ and the associated $\varepsilon_1$ described above. By a similar reasoning as before, for any $0 < \varepsilon < \varepsilon_1/2$ there exists a constant $C_\varepsilon > 0$ such that for any $\nu \in B_{\varepsilon_1}(\nu_j)$, we have with probability going to 1:

$$C_\varepsilon k_j^{1/\varepsilon} + o_p(n^{-d}) \leq \int_{\mathcal{N}(S_j)} \hat{K}_n(\theta) d\theta \leq \int_{\mathcal{N}(S_j)} \hat{K}_n(\theta) d\theta$$

where the last inequality hold if $\varepsilon$ is small enough so that $B_{\varepsilon}(\nu) \times B_{\varepsilon}(\{0\}) \subseteq \mathcal{N}(U_j) \times \mathcal{N}(\{0\})$ hold. Such $\varepsilon > 0$ exists by the definition of open sets and neighborhoods. This implies that for any two different $\nu_1, \nu_2$ in $B_{\varepsilon_1}(\nu_j)$ we can find a $\varepsilon > 0$ small enough such that the conditions in Lemma 1 hold. This concludes the proof.

### Appendix B  Proofs for the Results of Section 4

#### B.1 Weak or Set Identification

**Proof of Theorem 9.** The proof will treat (semi)-strong and weak identification separately.

**Case 1: (semi)-strong identification.**

Given the assumptions of Lemma D4 hold, $\hat{\ell}_n = 1$ with probability going to 1. Under the assumptions of Theorems 1, 2, 5 or 6, $\hat{\theta}_n$ computed using the sup-norm, least-squares approximations or by minimizing the GMM criterion is consistent and asymptotically normal. The second result is then a consequence of conditions 2.iii. in the Theorem.

**Case 2: weak/set identification.**

Under weak or set identification, Lemmas D4 and D6 imply that, with probability going to 1, $\hat{\ell}_n \geq \ell^*$. The remaining assumptions imply that the second step, inference, is asymptotically valid which concludes the proof.

**Proof of Remark 2.** Since neither $\bar{g}_n(\alpha_0, \cdot)$ nor $\hat{V}_n(\alpha_0, \cdot)$ depend on $\beta$, $S_n(\alpha_0)$ does not depend on $\beta$ so that equation (12) holds. The consistency of $\hat{V}_n$ and the central limit theorem for $\bar{g}_n$ imply that equation (13) holds. Under strong identification, $S_n(\alpha_0)$ is a Likelihood-ratio statistic so that equation (14) is a standard results, see e.g. Newey & McFadden (1994). If
the stacked moment and gradient vector \((\vec{g}_n(\alpha_0, \beta)', \text{vec}(\partial_{\alpha, \beta}\vec{g}_n(\alpha_0, \beta)))'\)' and its variance do not depend on \(\beta\) either then the infimum of the K statistic of Kleibergen (2005) over \(\beta\) is the numerically equal to the K statistic at an arbitrary \(\beta\). This implies that the limiting distribution is the same as for the full vector inference which coincides with the limiting distribution implied by projection inference. This in turn implies that the projected K-statistic has asymptotically exact coverage.

\[\square\]

B.2 Higher-Order Identification

Proof of Theorem 10. The proof will treat the two cases: (semi)-strong and weak identification separately.

Case 1: (semi)-strong identification.

By Lemma D8, with probability going to 1, \(\tilde{h}_n^2 \leq C[\sqrt{n}\kappa_n^2/\lambda_{\min}(\partial_\theta g_n(\theta_0)')\partial_\theta g_n(\theta_0)')]^2 \overset{def}{=} \varepsilon_n^2\) for some \(C \geq 0\). The size distortion implied by a non-central \(\chi_1^2\) distribution with non-centrality parameter \(\varepsilon_n\) is given by:

\[
\int_{-\sqrt{c_{1-\alpha}}}^{\sqrt{c_{1-\alpha}}} \phi(x + \varepsilon_n)dx - (1 - \alpha) = \int_{-\sqrt{c_{1-\alpha}}}^{\sqrt{c_{1-\alpha}}} [\phi(x + \varepsilon_n) - \phi(x)]dx
\]

\[
= \varepsilon_n \int_{-\sqrt{c_{1-\alpha}}}^{\sqrt{c_{1-\alpha}}} \phi'(x)dx + o(\varepsilon_n)
\]

\[
= 2\varepsilon_n [\phi(\sqrt{c_{1-\alpha}}) - \phi(0)] + o(\varepsilon_n).
\]

This implies result a. if \(\varepsilon_n = o(\tilde{\gamma}_n)\).

Case 2: weak/set identification.

First, by using similar arguments as in the proof of Lemma D6 it can be shown that Lemma D7 implies that \(\hat{\ell}_n \geq \ell^*\) with probability going to 1. Given the remaining assumptions, the rest of the proof is identical to the proof of Theorem 9 b. This concludes the proof. \(\square\)

Appendix C  Additional Results

C.1 Additional Rules of Thumb for Section 4.1.2

C.1.1 Over-Identified Models

Consider the over-identified linear Gaussian experiment:

\[ \bar{g}_n(\theta) = A_n + B_n \theta \]

where \( A_n - B_n \theta_0 = Z_1, B_n = \bar{B}_n + Z_2 \) and \( Z_1', \text{vec}(Z_2)' \)' Gaussian, \( d_\theta \leq \text{dim}(Z_1) \). Let \( W \) be a non-stochastic positive definite matrix which does not depend on \( \theta \). Let \( \mathbb{E}(Z_1Z_1') = V_1/n \) and \( \mathbb{E}(Z_2WZ_1) = V_{21} \). Furthermore, assume that \( \bar{B}_n = n^{-\delta} \times B \) with \( B \) full rank and \( \delta \in [0, 1/2) \). Under the stated assumptions:

\[ \hat{\theta}_n - \theta_0 = - (\bar{B}_n'W\bar{B}_n)^{-1} \bar{B}_n'WZ_1 - (\bar{B}_n'W\bar{B}_n)^{-1} Z_2'WZ_1 + O_p(n^{-3/2 + 3\delta}). \]

Take \( v_{j,n}' \) to be a right eigenvector of \( W^{1/2}\bar{B}_n \), associated with the eigenvalue \( \lambda_{j,n} \) then:

\[ v_{j,n}(\hat{\theta}_n - \theta_0) = -\lambda_{j,n}^{-1}W_{1/2}Z_1 - \lambda_{j,n}^{-2}Z_2'WZ_1 + O(n^{-3/2 + 3\delta}). \]

As in the just-identified case:

\[ \frac{|\text{bias}|^2}{|\text{variance}|} = \frac{1}{n|\lambda_{j,n}|^2} \frac{v_{j,n}'V_{21}V_{12}v_{j,n}}{v_{j,n}'V_{1}v_{j,n}} + o \left( \frac{1}{n|\lambda_{j,n}|^2} \right). \]

The rule-of-thumb then proceed the same way as in the just-identified case.

C.1.2 A non-local approach to the rule-of-thumb

When the model is set identified but the local identification condition holds, as in Examples 2 the rule-of-thumb above may not perform well because \( V_{12} \) will tend to be very small (\( \Theta_0 \) covers a wide range but \( \bar{g}_n \) is less than \( \kappa_n \)). A simple solution is to split \( \Theta_0 \) into clusters within which the local rule-of-thumb can provide a better approximation. In practice, one can apply the k-means algorithm\(^1\) to build clusters on \( \{ \theta, \|g_n(\theta)\|_{W_n} - \inf_\theta \|g_n(\theta)\|_{W_n} \leq \kappa_n \} \) and apply the rule of thumb within each cluster, \( B_n \) should be re-approximated within each cluster. The largest cutoff across clusters becomes the global rule-of-thumb for Algorithm 2. This yields an approximation for size distortion within clusters\(^2\). A concern may be that

---

\(^1\) See e.g. Hastie et al. (2009), Chapter 14.3, for an overview of cluster analysis.

\(^2\) This approach was applied in Appendix G.2 in Monte-Carlo simulations for Example 2.
when these clusters are far from one another which leads to between-cluster size distortion. A between-cluster rule-of-thumb will have to be computed. Suppose the k-means procedure picked \( C \geq 2 \) clusters. By construction, \( \hat{\theta}_n \) belongs to one of these clusters. Denote this cluster \( cl_n \) and take \( \theta_{cl_n} \), a solution to (2) within that cluster. For \( v_{j,n} \) described above, the t-statistic for testing \( v_{j,n}'(\theta - \theta_{cl}) = 0 \), where \( \theta_{cl} \) belongs to one of the several potential clusters \( cl \in \{1, \ldots, C\} \), is:

\[
t_n = \frac{v_{j,n}'(\hat{\theta}_n - \theta_{cl})}{\sqrt{v_{j,n}'B_nV_{cl_n}B_n'v_{j,n}}} = \frac{n}{\sqrt{n} \times \lambda_{j,n}^{-1}\times \sqrt{v_{j,n}'V_{cl_n}V_{cl_n}'v_{j,n}}}.
\]

The last equality suggests that the between-cluster size distortion is a function of the distance between the clusters relative the sampling uncertainty. If the distance is small relative to standard errors, then size distortion is minimal. This yields the between-cluster rule-of-thumb:

\[
\Lambda^2_{n,\text{between}} \geq \frac{n \times \sup_{cl,cl'} d(cl, cl')}{c(\gamma_n)^2 \times \inf_{d \in \{1, \ldots, C\}} \sqrt{\lambda_{\min}(V_d)}},
\]

where \( d(cl, cl') \) is the distance between the two clusters \( cl \) and \( cl' \). If there is only one cluster, this rule-of-thumb is not needed. The overall rule-of-thumb is simply the largest value of the between and within rules-of-thumb computed above. In the Monte-Carlo simulations, the following stopping rule was used to determine whether an additional cluster should be added: if the distance between centroids, with the other clusters, was greater than 1% of the diameters of the clusters then it would be added. This is a quick way to check if the two cluster are close to one another or not. Other criteria could be considered in future research.

C.2 Additional Results for Section 4.1

C.2.1 A quasi-CLT for \( A_{n,LS}, B_{n,LS} \)

**Lemma C2.** (Addional Asymptotic Results for \( A_{n,LS}, B_{n,LS} \) under Strong and Semi-Strong Identification) Suppose that the assumptions of Theorem 6 and the following hold:
i. uniform Central Limit Theorem:
\[
\sqrt{n} \begin{pmatrix}
\bar{g}_n(\theta_0) \\
\text{vec}[\partial_\theta \bar{g}_n(\theta_0)] - \text{vec}[\partial_\theta g_n(\theta_0)]
\end{pmatrix} \overset{d}{\rightarrow} \mathcal{N}(0, V).
\]

ii. stochastic equicontinuity condition, i.e. for all $\delta_n \downarrow 0$:
\[
\sup_{\|\theta_1 - \theta_2\| \leq \delta_n} \|\sqrt{n}(\bar{g}_n(\theta_1) - \bar{g}_n(\theta_2)) - \text{vec}[\partial_\theta g_n(\theta_1) - \partial_\theta g_n(\theta_2)]\| = o_p(1)
\]

then $A_{n,LS} = \bar{g}_n(\theta_0) - B_{n,LS} \theta_0 + o_p(n^{-1/2})$ and $B_{n,LS} = \partial_\theta g_n(\theta_0) H_n + o_p(n^{-1/2})$ so that
\[
\sqrt{n} \begin{pmatrix}
A_{n,LS} + B_{n,LS} \theta_0 \\
\text{vec}(B_{n,LS} - B_{n,LS})
\end{pmatrix} = \sqrt{n} \begin{pmatrix}
\bar{g}_n(\theta_0) \\
\text{vec}[\partial_\theta \bar{g}_n(\theta_0) - \partial_\theta g_n(\theta_0)]
\end{pmatrix} + o_p(1) \overset{d}{\rightarrow} \mathcal{N}(0, V)
\]

where $\bar{B}_{n,LS}$ corresponds to $B_{n,LS}$ computed using the random measure $\hat{\pi}_n$:
\[
\bar{B}_{n,LS}' = \Sigma_n^{-1} \int_{\Theta} (\theta - \theta_n)[\int_{\Theta} \{g_n(\theta) - g_n(\bar{\theta})\} \hat{\pi}_n(\bar{\theta}) d\bar{\theta}]' \hat{\pi}_n(\theta) d\theta.
\]

C.2.2 Primitive Conditions for Theorem 9

Lemma C3 (Asymptotic Distribution of the Profile S Statistic under (Semi)-Strong Identification). Suppose that $\theta = A(\beta', \gamma')$ where $A$ is an invertible matrix and $\gamma$ is (semi)-strongly identified: the assumptions of Theorem [4][5][6] or 4 hold for $\gamma$ holding $\beta = \beta_0$ fixed. Let $\hat{\gamma}_n \overset{p}{\rightarrow} \lim_{n \rightarrow \infty} n \times \text{var}(\bar{g}_n(\theta_0, \gamma_0))$ positive definite and $\hat{\gamma}_n$ is computed using $W_n = V_n^{-1}$, then:
\[
n \times \bar{g}_n \left(A(\beta'_0, \gamma'_0)\right)' \hat{\gamma}_n^{-1} \bar{g}_n \left(A(\beta'_0, \gamma'_0)\right) \overset{d}{\rightarrow} \chi^2_{\text{dim}(\beta') - \text{dim}(\gamma')}.
\]

Proposition C2 (Verifying Theorem 9’s Condition 2. for the S-statistic). Suppose the assumptions for Lemmas D4 and D6 hold. Suppose there exists a re-parameterization with an invertible matrix $A$ and vectors $\gamma_\ell$, $\ell = 1, \ldots, L$ such that:
\[
\theta = A(\gamma_1, \ldots, \gamma_L)', \quad R_\ell \theta = c \Leftrightarrow (\gamma'_1, \ldots, \gamma'_L)' = \tilde{c},
\]

for $c, \tilde{c} \in \mathbb{R}^{\text{rank}(R_\ell)}$. Let $\ell^*$, $\theta_{0,c}$ and $\hat{\theta}_{n,\ell,c}$ be defined as in Theorem 9, suppose that for each $\ell \geq \ell^*$:
\[
n \times \lambda_{\text{min}}(I_\ell A' \partial_\theta g_n(\theta_{0,c})' \partial_\theta g_n(\theta_{0,c}) A I_\ell) \rightarrow +\infty,
\]

3
as \( n \to \infty \), where \( \mathcal{I}_\ell = \text{blockdiag}(0_{\text{rank}(R_\ell)}, I_{d_\theta - \text{rank}(R_\ell)}) \). Then for each \( \ell > \ell^* \), \((\gamma'_\ell, \ldots, \gamma'_L)\) is semi-strongly identified. If furthermore, \( W_n(\theta) = \hat{V}_n(\theta)^{-1} \) is a uniformly consistent estimator for \( n \times \text{var}(\hat{g}_n(\theta)) \), then for each \( \ell \geq \ell^* \):

\[
S_{n,\ell} = \inf_{R_\ell \theta = c_\ell} n \times \left\| \hat{g}_n(\theta) \right\|_{\hat{V}_n^{-1}}^2 \overset{d}{\to} \chi^2_{\text{dim}(g) - [d_\theta - \text{rank}(R_\ell)]}.
\]

Let \( c_{1-\alpha,\ell} \) be the \( 1 - \alpha \) quantile of a \( \chi^2 \) distribution with \( \text{dim}(g) - [d_\theta - \text{rank}(R_\ell)] \) degrees of freedom, then the following holds:

\[
\inf_{\ell = \ell^*, \ldots, L} \mathbb{P}(T_{n,\ell} \leq c_{1-\alpha,\ell}) = 1 - \alpha + o(1).
\]

### C.3 (Counter)-Examples for Proposition 1 and Theorem 8

#### C.3.1 Examples for Theorem 8

Figure C5 shows several examples for cases i-iii considered in Theorem 8. The first row shows two sets with non-empty interior (shaded area) so that \( \Theta_0 \) has non-zero measure in \( \mathbb{R}^2 \). In each set, it is possible to find two disjoint balls that has non-zero measure in \( \mathbb{R}^2 \) and thus strictly positive posterior mass asymptotically.

The second row illustrates case ii. with finite collections of singletons arranged in various patterns. The particular alignment of the points is not relevant for the result as much as the local behaviour of the moments \( g_n \) around these points.

The third row illustrates case iii. with a one dimensional manifold on the left-hand-side: the circle can be represented as \( \{(\theta_1, \theta_2) = (\theta_{1,0}, \theta_{2,0}) + R \times (\cos(\vartheta), \sin(\vartheta)), \vartheta \in [0, 2\pi]\} \) for some \((\theta_{1,0}, \theta_{2,0}) \in \mathbb{R}^2, R > 0 \). There is thus a one-to-one mapping between the circle and \([0, 2\pi]\) which has non-empty interior in \( \mathbb{R} \). The example on the right-hand-side has \( S_1 = \text{line} \) and \( S_2 = \text{point} \) (0-dimensional manifold). In that setting it can be shown that \( \hat{\pi}_n(B_\varepsilon(S_2)) \overset{p}{\to} 0 \) for \( \varepsilon > 0 \) small, fixed. The posterior is dominated by \( S_1 \), i.e. the line. While the posterior variance is bounded below (in probability) in the direction \((1, 1)\), it converges to 0 in the direction \((1, -1)\) because \( S_2 \) has measure 0 and does not impact the posterior variance asymptotically as a result.
Figure C4: Examples of Topologies for $\Theta_0$ in Theorem 8

**case i.**

- $\theta_2$ vs $\theta_1$
- Graph showing a polygon.

**case ii.**

- $\theta_2$ vs $\theta_1$
- Scatter plot with points.

**case iii.**

- $\theta_2$ vs $\theta_1$
- Graph showing an ellipse and a line.
C.3.2 Counter-Example: a moment function that does not satisfy the conditions for Proposition 1

Consider the function:

\[ g_n(\theta) = \theta^6 \sin(1/\theta), \quad \theta \in [-1, 1]. \]

This function is twice continuously differentiable on \([-1, 1]\) with bounded second derivative. It has infinitely many zeros in \([-1, 1]\) and such that:

\[ \#\{\theta \in [-\varepsilon, \varepsilon], g_n(\theta) = 0\} = +\infty, \quad \#\{\theta \notin [-\varepsilon, \varepsilon], g_n(\theta) = 0\} < +\infty, \]

for any \(\varepsilon > 0\). This implies that:

\[ \int_{[-\varepsilon, \varepsilon]} \hat{\pi}_n(\theta) d\theta \overset{p}{\to} 1, \]

for any \(\varepsilon > 0\). In turn, the posterior variance can be bounded above by:

\[
\Sigma_n \leq \int_{[-1,1]} \theta^2 \hat{\pi}_n(\theta) d\theta \\
= \int_{[-\varepsilon, \varepsilon]} \theta^2 \hat{\pi}_n(\theta) d\theta + \int_{[-1,1]/[-\varepsilon, \varepsilon]} \theta^2 \hat{\pi}_n(\theta) d\theta \\
\leq \varepsilon^2 \times [1 + o_p(1)] + o_p(1),
\]

for any \(\varepsilon > 0\). This implies that \(\Sigma_n \overset{p}{\to} 0\) even though the model is set identified. Note that it is possible that \(\Sigma_n \overset{p}{\to} 0\) at a rate slower than \(\kappa_n^2\) so that \(\lambda_{\min}(B_{n,LS}) \overset{p}{\to} 0\) but at a slower than \(\kappa_n\) rate. Explicit rates are hard to compute analytically for this example.
Appendix D Preliminary Results for Section 4

D.1 Preliminary Results for Section 4.1

Lemma D4. (Detecting Weak/Set Identification Failures) Let \( \lambda_n = o(1) \) be a strictly positive sequence. Let \( B_{n,LS/\infty} \) be either \( B_{n,LS} \) or \( B_{n,\infty} \).

a. (Weak/Set Identification) Suppose that the assumptions of Theorem 4 or Lemma 1 hold so that \( \Sigma_n \) is a \( O_p(\tilde{\kappa}_n^2) \) on the span \( V \) defined in Theorem 4 and \( \tilde{\kappa}_n = o(\Delta_n) \), then

\[
\lim_{n \to \infty} P(\lambda_{\min}(B_{n,LS/\infty}) < \Delta_n) = 1,
\]

b. (Semi-Strong and Strong Identification) Suppose that the assumptions of Theorem 4, 5, or 6 hold and the Jacobian is such that \( \Delta_n^2 = o(\lambda_{\min}(\partial \theta g_n(\theta_0)\partial \theta g_n(\theta_0)' )) \), then

\[
\lim_{n \to \infty} P(\lambda_{\min}(B_{n,LS/\infty}) < \Delta_n) = 0.
\]
Lemma D4 a. is a direct implication of the results in Section 3. Lemma D4 b. suggests which sequences of (semi-)strongly identified models may lead to false positives when detecting identification failure. To illustrate, take $\kappa_n = \sqrt{2 \log(\log(n)) n^{-1/2}}$ and $\lambda_n = \sqrt{\log(n) n^{-1/2}}$. For these sequences, models with $n^{-1/2} \ll \lambda_{\min} (\partial_{\theta} g_n(\theta_0)) \ll \sqrt{\log(n) n^{-1/2}}$ may be detected as weakly identified. In practice, this range seems to be fairly small.

Lemma D5. (Collapsing the Weakly Identified Set into a Singleton) Let $V = \text{Span}\{v = \theta_1 - \theta_0, (\theta_1, \theta_0) \in \Theta_0^2\}$ where $\Theta_0$ is the weakly identified set defined in equation (9). Let $P_V$ be orthogonal projection matrix onto $V$ and $P_V^\perp$ its orthogonal, if $1 \leq \text{rank}(P_V^\perp) < d_\theta$ then:

a. $P_V^\perp \Theta_0 = \{P_V^\perp \theta_0\}$, with $\theta_0 \in \Theta_0$

b. let $(u^*, v^*) = (u^*_1, \ldots, u^*_k, v^*_1, \ldots, v^*_{d_\theta-k})$ be an orthogonal basis of $\mathbb{R}^{d_\theta}$ such that $\text{rank}(P_V P_v^*) = \text{rank}(P_V)$ then for any $c \in \mathbb{R}^{d_\theta-k}$

$$\Theta_0 \cap \{\theta \in \Theta, P_v^* \theta = c\} = \{\theta_{0,c}\} \text{ or } \emptyset.$$

Lemma D6. (Fixing the Span of Identification Failure) Suppose that the model is weakly or set identified and satisfies the assumptions of Lemma D4. Let $\hat{\ell}_n$ be the stopping value in Algorithm 1, then, with probability going to 1

$$\Theta_0 \cap \{\theta \in \Theta, R_{\hat{\ell}_n} \theta = c_{\hat{\ell}_n}\}$$

is either a singleton or the empty set.

Lemma D6 implies that the algorithm restores point identification in the model with high probability. If there is no concern for higher-order identification issues, then the free parameters can be estimated. Otherwise, the reader should consider following the steps in Section 4.2 at this stage. Assuming first-order identification failure is no concern, the following theorem provides the asymptotic results for projection-based two-step subvector inference.

D.2 Preliminary Results for Section 4.2

Lemma D7 (Behaviour of $\bar{h}^2$ under Higher-Order Identification). Suppose that the model is higher-order identified and satisfies the assumptions of Theorem 3 or 7. Furthermore, assume

$$a_n \lesssim b_n$$

implies that $a_n$ is bounded by $b_n$ modulo a constant: $\exists C > 0, a_n \leq C b_n$ for two sequences $(a_n)_{n \geq 1}$ and $(b_n)_{n \geq 1}$. 

3The relation $a_n \lesssim b_n$ implies that $a_n$ is bounded by $b_n$ modulo a constant: $\exists C > 0, a_n \leq C b_n$ for two sequences $(a_n)_{n \geq 1}$ and $(b_n)_{n \geq 1}$. 

8
that $\tilde{g}_n$ is continuously differentiable around $\theta_0$. Let $A_n = \tilde{g}_n(\hat{\theta}_n) - B_n \hat{\theta}_n$, $B_n = \partial_\theta \tilde{g}_n(\hat{\theta}_n)$ and $\tilde{R}_n(\theta) = \tilde{g}_n(\theta) - A_n - B_n \theta$, where $\hat{\theta}_n$ is a GMM estimator of $\theta_0$ for some weighting matrix $W_n = W + O_p(n^{-1/2})$, $W$ positive definite. Suppose that $\Delta_V + O_p(n^{-1/2}) \leq \lambda_{\text{min}}(V_1) \leq \lambda_{\text{max}}(V_1) \leq \Delta_V + O_p(n^{-1/2})$ for some $0 < \Delta_V \leq \Delta_V < +\infty$. Suppose that there exists $\tilde{C}_j \geq 0$, $j = 1, \ldots, r$, with strict inequality when $\tilde{C}_j > 0$ in Definition 5 such that for any $\theta_1, \theta_2$ with $\|g_n(\theta_1)\|_W = O(\kappa_n)$, $j \in \{1, 2\}$:

$$\|\tilde{g}_n(\theta_1) - \tilde{g}_n(\theta_2) - \partial_\theta \tilde{g}_n(\theta_2)(\theta_1 - \theta_2)\| \geq \sum_{j=2}^r \tilde{C}_j \|P_j(\theta_1 - \theta_2)\|^2 + O_p(n^{-1/2}),$$

where the $P_j$ are the same as in Definition 5 for each $\ell \in \{1, \ldots, \ell\}$. Suppose that $R_\ell \theta_0 = c_\ell$ holds.

Let $V_r = \text{Span}(P_2, \ldots, P_r)$ be the span of the first-order identification failure. Let $\tilde{h}^2$ be computed using the procedure in Algorithm 3. If $\text{rank}(P_V; P_{R_\ell}) < \text{rank}(P_V)$ then $\tilde{h}^2 \to +\infty$, as $n \to \infty$, with probability going to 1.

Lemma D7 shows that the criterion in Algorithm 3 diverges under higher-order identification. This implies that higher-order identification can be detected even when the sequence of tolerance $\tilde{\gamma}_n$ is fixed, i.e. $\tilde{\gamma}_n = \gamma$. The moments $\tilde{g}_n$ are assumed to be smooth to simplify the algorithm and the proofs. It is also assumed that the first-order identification failure occurs at $\theta_0$ as well as in shrinking neighborhoods of $\theta_0$. This will allow to substitute the residual curvature at the unknown $\theta_0$ with a plug-in estimate.

Lemma D8 (Behaviour of $\tilde{h}^2$ under (Semi)-Strong Identification). Suppose that the model is (semi)-strongly identified and satisfies the assumptions of Theorem 3 or 6. Furthermore, assume that $\tilde{g}_n$ is continuously differentiable around $\theta_0$ and $\partial_\theta \tilde{g}_n(\theta)$ is non-singular in a neighborhood of $\theta_0$. Let $A_n = \tilde{g}_n(\hat{\theta}_n) - B_n \hat{\theta}_n$, $B_n = \partial_\theta \tilde{g}_n(\hat{\theta}_n)$ and $\tilde{R}_n(\theta) = \tilde{g}_n(\theta) - A_n - B_n \theta$, where $\hat{\theta}_n$ is a GMM estimator of $\theta_0$ for some weighting matrix $W_n = W + O_p(n^{-1/2})$, $W$ positive definite. Suppose that $\tilde{R}_n(\theta) \leq \tilde{C}_n \|\theta - \hat{\theta}_n\|^2$ in a neighborhood of $\theta_0$ for some $\tilde{C}_n = O_p(1)$. Furthermore suppose that $\kappa_n$ is such that $\sqrt{n} \kappa_n^2 = o\left(\lambda_{\text{min}}(\partial_\theta g_n(\theta_0)') \partial_\theta g_n(\theta_0)\right)$, then:

$$\tilde{h}^2_n \leq O_p\left(\frac{\sqrt{n} \kappa_n^2}{\lambda_{\text{min}}(\partial_\theta g_n(\theta_0)') \partial_\theta g_n(\theta_0)}\right) = o_p(1).$$

Lemma D8 shows which (semi)-strongly identified models can be detected as such with high probability. Suppose $\tilde{\gamma}_n = \gamma$ fixed and $K_n = \sqrt{2 \log(\log[n])} n^{-1/2}$, then semi-strongly identified models with $\lambda_{\text{min}}(\partial_\theta g_n(\theta_0)') \partial_\theta g_n(\theta_0)) \lesssim \sqrt{2 \log(\log[n])} n^{-1/2}$ may be subject to false positives. To put this into perspective, when the second derivative is non-zero, the local
expansion is non-linear as soon as $\lambda_{\min}(\partial_{g_n}(\theta_0)')\partial_{g_n}(\theta_0)) \approx n^{-1/2}$. This implies that the range of rates between $n^{-1/2}$ and $\sqrt{2\log(\log[n])n^{-1/2}}$ is subject to false positives. As in the case of detecting weak identification, this is a fairly narrow range.\[2]

**Appendix E**  Proofs for the Results of Appendix C

**E.1 A quasi-CLT for $A_{n,LS}, B_{n,LS}$**

*Proof of Lemma C2.* First recall that Theorems 5 and 6 imply:

$$A_{n,LS} = \bar{g}_n(\hat{\theta}_n) - B_{n,LS}\hat{\theta}_n + o_p(n^{-1/2})$$

$$B_{n,LS}H_n = \partial_{\theta g_n}(\hat{\theta}_n)H_n + o_p(n^{-1/2}\kappa_n^{-1}).$$

The proof is divided into two parts, the first provides results for $A_{n,LS}$ and the second part derives the result for $B_{n,LS}$.

**Step 1. Re-expressing $A_{n,LS}$ in terms of $\theta_0$:**

First, $A_{n,LS}$ can be expressed in terms of $\theta_0$ rather than $\hat{\theta}_n$ up to a $o_p(n^{-1/2})$ term:

$$A_{n,LS} = \bar{g}_n(\theta_0) - B_{n,LS}\theta_0 + o_p(n^{-1/2})$$

$$= \bar{g}_n(\theta_0) - B_{n,LS}\theta_0 + \bar{g}_n(\hat{\theta}_n) - \bar{g}_n(\theta_0) - B_{n,LS}(\hat{\theta}_n - \theta_0) + o_p(n^{-1/2}).$$

Note that $[B_{n,LS} - \partial_{\theta g_n}(\hat{\theta}_n)]H_nH_n^{-1}(\hat{\theta}_n - \theta_0) = o_p(n^{-1/2}\kappa_n^{-1})O_p(n^{-1/2}) = o_p(n^{-1/2})$ which implies:

$$B_{n,LS}(\hat{\theta}_n - \theta_0) = \partial_{\theta g_n}(\hat{\theta}_n)(\hat{\theta}_n - \theta_0) + o_p(n^{-1/2}).$$

Substituting this into $A_{n,LS}$ together with condition iii. in Definition 4 yields:

$$A_{n,LS} = \bar{g}_n(\theta_0) - B_{n,LS}\theta_0 + \bar{g}_n(\hat{\theta}_n) - \bar{g}_n(\theta_0) - \partial_{\theta g_n}(\hat{\theta}_n)(\hat{\theta}_n - \theta_0) + o_p(n^{-1/2})$$

$$= \bar{g}_n(\theta_0) - B_{n,LS}\theta_0 + O(||\partial_{\theta g_n}(\hat{\theta}_n)(\hat{\theta}_n - \theta_0)||^2) + o_p(n^{-1/2}).$$

Using condition iv. in Definition 4 the last term can be re-written as:

$$\partial_{\theta g_n}(\hat{\theta}_n)(\hat{\theta}_n - \theta_0) = \partial_{\theta g_n}(\theta_0)H_nH_n^{-1}(\hat{\theta}_n - \theta_0) + \partial_{\theta g_n}(\hat{\theta}_n)(\hat{\theta}_n - \theta_0)$$

$$= \partial_{\theta g_n}(\theta_0)H_nH_n^{-1}(\hat{\theta}_n - \theta_0) + \partial_{\theta g_n}(\hat{\theta}_n)(\hat{\theta}_n - \theta_0)$$

$$= O_p(n^{-1/2}).$$

\[4\]In terms of $\lambda_{\min}(\partial_{g_n}(\theta_0))$ it corresponds to the $n^{-1/4}$ to $[\log(\log[n])]^{1/4}n^{-1/4}$ range.
As a result, \( \| \partial_\theta g_n(\hat{\theta}_n - \theta) \|_2 = o_p(n^{-1/2}) \), and \( A_{n,LS} = \bar{g}_n(\theta_0) - B_{n,LS} \theta_0 + o_p(n^{-1/2}) \).

**Step 2. Expressing \( B_{n,LS} \) as a function of \( \partial_\theta \bar{g}_n \):**

Using the least-squares formula, \( B_{n,LS} \) can be expressed as:

\[
B'_{n,LS} = \sum_n^{-1} \int_{\Theta} (\theta - \tilde{\theta}_n) \left\{ g_n(\theta) - g_n(\tilde{\theta}) \right\} \tilde{\pi}_n(\tilde{\theta})d\tilde{\theta}' \tilde{\pi}_n(\theta)d\theta
\]

\[
= \sum_n^{-1} \int_{\Theta} (\theta - \tilde{\theta}_n) \left\{ \{\bar{g}_n(\theta) - \bar{g}_n(\tilde{\theta})\} - \{g_n(\theta) - g_n(\tilde{\theta})\} \right\} \tilde{\pi}_n(\tilde{\theta})d\tilde{\theta}' \tilde{\pi}_n(\theta)d\theta
\]

\[
= \sum_n^{-1} \int_{\Theta} (\theta - \tilde{\theta}_n) \left\{ \partial_\theta \bar{g}_n(\theta) - \partial_\theta g_n(\tilde{\theta}) \right\} \{\theta - \tilde{\theta}\} \tilde{\pi}_n(\tilde{\theta})d\tilde{\theta}' \tilde{\pi}_n(\theta)d\theta
\]

for some intermediate values \( \tilde{\theta} \) such that \( \| \theta - \tilde{\theta} \| \leq \| \theta - \tilde{\theta} \| \) for each pair \( \theta, \tilde{\theta} \). Using the arguments from the proofs of Theorems 5 and 6, for any \( d \geq 1 \) there exists a \( C_K > 0 \) such that, with probability going to 1:

\[
\int_{\Theta} (\theta - \tilde{\theta}_n) \left\{ \partial_\theta \bar{g}_n(\theta) - \partial_\theta g_n(\tilde{\theta}) \right\} \{\theta - \tilde{\theta}\} \tilde{\pi}_n(\tilde{\theta})d\tilde{\theta}' \tilde{\pi}_n(\theta)d\theta + o_p(n^{-d})
\]

\[
= \int_{\Theta} (\theta - \tilde{\theta}_n) \left\{ \partial_\theta \bar{g}_n(\theta) - \partial_\theta g_n(\tilde{\theta}) \right\} \{\theta - \tilde{\theta}\} \tilde{\pi}_n(\tilde{\theta})d\tilde{\theta}' \tilde{\pi}_n(\theta)d\theta + o_p(n^{-d})
\]

\[
= \sum_n \left( \partial_\theta \bar{g}_n(\theta_0) - \partial_\theta g_n(\theta_0) + o_p(n^{-1/2}) \right) + o_p(n^{-d})
\]

where the \( o_p(n^{-1/2}) \) term is due to the stochastic equicontinuity assumption for \( \partial_\theta \bar{g}_n(\theta) \). Pick \( d \) large enough such that we have \( \sum_n^{-1} o_p(n^{-d}) = o_p(n^{-1/2}) \) and then:

\[
B_{n,LS} - \bar{B}_{n,LS} = \partial_\theta \bar{g}_n(\theta_0) - \partial_\theta g_n(\theta_0) + o_p(n^{-1/2}).
\]

This implies that \( A_{n,LS} \) and \( B_{n,LS} \) satisfy the following:

\[
\sqrt{n} \left( \begin{array}{c} A_{n,LS} + B_{n,LS} \theta_0 \\ \text{vec}(B_{n,LS} - \bar{B}_{n,LS}) \end{array} \right) = \sqrt{n} \left( \begin{array}{c} \bar{g}_n(\theta_0) \\ \text{vec}(\partial_\theta \bar{g}_n(\theta_0) - \partial_\theta g_n(\theta_0)) \end{array} \right) + o_p(n^{-1/2}) \overset{d}{\rightarrow} \mathcal{N}(0, V),
\]

which concludes the proof.

**E.2 Primitive Conditions for Theorem 9**

**Proof of Lemma 3.** To simplify notation, the proof will consider \( \theta = (\alpha, \gamma) \) and \( H_n \) will be defined using derivatives of \( \gamma \) only in the below. Using a similar argument to the proof of
Theorem 6, writing the GMM estimator as \( \hat{\gamma}_{n,GMM} = \gamma_0 + H_n \hat{h}_n / \sqrt{n} \) yields via the Argmax Theorem (van der Vaart & Wellner, 1996):

\[
\hat{h}_n = \arg\min_h \left( \mathbb{G}_n(\beta_0, \gamma_0) + \partial_\gamma g_n(\beta_0, \gamma_0) H_n \hat{h} \right) - \left( \mathbb{G}_n(\beta_0, \gamma_0) + \partial_\gamma g_n(\beta_0, \gamma_0) H_n \hat{h} \right) - \left( H_n \partial_\gamma g_n(\beta_0, \gamma_0) \right)^{-1} H_n \partial_\gamma g_n(\beta_0, \gamma_0) \hat{V}_n^{-1} \mathbb{G}_n(\beta_0, \gamma_0) + o_p(1).
\]

Consider an estimator \( \hat{\gamma}_n \) satisfying \( H_n^{-1}(\hat{\gamma}_n - \hat{\gamma}_{n,GMM}) = o_p(n^{-1/2}) \), then:

\[
\bar{g}_n(\beta_0, \hat{\gamma}_n) = (I - P_n) \bar{g}_n(\alpha_0, \gamma_0) + o_p(n^{-1/2}).
\]

where \( P_n = \partial_\gamma g_n(\alpha_0, \gamma_0) H_n \left( H_n \partial_\gamma g_n(\beta_0, \gamma_0) \hat{V}_n^{-1} H_n \partial_\gamma g_n(\beta_0, \gamma_0) \right)^{-1} H_n \partial_\gamma g_n(\beta_0, \gamma_0) \hat{V}_n^{-1}. \) Using usual arguments, \( P_n \) is a projection matrix and:

\[
S_n(\beta_0) = n \times \bar{g}_n(\beta_0, \hat{\gamma}_n) \hat{V}_n^{-1} \bar{g}_n(\beta_0, \hat{\gamma}_n) \overset{d}{\to} \chi^2_{\dim(g) - \dim(\gamma)}.
\]

This concludes the proof.

Proof of Proposition C2. The first result is a consequence of Lemma C3. For the second results, note that for each \( \ell = \ell^*, \ldots, \mathcal{L} \):

\[
\left| \mathbb{P}(S_{n,\ell} \leq c_{1-\alpha,\ell}) - (1 - \alpha) \right| = o(1).
\]

Since this holds for finitely many \( \ell \), this implies that:

\[
\sup_{\ell = \ell^*, \ldots, \mathcal{L}} \left| \mathbb{P}(S_{n,\ell} \leq c_{1-\alpha,\ell}) - (1 - \alpha) \right| = o(1).
\]

Note that:

\[
\left| \inf_{\ell = \ell^*, \ldots, \mathcal{L}} \mathbb{P}(S_{n,\ell} \leq c_{1-\alpha,\ell}) - (1 - \alpha) \right| \leq \sup_{\ell = \ell^*, \ldots, \mathcal{L}} \left| \mathbb{P}(S_{n,\ell} \leq c_{1-\alpha,\ell}) - (1 - \alpha) \right| = o(1).
\]

This concludes the proof.

Appendix F  Proofs for the Results of Appendix D

F.1 Weak or Set Identification

Proof. Proof of Lemma D4

a. Weak/set identification:

Under the stated assumptions, either Theorem 4 or Lemma 1 hold. These results indicate
that $\lambda_{\min}(B_{n,LS/\infty}) = O_p(\kappa_n) = o_p(\Lambda_n)$ which implies the result.

b. (Semi)-strong identification:
Under the stated assumptions, $B_{n,LS/\infty}$ is such that:

$$[B_{n,LS/\infty} - \partial_\theta g_n(\theta_0)]H_n = o_p(n^{-1/2}\kappa_n^{-1})$$

Let $\|\cdot\|_*$ be the spectral norm, i.e. the absolute value of the largest eigenvalue, which is well defined for real symmetric matrices. We have:

$$H_n^{-1}[B'_{n,LS/\infty} B_{n,LS/\infty}]^{-1}H_n^{-1} = H_n^{-1}[\partial_\theta g_n(\theta_0)' \partial_\theta g_n(\theta_0)]^{-1}H_n^{-1} + o_p(n^{-1/2}\kappa_n^{-1}).$$

Note that by definition of $H_n$, we have $\lambda(H_n \partial_\theta g_n(\theta_0)' \partial_\theta g_n(\theta_0)H_n) = (1, \ldots, 1)$, i.e. all the eigenvalues are equal to 1. Using Problem III.6.14 in Bhatia (1997), this implies:

$$\lambda_{\min}(H_n^{-2}) \times \lambda_{\max}([B'_{n,LS/\infty} B_{n,LS/\infty}]^{-1}) \leq d_\theta + o_p(n^{-1/2}\kappa_n^{-1}).$$

Given that $\lambda_{\max}([B'_{n,LS/\infty} B_{n,LS/\infty}]^{-1}) = [\lambda_{\min}(B'_{n,LS/\infty} B_{n,LS/\infty})]^{-1}$ and $\lambda_{\min}(H_n^{-2}) = \lambda_{\max}(H_n^2) = [\lambda_{\min}(\partial_\theta g_n(\theta_0)' \partial_\theta g_n(\theta_0))]^{-1}$, this implies:

$$\frac{\lambda_{\min}(\partial_\theta g_n(\theta_0)' \partial_\theta g_n(\theta_0))}{d_\theta + o_p(n^{-1/2}\kappa_n^{-1})} \leq \lambda_{\min}(B'_{n,LS/\infty} B_{n,LS/\infty}).$$

Since by assumption $\Lambda_n^2 = o (\lambda_{\min}(\partial_\theta g_n(\theta_0)' \partial_\theta g_n(\theta_0)))$, the above inequality implies that

$$\Lambda_n^2 = o_p (\lambda_{\min}(B'_{n,LS/\infty} B_{n,LS/\infty})),$$

which concludes the proof.

Proof of Lemma D3. The first result is an immediate implication of the definition of $V$ as the span of the identification failure, by definition it’s orthogonal span a linear subset where the values of $\theta \in \Theta_0$ are unique. For the second result, suppose that the intersection is non-empty, pick $\theta \in \Theta_0 \cap \{\theta \in \Theta, P_{v^*} \theta = c\}$. The following holds:

$$\begin{pmatrix} P_{v^*}^\perp \\ P_{v^*} \end{pmatrix} \theta = \begin{pmatrix} P_{v^*}^\perp \theta_0 \\ c \end{pmatrix}.$$

The two terms on the right-hand side are unique since $c$ is fixed and $P_{v^*}^\perp \Theta_0$ is a singleton. By construction $(P_{v^*}^\perp, P_v)$ is invertible, $(P_{v^*}^\perp, P_{v^*})$ also has full rank since $\text{rank}(P_{v^*} P_{v^*}) = \text{rank}(P_{v^*})$ i.e. $P_{v^*}$ preserves the span of $P_{v^*}$. This concludes the proof.
Proof of Lemma D6. First, recall the definition of the identification failure:

\[ V = \text{Span} \left( \theta_0 - \theta_1, \theta_0, \theta_1 \in \Theta_0 \right), \]

where \( \Theta_0 \) is the weakly identified set of Definition 6. By definition of \( V \) and of projection matrices for any two \( \theta_0, \theta_1 \in \Theta_0 \): \( P_V^\perp \theta_0 = P_V^\perp \theta_1 \). This means that \( P_V^\perp \theta_0 \) is unique in \( \Theta_0 \).

Pick \( \ell \in \{1, \ldots, \ell^* \} \), \( \text{rank}(P_V P_{R_\ell}^\perp) < \text{rank}(P_V) \) implies that there exists a pair \( \theta_0 \neq \theta_1 \) in \( \Theta_0 \) such that:

\[
\begin{pmatrix}
P_V^\perp \\
P_{R_\ell}
\end{pmatrix}
(\theta_0 - \theta_1) = 0
\]

since the matrix on the left-hand side does not have full rank. This implies that:

\[ \Theta_0 \cap \{ \theta, R_\ell \theta = R_\ell \theta_0 \} \]

is neither empty nor a singleton since it contains \( \theta_1 \neq \theta_0 \) as well as \( \theta_0 \). By Lemma D5, \( \text{rank}(P_V P_{R_\ell}^\perp) = \text{rank}(P_V) \) implies that such sets are either empty or a singleton. By definition of \( \ell^* \), this is the case for any \( \ell \in \{ \ell^*, \ldots, \ell \} \).

Lemma D6 can thus be re-stated as \( \ell_n \geq \ell^* \) with probability going to 1. Take \( \ell < \ell^* \), there exists a basis \( v_1, \ldots, v_{\text{rank}(R_\ell)} \) such that \( P_{R_\ell}^\perp v_j = 0 \) for all \( j \in \{1, \ldots, \text{rank}(R_\ell)\} \). This implies that 0 is an eigenvalue of \( B_{n,LS/\infty} P_{R_\ell}^\perp \) with multiplicity (at least) \( \text{rank}(R_\ell) \). Now, we only have to find one more eigenvalue which is less than \( \Delta_n \) with probability going to 1 to show that \( \ell \neq \ell_n \) with probability going to 1.

Since \( \text{rank}(P_V P_{R_\ell}) < \text{rank}(P_V) \), there exists \( v^* \neq 0 \) such that \( v^* \in V, \ p_V^\perp v^* = 0 \), \( P_{R_\ell}^\perp v^* = 0 \) and \( P_{R_\ell}^\perp v^* \neq 0 \). By construction, the family \( (v_1, \ldots, v_{\text{rank}(R_\ell)}, v^*) \) has rank equal to \( \lceil \text{rank}(R_\ell) + 1 \rceil \). Also, \( v^* \) is such that \( P_{R_\ell}^\perp v^* = v^* \) so that \( B_{n,LS/\infty} v^* = O_p(\kappa_n) \). This implies that \( |\lambda_{d_o-\text{rank}(R_\ell)}(B_{n,LS/\infty} P_{R_\ell}^\perp)| = O_p(\kappa_n) \) which is strictly less than \( \lambda_n \) with probability going to 1. This implies that \( B_{n,LS/\infty} P_{R_\ell}^\perp \) has, with probability going to 1, at least \( \lceil \text{rank}(R_\ell) + 1 \rceil \) eigenvalues which are strictly less than \( \lambda_n \) so that the smallest \( \lceil \text{rank}(R_\ell) + 1 \rceil \) eigenvalues: \( \lambda_{d_o-\text{rank}(R_\ell)}(B_{n,LS/\infty} P_{R_\ell}^\perp), \ldots, \lambda_{d_o-\text{rank}(R_\ell)}(B_{n,LS/\infty} P_{R_\ell}^\perp) \) are \( o_p(\Delta_n) \). This implies that \( \ell \neq \ell_n \) with probability going to 1.

Now, to show that \( \ell_n \geq \ell^* \) with probability going to 1, consider the family-wise probability over \( \ell \in \{1, \ldots, \ell^* - 1\} \) for the event \( \{ \lambda_{d_o-\text{rank}(R_\ell)}(B_{n,LS/\infty} P_{R_\ell}^\perp) < \lambda_n \} \):

\[
P \left( \ell_n < \ell^* \right) = P \left( \max_{\ell = 1, \ldots, \ell^* - 1} \left[ \lambda_{d_o-\text{rank}(R_\ell)}(B_{n,LS/\infty} P_{R_\ell}^\perp) \right] > \Delta_n \right)
\leq \sum_{\ell = 1}^{\ell^* - 1} P \left( \lambda_{d_o-\text{rank}(R_\ell)}(B_{n,LS/\infty} P_{R_\ell}^\perp) > \Delta_n \right) \to 0,
\]
as \( n \to \infty \) since the sum is finite and each element converges to 0. This concludes the proof.

\[ \square \]

F.2 Higher-Order Identification

Proof of Lemma \[D7\] If \( B_{n,\ell} = (B'_n, R'_\ell)' \) is singular then \( \bar{h}^2 = +\infty \). Suppose it is not singular, Definition \[\bar{g}\] and the stated assumptions imply that:

\[
\|R_\ell(\theta - \theta_0)\| + \lambda^{-1} \sum_{j=1}^r C_j \|P_j(\theta - \theta_0)\|^j + O_p(n^{-1/2})
\]
\[
\leq \|R_\ell(\theta - \theta_0)\| + \|\bar{g}_n(\theta)\|_W
\]
\[
\leq \|R_\ell(\theta - \theta_0)\| + \lambda \sum_{j=1}^r C_j \|P_j(\theta - \theta_0)\|^j + O_p(n^{-1/2}).
\]

By assumption \( R_\ell \theta_0 = c_\ell \). Given that \( \text{rank}(P_\ell P_\ell') < \text{rank}(P_\ell) \), there exists \( j_\ell \geq 2 \), \( v_{j_\ell} \in \text{Span}(P_{j_\ell}) \) non-zero with \( \|v_{j_\ell}\| = 1 \) such that \( P_{R_\ell} v_{j_\ell} = 0 \) and for \( h \in \mathbb{R} \) not too large:

\[
\|\bar{g}_n(\theta_0 + h\kappa_n^{1/j_\ell} v_{j_\ell})\|_W + \|R_\ell(\theta_0 + h\kappa_n^{1/j_\ell} v_{j_\ell}) - c_\ell\| \leq \lambda \times \bar{C}_{j_\ell} |h|^{j_\ell} \kappa_n + O_p(n^{-1/2}) \leq 3/4 \times \kappa_n
\]

with probability going to 1 when \( |h| \leq 1/[2\bar{C}_j \lambda]^{1/j_\ell} \). This implies that \( |h| = 1/[2\bar{C}_j \lambda]^{1/j_\ell} \) is in the maximization set of Algorithm \[2\] with probability going to 1. The following shows that the criterion will diverge for this choice of \( h \). By definition of \( \hat{R}_n \) and the assumptions on the behaviour of \( \bar{g}_n \) around \( \theta_0 \):

\[
\|\hat{R}_n(\theta_0 + h\kappa_n^{1/j_\ell} v_{j_\ell})\| \geq \bar{C}_{j_\ell} |h|^{j_\ell} \times \kappa_n + O_p(n^{-1/2}).
\]

Now note that for any \( \theta \), we have:

\[
\sup_{\|v\| = 1} \frac{\hat{R}_n(\theta)' \bar{B}_{W,\ell}' v v' \bar{B}_{W,\ell} \hat{R}_n(\theta)}{v' \bar{B}_{W,\ell} V_1 \bar{B}_{W,\ell}' v} = \sup_{\|\tilde{v}\| = 1} \frac{\hat{R}_n(\theta)' \tilde{v} \tilde{v}' \hat{R}_n(\theta)}{\tilde{v}' V_1 \tilde{v}}.
\]

This holds because \((B'_n, R'_\ell)\) is non-singular by assumption so that \( B_{W,\ell} \) is also non-singular. Given the bounds on the eigenvalues of \( V_1 \), the following inequality holds:

\[
\frac{\hat{R}_n(\theta)' \tilde{v} \tilde{v}' \hat{R}_n(\theta)}{\lambda \bar{V} \tilde{v} \tilde{v}'} + O_p(n^{-1/2}) \leq \frac{\hat{R}_n(\theta)' \tilde{v} \tilde{v}' \hat{R}_n(\theta)}{\tilde{v}' V_1 \tilde{v}} \leq \frac{\hat{R}_n(\theta)' \tilde{v} \tilde{v}' \hat{R}_n(\theta)}{\lambda \tilde{v} \tilde{v}'} + O_p(n^{-1/2}).
\]

Since \( \tilde{v} \) covers the full unit circle, there exists a \( \tilde{v} \neq 0 \) over the optimizing set such that \( \hat{R}_n(\theta)' \tilde{v} \tilde{v}' \hat{R}_n(\theta) = \|\hat{R}_n(\theta)\|_\infty^2 \) (the sup-norm). This, in turn, implies the following inequality:

\[
\|\hat{R}_n(\theta)\|_\infty^2 / \lambda V + O_p(n^{-1/2}) \leq \sup_{\|\tilde{v}\| = 1} \frac{\hat{R}_n(\theta)' \tilde{v} \tilde{v}' \hat{R}_n(\theta)}{\tilde{v}' V_1 \tilde{v}}.
\]
Also note that \(\|\hat{R}_n(\theta)\|_\infty^2 \geq \|\hat{R}_n(\theta)\|^2 / \dim(g_n)^2\) by equivalence between norms. Combining this with the previous result, we have with probability going to 1:

\[
\tilde{h}_n^2 \geq n \times \|\hat{R}_n(\theta_0 + h \kappa_n^{1/2} v_{j_k})\|_V^2 / \lambda_V \times (1 + o_p(1)) \geq \frac{\tilde{C}_{j_k} |h|^{j_k}}{\lambda_V \times \dim(g_n)^2} \times (1 + o_p(1)).
\]

Assumption 1 implies that \(\sqrt{n} \times \kappa_n \to +\infty\) which implies that \(\tilde{h}^2 \to +\infty\) with probability going to 1. This concludes the proof.

\(\Box\)

**Proof of Lemma D8.** From Definition 4 and Assumptions 1,[1,2] for \(\|\theta - \theta_0\| \leq \varepsilon\):

\[
\|\bar{g}_n(\theta)\|_{W_n} \geq C \|\partial g_n(\theta_0)(\theta - \theta_0)\| \times (1 + o_p(1)) - O_p(n^{-1/2})
\]

\[
\geq C \sqrt{\lambda_{\text{min}}(\partial g_n(\theta_0)'(\partial g_n(\theta_0)))} \times \|\theta - \theta_0\| \times (1 + o_p(1)) - O_p(n^{-1/2}).
\]

Hence, with probability going to 1, \(\|\theta - \theta_0\| \geq 2 \kappa_n / [C \sqrt{\lambda_{\text{min}}(\partial g_n(\theta_0)'(\partial g_n(\theta_0)))}]\) implies that \(\|\bar{g}_n(\theta)\|_{W_n} \geq 3 / 2 \kappa_n > \kappa_n\). Also, \(\|\theta - \theta_0\| > \varepsilon\) implies \(\|\bar{g}_n(\theta)\|_{W_n} \geq 3 / 2 \kappa_n\) by point identification. Then, under the stated assumptions:

\[
\sup_{\theta, \|\bar{g}_n(\theta)\|_{W_n} \leq \kappa_n} \|\hat{R}_n(\theta)\| \leq \sup_{\theta, \|\bar{g}_n(\theta)\|_{W_n} \leq \kappa_n} \bar{C}_n \|\theta - \hat{\theta}_n\|^2
\]

\[
\leq 4 \times \bar{C}_n \sup_{\theta, \|\bar{g}_n(\theta)\|_{W_n} \leq \kappa_n} \|\theta - \theta_0\|^2
\]

\[
\leq 16 \times \bar{C}_n / C \times \kappa_n^2 / \lambda_{\text{min}}(\partial g_n(\theta_0)'(\partial g_n(\theta_0))).
\]

Since \(\partial \bar{g}_n(\hat{\theta}_n)\) is non-singular, using a similar argument as in Lemma D7 implies:

\[
\tilde{h}_n^2 \leq O_p([\sqrt{n} \kappa_n^2 / \lambda_{\text{min}}(\partial g_n(\theta_0)'(\partial g_n(\theta_0))]^2) = o_p(1),
\]

which concludes the proof.

\(\Box\)

**Appendix G Additional Monte-Carlo Simulations**

**G.1 Example 1. Non-Linear Least Squares**

Figure G6 compares the power curves for three tests: an oracle who re-parameterizes the model into a simple OLS regression model, inference based on a projected Anderson-Rubin confidence set and inference based on the two-step approach with the rule-of-thumb. When \(c = 0\), the two-step approach is identical to AR inferences and has the same power curve. The oracle has higher power. For \(c = 1\), the two-step’s power is between the AR and the oracle. Note that the power of the AR test is higher than for the oracle for alternatives such
that $\delta + c = 0 \Leftrightarrow H_0: \theta_{1,0} = 0$ when $c \neq 0$ i.e. $\theta_2$ is not completely unidentified. Indeed, the second moment becomes $\theta_{1,0} \times \theta_2 = 0$ under the this null hypothesis for any $\theta_2$ whereas the true $\theta_{1,n} \times \theta_2$ is away from zero when the true $\theta_2$ is large enough, which is the case here. This leads to higher power for AR test compared to a test which only relies on the first moment for inference, the oracle. Finally, when $c = 3$ the two-step approach has the highest power; matching the oracle for most values of $\delta$ (the Pittman drift coefficient) except for $\delta + c \simeq 0$ where power is higher than the oracle’s for reasons described above. The figure suggests that the two-step approach has good power properties in this setting. Also, even though a well identified reduced-form model leads to better size control, the figure suggests it can result in power loss against some alternatives.
Figure G6: Power Comparison: Oracle, Projection and Two-Step Inferences

Note: Model \( y_i = \theta_{1,n} x_{i,1} + \theta_{1,n} \theta_{2,x_{i,2}} + e_i, \) \( \theta_{1,n} = c \times n^{-1/2}, \) for \( c \in \{0, 1, 3\} \) (top/middle/bottom panel), \( n = 1,000, B = 5,000 \) Monte-Carlo replications and \( \kappa_n = \sqrt{2 \log(\log(n))} n^{-1/2}. \)

Legend: Oracle (solid) - OLS based reduced-form inference, the reduced form model is \( y_i = \theta_{1,n} x_{i,1} + \theta_{2,x_{i,2}} + e_i; \) Anderson-Rubin (dashed) - projection-based confidence interval; Rule-of-Thumb (dotted) - QLR based two-step confidence interval with data-driven rule-of-thumb. y-axis: rejection rate when testing \( \theta_{1,n} = \theta_{1,n} + \delta \times n^{-1/2}. \) x-axis: Pittman coefficient \( \delta. \)
G.2 Example 2. Possibly Non-Invertible MA Model

The second example uses the MA(1) process:

\[ y_t = \sigma [e_t - \vartheta e_{t-1}], \]

with \( e_t \) iid distributed from a Generalized Extreme Value (GEV) distribution with mean 0, variance 1 and skewness \( \tau \). For \( \tau = 0 \), \((\vartheta, \sigma)\) is not identified (Gospodinov & Ng, 2015). When \( \tau_n \approx n^{-1/2} \), the model is weakly identified as discussed in Section 2. The estimating moments are given by:

\[
\bar{g}_n(\theta) = \frac{1}{n} \sum_{t=2}^{n} \left( y_t^2 - [1 + \vartheta^2] \sigma^2, y_t y_{t-1} + \vartheta \sigma^2, y_t^3 + [1 - \vartheta^3] \sigma^3 \tau, y_t^2 y_{t-1} + \vartheta \sigma^3 \tau, y_t y_{t-1}^2 + \theta \sigma^3 \tau \right)'.
\]

Figure G7: Distribution of \( \lambda_{\min}(B_{n,LS}) \) and sample size \( n \)

Note: Model \( y_t = \sigma [e_t - \vartheta e_{t-1}], e_t \sim (0,1) \), \( E(e_t^3) = 2 \times n^{-1/2}, (\vartheta_0, \sigma_0) = (0.5, 1) \), 100 \( \leq n \leq 5,000 \), \( B = 500 \) Monte-Carlo replications and \( \kappa_n = \max(\sqrt{q_{0.99}(\chi_4^2)}, \sqrt{2 \log(\log[n])n^{-1/2}}) \).

Legend: Black lines - boxplot of the distribution of \( \lambda_{\min}(B_{n,LS}) \) for each \( n \); Blue crosses - fitted rate from regressing the Monte-Carlo \( \lambda_{\min}(B_{n,LS}) \) draws on \( \kappa_n \) by OLS with no intercept.

Figure G7 shows the distribution of \( \lambda_{\min}(B_{n,LS}) \) for sample sizes 100 \( \leq n \leq 5,000 \). The distribution is compared to the rate derived in Section 3. The theoretical results appear to be in line with the theory. Note that there is a value of \( \lambda_{\min}(B_{n,LS}) \) which is much larger \((\simeq 0.5)\) than the rest of the distribution. A closer investigation into this draw reveals \( 5^{\text{See e.g. Ruge-Murcia (2017) for more details on the GEV distribution and an application in economics.}} \)

that the set $\hat{\Theta}_n = \{\theta, \|\bar{g}_n\|_{W_n} - \inf_{\theta \in \Theta} \|\bar{g}_n\|_{W_n} \leq \kappa_n\}$ (which is a conservative identification robust confidence set) is centered around a singleton. This implies that, for this occurrence, non-conservative robust and standard inferences yield similar conclusions.

The top panel of Figure [G8](#) shows the coverage of the two-step, Anderson-Rubin and QLR 95% confidence sets. The projection-based confidence sets are computed using:

$$\{\vartheta, n \times \inf_{\sigma, \tau} \|\bar{g}_n(\vartheta, \sigma, \tau)\|_{\hat{V}_n^{-1}}^2 \leq c_{1-\alpha}\}.$$

The projected Anderson-Rubin confidence set assumes that the econometrician knows $\sigma$ and $\tau$ are point identified when $\vartheta$ is fixed. The critical value is the 95% quantile of a $\chi^2_2$ distribution.

The true value $\vartheta_0 = 2$ lies outside the unit circle. For this Monte-Carlo design, the unconstrained estimator $\hat{\vartheta}_n$ is biased towards $\vartheta = 0.5$, which is inside the unit circle. This leads to some size distortion for QLR inferences as shown in the top panel of the figure. The bottom panel shows similar results for Wald rather than QLR inferences. Size distortion is much more severe. Note that the two-step procedure which relies on Wald inferences when there is no indication of identification failure (bottom panel) is not too significantly size distorted.

The two-step approach uses the rule-of-thumb and $\lambda_n = \sqrt{\log[n]}$ as cutoffs. The sequential search fixes $\vartheta$, as implied by $H_0$, then $\sigma$ and finally $\tau$ - with critical values corresponding the 95% quantile of a $\chi^2_2$, $\chi^2_3$ and $\chi^2_4$ distribution respectively. When $\lambda_{\min}(B_{n,LS}) > \lambda_n$, the test switches to a QLR statistic with critical values corresponding the 95% quantile of a $\chi^2_1$ distribution (top panel) or a Wald statistic (bottom panel). The rule-of-thumb implemented here relies on the between and within cluster rule-of-thumb described in Appendix [C.1.2](#).

First, the set $\hat{\Theta}_n = \{\theta, \|\bar{g}_n(\theta)\|_{W_n} - \inf_{\theta \in \Theta} \|\bar{g}_n\|_{W_n} \leq \kappa_n\}$ is split into clusters using the k-means algorithm when the estimated clusters display enough separation. Since the null hypothesis fixes the cluster in this example, the rule-of-thumb switches to a within cluster decision rule after the determining if robust inference is required. The results rely on $B_{n,LS}$ computed on the whole parameter space. Using a $B_{n,LS}$ computed in the only $H_0$ compatible cluster could lead to a less conservative decision rule and potential power improvements. This was not investigated in the simulations.

---

6For these simulations, the criterion to pick the number of clusters relied on a ratio of the distance between the centroids of the clusters to the diameter of these clusters. Other approaches may be considered.
**Figure G8: Coverage of the 95% Confidence Intervals**

Note: Model $y_t = \sigma[e_t - \vartheta e_{t-1}], e_t \sim (0, 1), \mathbb{E}(e_t^3) = \tau_n = c \times n^{-1/2}, c \in [0, 24]$, $(\vartheta, \sigma_0) = (2, 1)$, $n = 1,000$, $B = 2,000$ Monte-Carlo replications and $\kappa_n = \max(\sqrt{q_{0.99}(\chi^2_4)}, \sqrt{2\log(\log(n))}n^{-1/2})$.

Legend: Anderson-Rubin (solid/dot) - projection-based confidence interval; Standard (dashed/square) - QLR (top panel)/Wald (bottom panel)-based confidence interval; Two-step (dashed/cross) - two-step procedure with $\lambda_n =$ data-driven rule-of-thumb; $\sqrt{\log(n)}$ (dotted/triangle) - two-step procedure with $\lambda_n = \sqrt{\log(n)}$. 

21
Figure G9: Detection of Identification Failure and Size Distortion of the Wald test

Note: Model \( y_t = \sigma [e_t - \vartheta e_{t-1}] \), \( e_t \sim (0, 1), \mathbb{E}(e_t^3) = \tau_n = c \times n^{-1/2}, c \in [0, 24] \), \( (\vartheta_0, \sigma_0) = (2, 1) \), \( n = 1,000 \), \( B = 5,000 \) Monte-Carlo replications and \( \kappa_n = \max(\sqrt{\vartheta_{0.99}(\chi^2_1)}, \sqrt{2\log(\log[n])n^{-1/2}}) \).

Legend: Size distortion (dotted/triangle) - size distortion of a 95% Wald confidence interval; Two-step (dashed/square) - detection rate for identification failure using the rule-of-thumb.

Even though the distribution of the QLR statistic is not closed form under identification failure, bounds can be computed to quantify the degree of potential size distortion. First recall that:

\[
QLR(\vartheta_0) = n \times \left( \inf_{\sigma, \tau} \| \bar{g}_n(\vartheta_0, \sigma, \tau) \|_{\hat{V}_n^{-1}}^2 - \inf_{\vartheta, \sigma, \tau} \| \bar{g}_n(\vartheta, \sigma, \tau) \|_{\hat{V}_n^{-1}}^2 \right).
\]

Now, let \( \hat{\vartheta}_{0,n} \) be the constrained estimator with \( |\vartheta| \geq 1 \), then \(^7\)

\[
QLR(\vartheta_0) \geq n \times \left( \inf_{\sigma, \tau} \| \bar{g}_n(\vartheta_0, \sigma, \tau) \|_{\hat{V}_n^{-1}}^2 - \| \bar{g}_n(\hat{\vartheta}_{0,n}, \hat{\sigma}_{0,n}, \hat{\tau}_{0,n}) \|_{\hat{V}_n^{-1}}^2 \right) \overset{d}{\to} \chi^2_1.
\]

This first inequality implies that the standard critical value may be too small. An upper bound can also be computed:

\[
QLR(\vartheta_0) \leq n \times \inf_{\sigma, \tau} \| \bar{g}_n(\vartheta_0, \sigma, \tau) \|_{\hat{V}_n^{-1}}^2 \overset{d}{\to} \chi^2_2.
\]

This corresponds to the projection-based critical value. Under identification failure, the limiting distribution of the QLR statistic is somewhere between a \( \chi^2_1 \) and a \( \chi^2_2 \) distribution.

\(^7\)Under identification failure, \( \vartheta_0 \) and \( 1/\vartheta_0 \) are both global minima, adding a set constraint restores global identification and standard asymptotics are valid if \( \vartheta_0 \) is bounded away from \( \{-1, 1\} \).
This implies that size distortion is at most 9.6\% asymptotically; far less than for Wald inferences.\footnote{This observation does not appear to be new. Figure 6 in Andrews & Cheng (2012) also suggests that the QLR statistic has far less severe size distortion under weak identification than the t and Wald statistics.}

### G.3 Example 3. Second-Order Identified Non-Linear Least-Squares Model

The third example considers the simple non-linear least-squares model:

\[
y_i = \theta_1 x_{i,1} + \theta_{2,n} (\theta_{2,n} - \theta_1)^2 x_{i,2} + e_i, \quad x_{i,1}, x_{i,2} \sim N(0, I_2)
\]

where \(\theta_{2,n}\) is bounded away from zero. This model can be estimated using the following set of moment conditions:

\[
g_n(\theta) = \mathbb{E} (y_i(x_{i,1}, x_{i,2})') - (\theta_1, \theta_2(\theta_2 - \theta_1)^2)' .
\]

This model is second-order identified, consider the re-parameterization \((\vartheta_1, \vartheta_2) = (\theta_1, \theta_2 - \theta_1)\):

\[
g_n(\vartheta) = g_n(\vartheta_0) - (\vartheta_1, [\vartheta_1 + \vartheta_2] \vartheta_2^2)' .
\]

For \(\vartheta_1\) bounded away from zero and \(\vartheta_{2,n} = c \times n^{-1/4}\) the second-order term is non-negligible in the Taylor expansion of \(g_n\) around the true \((\vartheta_1, \vartheta_{2,n})\). This example is different from the types of identification failures considered in Andrews & Cheng (2012); Antoine & Renault (2009) for instance where local and global identification are connected. Here the model is globally identified but local identification fails as in Dovonon & Hall (2018); Dovonon et al. (2019). This implies that \(\hat{\theta}_n\) is consistent and converges at a slower than \(\sqrt{n}\) with non-standard asymptotic distribution. When \(c\), described above, is equal to zero - the Jacobian evaluated at \(\theta_0\) is singular so that the higher-order identification failure problem is summarized by the rank of the Jacobian. However, when \(c \neq 0\), the Jacobian is non singular and the information from the eigenvalues may be misleading. Indeed, even if the smallest eigenvalue of the Jacobian is not too small, the moments are not approximately linear around \(\theta_0\) which results in non-standard asymptotics.

This is illustrated in Figure G10 which shows the distribution of the smallest eigenvalue of \(B_{n,LS}\) but also the sample Jacobian evaluated at \(\theta_0\) (the true value) and at \(\hat{\theta}_n\) (the GMM estimate). The Figure shows a large disconnect between the quasi-Jacobian and the usual Jacobian matrices under higher-order identification. Wright (2003) suggest to compute a
rank test on $\partial_\theta \bar{g}_n(\theta_0)$, this plot suggest his test would most likely reject the null hypothesis of local identification failure. The distribution of $\partial_\theta \bar{g}_n(\hat{\theta}_n)$ suggests that false negatives are quite likely when considering a set of values around $\theta_0$ as in [Wright (2003)]. The smallest eigenvalue of the quasi-Jacobian, however, is very small because of the non-linearity in $\bar{g}_n$ around $\theta_0$.

Figure G10: Distribution of $\lambda_{\min}(B_{n,LS})$, $\lambda_{\min}(\partial_\theta \bar{g}_n(\hat{\theta}_n))$, $\lambda_{\min}(\partial_\theta \bar{g}_n(\theta_0))$ and sample size $n$

Note: Model $y_i = \theta_1 x_{i,1} + \theta_{2,n}(\theta_{2,n} - \theta_1)^2 x_{i,2} + e_i$, $e_i, x_{i,1}, x_{i,2} \sim \mathcal{N}(0, I_3)$, $(\theta_1, \theta_{2,n}) = (3, 3 + 0.4 \times n^{-1/4})$, $100 \leq n \leq 5,000$. $B = 500$ Monte-Carlo replications and $\kappa_n = \max(\sqrt{\chi^2_{0.99}}, \sqrt{2 \log(\log[n])} n^{-1/2})$.
Legend: top panel: smallest eigenvalue of $B_{n,LS}$, middle panel: smallest eigenvalue of the sample Jacobian $\partial_\theta \bar{g}_n$ evaluated at $\hat{\theta}_n$ the GMM estimates, bottom panel: smallest eigenvalue of the sample Jacobian $\partial_\theta \bar{g}_n$ evaluated at $\theta_0$, the true value.

To further illustrate the results from Section 3, consider a sample simulated with $n =$
1,000, $c = 0.4$. The estimated quasi-Jacobian and Jacobians are:

\[
B_{n,LS} = \begin{pmatrix}
0.001 & -0.997 \\
0.022 & 0.014
\end{pmatrix}, \quad \partial_{\theta} \bar{g}_n(\hat{\theta}_n) = \begin{pmatrix}
1.078 & -1.146 \\
-0.958 & -0.043
\end{pmatrix}, \quad \partial_{\theta} \bar{g}_n(\theta_0) = \begin{pmatrix}
-0.459 & -1.015 \\
0.417 & 0.015
\end{pmatrix}.
\]

Clearly, the quasi-Jacobian is very close to being singular while the other two are not. Now setting $c = 2$, which is much closer to (semi)-strong identification yields:

\[
B_{n,LS} = \begin{pmatrix}
-2.329 & 2.135 \\
-1.084 & 0.079
\end{pmatrix}, \quad \partial_{\theta} \bar{g}_n(\hat{\theta}_n) = \begin{pmatrix}
-2.333 & 2.139 \\
-1.084 & 0.079
\end{pmatrix}, \quad \partial_{\theta} \bar{g}_n(\theta_0) = \begin{pmatrix}
-2.147 & 1.985 \\
-1.077 & 0.074
\end{pmatrix}.
\]

This is in line with the predictions of Theorems 5 and 6. Finally, for $c = 0$, these matrices become:

\[
B_{n,LS} = \begin{pmatrix}
-0.148 & -0.037 \\
-1.003 & -0.001
\end{pmatrix}, \quad \partial_{\theta} \bar{g}_n(\hat{\theta}_n) = \begin{pmatrix}
0.976 & -1.039 \\
-0.961 & -0.039
\end{pmatrix}, \quad \partial_{\theta} \bar{g}_n(\theta_0) = \begin{pmatrix}
-0.037 & 0.000 \\
-0.999 & 0.000
\end{pmatrix}.
\]

Overall, this suggests that the Jacobian will be informative when local identification fails exactly ($c = 0$), but may be misleading in intermediate cases where the first-order term is not strictly zero yet higher-order terms matter.
Note: Model \( y_i = \theta_1 x_{i,1} + \theta_2 x_{i,2} + e_i, \quad e_i, x_{i,1}, x_{i,2} \sim N(0, I_3), \)</p>\[(\theta_1, \theta_2, n) = (3, 3 + c \times n^{-1/4}), \quad c \in [0, 3], \quad n = 1,000, \quad B = 2,000 \text{ Monte-Carlo replications and}\]
\[
\kappa_n = \max(\sqrt{q_{0.99}(\chi^2_2)}, \sqrt{2 \log(\log(n))} n^{-1/2}).
\]

Legend: Standard (solid/dot) - Wald-based confidence interval; Two-step - Rule 1 (dotted/triangle) - two-step procedure rule-of-thumb described in Algorithm \[2\] without \( B_n \) in \( \bar{h}^2 \); Two-step - Rule 2 (dashed/square) - two-step procedure rule-of-thumb described in Algorithm \[2\] with \( B_n = B_{n,LS} \) in \( \bar{h}^2 \).

The top panel in Figure \[G11\] illustrates the properties of standard inferences using the QLR test as well as the two-step procedure from Algorithm \[2\]. The subvector hypothesis considered here is:
\[
H_0 : \theta_2 = \theta_{2,n}
\]
with \( \theta_{2,n} = \theta_1 + c \times n^{-1/4} = 3 + 0.4 \times n^{-1/4} \). The criterion \( \bar{h}^2 \) in the algorithm is computed in
two ways, the first ignores the $B_n$ in the formula (since $B'_n v' = u'$ for some vector $u$ when $B_n$ is non-singular) and the second uses the formula in the algorithm but with $B_w = B_{n,LS}$. To simplify the Monte-Carlo exercise, the procedure switches between Anderson-Rubin based full projection inference and a standard QLR test. Some power improvements could be made by checking if $\theta_1$ is semi-strongly identified when $\theta_2$ is fixed as in the previous two examples. Both two-step procedures seem to perform reasonably well in the simulations. The second rule appears to be somewhat more conservative. The bottom panel in Figure [G11] presents similar results using the Wald test. Comparing both panels suggests, again, that QLR inferences are less prone to size distortion than Wald-based inference. Again, the two-step procedure performs reasonably well in this particular example.

**Appendix H Additional Empirical Results**

**H.1 US Euler Equation**

The following replicates the results with the additional restriction $\delta \leq 1$. Indeed, Figure 3 suggests that the range of values for $\gamma$ would be much smaller should $\delta$ be restricted to $[0.7, 1.0]$. The results were replicated with the grid $[0.7, 1.0] \times [0, 20]$ for the pair $(\delta, \gamma)$:

$$B'_{n,LS} = \begin{pmatrix} 1.012 & 1.032 & 1.030 \\ -0.016 & -0.017 & -0.016 \end{pmatrix}.$$  

The singular value decomposition yields:

$$U_n = \begin{pmatrix} -1.0 & 0.016 \\ 0.016 & 1.0 \end{pmatrix}, \quad D_n = \text{diag}(1.775, 0.000), \quad V'_n = \begin{pmatrix} -0.570 & -0.580 & -0.582 \\ -0.632 & -0.143 & 0.762 \end{pmatrix},$$

where, again, $B_{n,LS} = U_n D_n V'_n$. Note that $\sqrt{n} \times \text{diag}(D_n) = (18.015, 0.002)$. It appears that the additional restriction does not improve the identification of $\gamma$ but does help with $\delta$. Though, this is simply the mechanical effect of reducing its range. Combining the restriction $\delta \leq 1$ with the singularity and indentification robust inference described in the main text yields a confidence interval for $\gamma$ equal to $[0, 3] \cup [11.6, 20]$. 

27
Figure H12: US Euler Equation - Time-Series Plot of the Moments $g_t(\delta, \gamma)$

Note: annual series $g_t(\delta, \gamma) = [\delta(\frac{C_t}{C_{t-1}})^{-\gamma}R_t - 1]Z_{j,t}$ with $Z_{j,t} = 1,$ $C_{t-1}/C_{t-2}, R_{t-1}$ for $j \in \{1, 2, 3\}$ respectively and a fixed value of $\theta = (\delta, \gamma)$. The vector of sample moments are computed as $\bar{g}_n(\theta) = \frac{1}{n}\sum_{t=1}^{n} g_t(\theta)/n$. This figure highlights that all three moments are nearly identical.

H.2 Quantile IV

This additional empirical application deals with the quantile IV model of Chernozhukov & Hansen (2005) using the Fish data of Chernozhukov et al. (2007). For a given quantile $\tau$, the estimating moments for fish demand are:

$$\bar{g}_n(\theta(\tau), \tau) = \frac{1}{n}\sum_{i=1}^{n} \mathbb{1}(\log(q_i) - [\alpha(\tau) + \beta(\tau) \log(p_i)]_{-\tau} \leq -\tau) \times (1, z_i')',$$

where $q_i$ is the quantity of fish sold, $p_i$ is the endogenous price of fish and, $z_i$ is the vector of exogenous instruments - an indicator for stormy weather and another for mixed weather.
conditions. The following will focus on a specific quantile: $\tau = 0.85$. Since the model is non-smooth and non-linear it is not possible to check the relevance of the instrument using a first-stage F-statistic. The bounds used to compute the integral in $B_{n,LS}$ are\(^9\) $\theta(\tau) = (\alpha(\tau), \beta(\tau)) \in [6, 12] \times [-15, 6]$. The sample consists of $n = 111$ observations. Figure H13: Demand for Fish - $\hat{\Theta}_n = \{\theta \in \Theta, \|\tilde{g}_n(\theta)\|w_n - \inf_{\theta \in \Theta} \|\tilde{g}_n(\theta)\|w_n \leq \kappa_n\}$ for $\tau = 0.85$

Note: region $\hat{\Theta}_n$ computed for $\kappa_n = \max(\sqrt{q_{0.99}(\chi^2_3)}, \sqrt{2\log(\log[n])n^{-1/2}})$ where $q_{0.99}$ is the 99% quantile of a $\chi^2_3$ distribution. $W_n = \hat{V}_n^{-1}$. $\alpha(0.85) =$ intercept, $\beta(0.85) =$ slope.

Figure H13 shows the region $\hat{\Theta}_n$ selected by the compact kernel to compute the integrals. It suggests either set or weak identification. The eigenvalues are (0.027, 0.005) which is quite small. The cutoff $\hat{\lambda}_n = 0.15$ is greater than both eigenvalues. The 95% level robust confidence set for $\beta(0.85)$ is $[-2.88, 0.03] \cup [-14.81, -11.29] \cup [5.55, 5.83]$.

\(^9\)The grid was constructed using 20,000 points from the Sobol sequence.
