COVERING GRAPHS, MAGNETIC SPECTRAL GAPS AND APPLICATIONS TO POLYMERS AND NANORIBBONS

JOHN STEWART FABILA-CARRASCO AND FERNANDO LLEDÓ

Abstract. In this article, we analyze the spectrum of discrete magnetic Laplacians (DML) on an infinite covering graph $\tilde{G} \rightarrow G = \tilde{G}/\Gamma$ with (Abelian) lattice group $\Gamma$ and periodic magnetic potential $\tilde{\beta}$. We give sufficient conditions for the existence of spectral gaps in the spectrum of the DML and study how these depend on $\tilde{\beta}$. The magnetic potential may be interpreted as a control parameter for the spectral bands and gaps. We apply these results to describe the spectral band/gap structure of polymers (polyacetylene) and of nanoribbons in the presence of a constant magnetic field.

1. Introduction

It is a well known fact that the spectrum of Laplacians or, more generally, Schrödinger operators with periodic potentials, on Abelian coverings have band structure. That is to say the spectrum consists of the union of intervals (bands) described in terms of a so-called Floquet (or Bloch) parameter which is the dual of the Abelian group acting on the structure. If two consecutive spectral bands of a bounded self-adjoint operator $T$ do not overlap, then we say that the spectrum has a spectral gap, i.e., a maximal nonempty interval $(a, b) \subset [-||T||, ||T||]$ that does not intersect the spectrum of the operator. This is a quite natural situation in solid state physics, where – for example in semiconductors or its optical counterparts, photonic crystals – the operators modeling the dynamics of particles have some forbidden energy regions (see, e.g., [Kuc01, KK02]). Depending on the type of the periodic structure involved, spectral gaps may be produced by deformation of the geometry (cf., [P03, LP07, LP08b]) or by a suitable periodic decoration of the metric or the discrete covering graph (see, e.g., [AS00, EKW10, KS15, LP08a, Suz13] and [Kuc05, Section 4]).

In this article we study the spectrum of discrete magnetic Laplacians (DMLs for short) on infinite discrete coverings graphs $\pi: \tilde{G} \rightarrow G = \tilde{G}/\Gamma$, where $\Gamma$ is an (Abelian) lattice group acting freely and transitively on $\tilde{G}$ (also the graph $\tilde{G}$ is called as $\Gamma$-periodic graph with finite quotient $G$). We will present our analysis for graphs with arbitrary weights $m$ on vertices and arcs although the graphs presented in the examples of the last section will initially have standard weights which are more usual in the context of mathematical physics. In addition, we consider a periodic magnetic potential $\tilde{\beta}$ on the arcs of the covering graph $\tilde{G}$ modeling a magnetic field acting on the graph.

We denote a weighted graph as $W = (G, m)$, and a magnetic weighted graph (MW-graph for short) is a weighted graph $W$ together with a magnetic potential acting on its arcs. Any MW-graph $W = (G, m)$ with magnetic potential $\beta$ has canonically associated a DML denoted as $\Delta_W^\beta$. We say that $\tilde{W} = (\tilde{G}, \tilde{m})$ with magnetic potential $\tilde{\beta}$ is a $\Gamma$-periodic MW-graph if $\tilde{G} \rightarrow G = \tilde{G}/\Gamma$ is a $\Gamma$-covering and $\tilde{m}$ and $\tilde{\beta}$ are periodic with respect to the group action.

In this article we generalize the geometric condition obtained in [FLP18, Theorem 4.4] for $\tilde{\beta} = 0$ to non-trivial periodic magnetic potentials. In particular, if $\tilde{W} = (\tilde{G}, \tilde{m})$ is a $\Gamma$-periodic MW-graph with magnetic potential $\tilde{\beta}$, we will give in Theorem 4.8 a simple geometric condition on the quotient graph $G = \tilde{G}/\Gamma$ that guarantees the existence of non-trivial spectral gaps on the spectrum of the discrete magnetic Laplacian $\Delta_{\tilde{W}}^\tilde{\beta}$. To show the existence of spectral gaps, we develop a purely discrete spectral
localization technique based on virtualization of arcs and vertices on quotient $\mathbf{G}$. These operations produce new graphs with, in general, different weights that allow to localize the eigenvalues of the original Laplacian in certain intervals. We call this procedure a discrete bracketing and we refer to [FLP18] for additional motivation and proofs.

One of the new aspects of the present article is the generalization of results in [FLP18] to include a periodic magnetic field $\hat{\beta}$ on the covering graph $\pi: \tilde{\mathbf{G}} \to \mathbf{G} = \tilde{\mathbf{G}}/\Gamma$. In this sense, $\hat{\beta}$ may be used as a control parameter for the system that serves to modify the size and the regions where the spectral gaps are localized. We apply our techniques to the graphs modeling the polyacetylene polymer as well as to graphene nanoribbons. The nanoribbons are $\mathbb{Z}$-periodic strips of graphene either with armchair or zig-zag boundaries. The graphic in Fig. 1 corresponds to an armchair nanoribbon with width 3. It can been seen how a periodic magnetic potential with constant value $\hat{\beta} \in [0, 2\pi)$ on each cycle (and plotted on the horizontal axis) affects the spectral bands (gray vertical intervals that appear as intersection of the region with a line $\hat{\beta} = \text{const}$) and the spectral gaps (white vertical intervals). We refer to Subsection 5.2 for additional details of the construction.

![Figure 1. Structure of the spectrum in spectral bands (gray) and spectral gaps (white) as a function of the constant (periodic) magnetic potential $\hat{\beta}$ of 3-aGNR.](image)

In the case of the polyacetylene polymer we find a spectral gap that is stable under perturbation of the (constant) magnetic field. Moreover, if the value of the magnetic field is $\pi$ then the spectrum of the DML degenerates to four eigenvalues of infinite multiplicity making the material almost an insulator.

The article is structured in five sections. In Section 2 we collect the basic definitions and results on discrete weighted multigraphs (graphs which may have loops and multiple arcs). We consider discrete magnetic potentials on the arcs and define the discrete magnetic Laplacian on the graph which will be the central operator in this work. In Section 3 we present a spectral relation between finite MW-graphs based on an order relation between the eigenvalues of the corresponding DMLs. Moreover, we will present the basic arc and vertex virtualization procedure that will allow one to localize the spectrum of the DML on the infinite covering graph. In Section 4 we extend the discrete Floquet theory considered in [FLP18, Section 5] to the case of covering graphs with periodic magnetic potentials. In Section 5 we apply the spectral localization results developed before to the example of $\mathbb{Z}$-periodic graphs modeling the polyacetylene polymer as well as graphene nanoribbons in the presence of a constant magnetic field.

**Acknowledgements:** It is a pleasure to thank Manuel Asorey for useful conversations on the graphene nanoribbons example of the Section 5 during the IWIGQMA workshop in Grajera 2019, Spain.
2. Weighted graphs and discrete magnetic Laplacians

In this section we introduce the basic definitions and results concerning MW-graphs and give also the definition of discrete magnetic Laplacians. For further motivation and results we refer to [Sun94, LP08a, FLP18] and references cited therein.

We denote by $G = (V, E, \partial)$ a (discrete) directed multigraph which in the following we call simply a graph; here $V = V(G)$ is the set of vertices and $E = E(G)$ the set of arcs. The orientation map is given by $\partial: E \to V \times V$ and $\partial e = (\partial_- e, \partial_+ e)$ is the pair of the initial and terminal vertices. Graphs are allowed to have multiple arcs, i.e., arcs $e_1 \neq e_2$ with $(\partial_- e_1, \partial_+ e_1) = (\partial_- e_2, \partial_+ e_2)$ or $(\partial_+ e_1, \partial_- e_1) = (\partial_+ e_2, \partial_- e_2)$ as well as loops, i.e., arcs $e_1$ with $\partial_- e_1 = \partial_+ e_1$. Moreover, we define

$$E_v := E_v^+ \cup E_v^- \quad \text{(disjoint union), where} \quad E_v^\pm := \{e \in E \mid v = \partial_{\mp} e\}.$$ 

With this notation the degree of a vertex is $\deg(v) = |E_v|$ and a loop increases the degree by 2.

Given subsets $A, B \subset V$, we define

$$E^+(A, B) := \{e \in E \mid \partial_- e \in A, \partial_+ e \in B\} \quad \text{and} \quad E^-(A, B) := E^+(B, A).$$

Moreover, we put $E(A, B) := E^+(A, B) \cup E^-(A, B)$ and $E(A) := E(A, A)$.

To simplify the notation, we write $E(v, w)$ instead of $E(\{v\}, \{w\})$ etc. Note that loops are not counted double in $E(A, B)$, in particular, $E(v) := E(v, v)$ is the set of loops based at the vertex $v \in V$. The Betti number $b(G)$ of a finite graph $G = (V, E, \partial)$ is defined as

$$b(G) := |E| - |V| + 1. \quad (2.1)$$

To study the virtualization processes of vertices, arcs and the structure of covering graphs we will need to introduce the following substructures of a graph.

**Definition 2.1.** Let $G = (V, E, \partial)$ be a graph and denote by $H = (V_0, E_0, \partial_0)$ a triple such that $V_0 \subset V$, $E_0 \subset E$ and $\partial_0 = \partial \mid E_0$.

(a) If $E_0 \cap E(V \setminus V_0) = \emptyset$, we say that $H$ is a partial subgraph in $G$. We call

$$B(H, G) := E(V_0, V \setminus V_0) = \{e \in E \mid \partial_- e \in V_0, \partial_+ e \in V \setminus V_0 \text{ or } \partial_+ e \in V_0, \partial_- e \in V \setminus V_0\} \quad (2.2)$$

the set of connecting arcs of the partial subgraph $H$ in $G$.

(b) If $E_0 \subset E(V_0)$, then $H$ is a subgraph of $G$.

Note that, in general, a partial subgraph $H = (V_0, E_0, \partial_0)$ is not a graph as defined above, since we may have arcs $e \in E$ with $\partial_{\mp} e \notin V_0$. We do exclude though the case that $\partial_+ e \notin V_0$ and $\partial_- e \notin V_0$. The arcs not mapped into $V_0 \times V_0$ under $\partial_0$ are precisely the connecting arcs of $H$ in $G$. Partial subgraphs appear naturally as fundamental domains of covering graphs (cf., Section 4).

Let $G = (V, E, \partial)$ be a graph; a weight on $G$ is a pair of functions denoted by a unique symbol $m$ on the vertices and arcs $m: V \to (0, \infty)$ and $m: E \to (0, \infty)$ such that $m(v)$ is the weight at the vertex $v$ and $m_e$ is the weight at $e \in E$. We call $W = (G, m)$ a weighted graph. It is natural to interpret $m$ as a positive measure and consider $m(E_0) := \sum_{e \in E_0} m_e$ for any $E_0 \subset E$. The relative weight is $\rho: V \to (0, \infty)$ defined as

$$\rho(v) := \frac{m(E_v)}{m(v)} = \frac{m(E_v^+) + m(E_v^-)}{m(v)}. \quad (2.3a)$$

In order to work with bounded discrete magnetic Laplacians we will assume that the relative weight is uniformly bounded, i.e.,

$$\rho_\infty := \sup_{v \in V} \rho(v) < \infty. \quad (2.3b)$$

The most important and intrinsic examples of weights are

- **Standard weight:** $m(v) = \deg(v), v \in V$, and $m_e = 1, e \in E$, so that $\rho(v) = \rho_\infty = 1$.
- **Combinatorial weight:** $m(v) = m_e = 1, v \in V, e \in E$ hence $\rho(v) = \deg(v)$ and $\rho_\infty = \sup_{v \in V} \deg(v)$.  

1Note that we use the name partial subgraph in a different sense as in usual combinatorics literature.
Giving a weighted graph $W = (G, m)$, we associate the following two natural Hilbert spaces which we interpret as 0-forms and 1-forms, respectively.
\[
\ell_2(V, m) := \left\{ f : V \to \mathbb{C} \mid \| f \|_{V, m}^2 = \sum_{v \in V} |f(v)|^2 m(v) < \infty \right\} \quad \text{and} \quad \ell_2(E, m) := \left\{ \eta : E \to \mathbb{C} \mid \| \eta \|_{E, m}^2 = \sum_{e \in E} |\eta_e|^2 m_e < \infty \right\},
\]
with corresponding inner products
\[
\langle f, g \rangle_{\ell_2(V, m)} = \sum_{v \in V} f(v)g(v)m(v) \quad \text{and} \quad \langle \eta, \zeta \rangle_{\ell_2(E, m)} = \sum_{e \in E} \eta_e \zeta_e m_e.
\]

Let $G$ a graph; a magnetic potential $\alpha$ acting on $G$ is a $\mathbb{T}$-valued function on the arcs as follows, $\alpha : E(G) \to \mathbb{T} = \mathbb{R}/2\pi \mathbb{Z}$. We denote the set of all vector potentials on $E(G)$ just by $A(G)$. We say that two magnetic potentials $\alpha_1$ and $\alpha_2$ are cohomologous, and denote this as $\alpha_1 \sim \alpha_2$, if there is $\varphi : V \to \mathbb{T}$ with
\[
\alpha_1 = \alpha_2 + d\varphi.
\]
Given an $E_0 \subset E(G)$, we say that a magnetic potential $\alpha$ has support in $E_0$ if $\alpha_e = 0$ for all $e \in E(G) \setminus E_0$. We call the class of weighted graphs with magnetic potential $\alpha$-graphs.

It can be shown that any magnetic potential on a finite graph can be supported in $b(G)$ many arcs. For example, if $G$ is a cycle, any magnetic potential is cohomologous to a magnetic potential supported in only one arc. Moreover, if $G$ is a tree any magnetic potential on a tree is cohomologous to 0.

The twisted (discrete) derivative is the following linear operator mapping 0-forms into 1-forms:
\[
d_{\alpha} : \ell_2(V, m) \to \ell_2(E, m) \quad \text{with} \quad (d_{\alpha} f)_e = e^{i\alpha_e/2} f(\partial_+ e) - e^{-i\alpha_e/2} f(\partial_- e).
\]

We present next the following geometrical definition of Laplacian with magnetic field as a generalization of the discrete Laplace-Beltrami operator.

**Definition 2.2.** Let $W = (G, m)$ a weighted graph with $\alpha : E \to \mathbb{T}$ a vector potential. The discrete magnetic Laplacian (DML for short) $\Delta_{\alpha} : \ell_2(V) \to \ell_2(V)$ is defined by $\Delta_{\alpha} = d_{\alpha}^* d_{\alpha}$, i.e., by
\[
(\Delta_{\alpha} f)(v) = \rho(v) f(v) - \frac{1}{m(v)} \sum_{e \in E_v} e^{i\alpha_e(v)} f(v_e)m_e,
\]
where $\alpha_e(v)$ is the oriented evaluation and $v_e$ is the vertex opposite to $v$ along the arc $e$, i.e.,
\[
\alpha_e(v) = \begin{cases} 
-\alpha_e, & \text{if } v = \partial_- e, \\
\alpha_e, & \text{if } v = \partial_+ e,
\end{cases} \quad \text{and} \quad v_e = \begin{cases} 
\partial_+ e, & \text{if } v = \partial_- e, \\
\partial_- e & \text{if } v = \partial_+ e.
\end{cases}
\]

If we need to stress the dependence of the operator of the weighted graph $W = (G, m)$ we will denote the DML as $\Delta_{\alpha}^W$.

From this definition it follows immediately that the DML $\Delta_{\alpha}$ is a bounded, positive and self-adjoint operator. Its spectrum satisfies $\sigma(\Delta_{\alpha}) \subset [0, 2\rho_\infty]$ and, in contrast to the usual Laplacian without magnetic potential, the DML does depend on the orientation of the graph. If $\alpha \sim \alpha'$, then $\Delta_{\alpha}$ and $\Delta_{\alpha'}$ are unitary equivalent; in particular, $\sigma(\Delta_{\alpha}) = \sigma(\Delta_{\alpha'})$. Moreover, if $\alpha \sim 0$ then $\Delta_{\alpha} \cong \Delta$ where $\Delta$ denotes the usual discrete Laplacian (with vector potential 0). For example, if $W = (G, m)$ and $G$ is a tree, then $\Delta_{\alpha}^W \cong \Delta^W$ for any magnetic potential $\alpha$.

### 3. Spectral ordering on finite graphs and magnetic spectral gaps

In this section we will introduce a spectral ordering relation $\preceq$ which is invariant under unitary equivalence of the corresponding operators. Moreover, we will introduce two operations on the graphs (virtualization of arcs and vertices) that will be used later to develop a spectral localization ( bracketing) of DML on finite graphs. This technique will finally be applied to discuss the existence of spectral gaps for magnetic Laplacians on covering graphs. We refer to [FLP18], [KS15], [LP08a] for additional motivation and examples. For proofs of the results stated in this section see [FLP18] Sections 3 and 4]
Let $W = (G, m)$ a weighted graph. Throughout this section, we will assume that $|V(G)| = n < \infty$. We denote the spectrum of the DML by $\sigma(\Delta^W_\alpha) := \{\lambda_k(\Delta^W_\alpha) \mid k = 1, \ldots, n\} \subset [0, 2\rho_\infty]$, where we will write the eigenvalues in ascending order and repeated according to their multiplicities, i.e.,

$$0 \leq \lambda_1(\Delta^W_\alpha) \leq \lambda_2(\Delta^W_\alpha) \leq \cdots \leq \lambda_n(\Delta^W_\alpha).$$

**Definition 3.1.** Let $W^-$ and $W^+$ be two finite MW-graphs of order $n^-$ and $n^+$, respectively, and magnetic potential $\alpha^\pm$. Consider the eigenvalues of the DMLs $\Delta^W_\alpha$ written in ascending order and repeated according to their multiplicities.

(a) We say that $W^-$ is spectrally smaller than $W^+$ (denoted by $W^- \ll W^+$), if $n^- \geq n^+$ and if $\lambda_k(\Delta^W_-) \leq \lambda_k(\Delta^W_+)$ for all $1 \leq k \leq n^-$, where we put $\lambda_k(\Delta^W_+) := 2\rho_\infty$ for $k = n^+ + 1, \ldots, n^-$ (the maximal possible eigenvalue).

(b) Consider $W^\pm$ as above with $W^- \not\ll W^+$. We define the associated $k$-th bracketing interval $J_k = J_k(W^-, W^+)$ by

$$J_k := [\lambda_k(\Delta^W_-), \lambda_k(\Delta^W_+)] \quad (3.1)$$

for $k = 1, \ldots, n^-$. Given a MW-graph, we introduce two elementary operations that consist on virtualizing arcs and vertices. The first one will lead to a spectrally smaller graph.

**Definition 3.2 (virtualizing arcs).** Let $W = (G, m)$ a weighted graph with magnetic potential $\alpha$ and $E_0 \subset E(G)$. We denote by $W^- = (G^-, m^-)$ the weighted subgraph with magnetic potential $\alpha^-$ defined as follows:

(a) $V(G^-) = V(G)$ with $m^-(v) := m(v)$ for all $v \in V(G)$;

(b) $E(G^-) = E(G) \setminus E_0$ with $m^- := m_e$ and $\partial^G_- e = \partial^G_- e$ for all $e \in E(G^-)$;

(c) $\alpha^- := \alpha_e, e \in E(G^-)$.

We call $W^-$ the weighted subgraph obtained from $W$ by virtualizing the arcs $E_0$. We will sometimes denote the weighted graph simply by $W^- = W - E_0$ and we write the corresponding discrete magnetic Laplacian as $\Delta^W_\alpha$.

The second elementary operation on the graph will lead now to a spectrally larger graph.

**Definition 3.3 (virtualizing vertices).** Let $W = (G, m)$ a weighted graph with magnetic potential $\alpha$ and $V_0 \subset V(G)$. We denote by $W^+ = (G^+, m^+)$ the weighted partial subgraph with magnetic potential $\alpha^+$ defined as follows:

(a) $V(G^+) = V(G) \setminus V_0$ with $m^+(v) := m(v)$ for all $v \in V(G^+)$;

(b) $E(G^+) = E(G) \setminus \bigcup_{v \in V_0} E(v)$ with $m^+ = m_e$ for all $e \in E(G^+)$;

(c) $\alpha^+ := \alpha_e, e \in E(G^+)$.

We call $W^+$ the weighted partial subgraph obtained from $W$ by virtualizing the vertices $V_0$. We will denote it simply by $W^+ = W - V_0$. The corresponding discrete magnetic Laplacian is defined by

$$\Delta^W_\alpha = (d^+\alpha)^* d_\alpha^+, \quad \text{where} \quad d_\alpha := d_\alpha \circ \iota$$

with

$$\iota: \ell_2(V(G^+), m^+) \to \ell_2(V(G), m), \quad (\iota f)(v) = \begin{cases} f(v), & v \in V(G^+), \\ 0, & v \in V_0. \end{cases}$$

It can be shown that the operator $\Delta^W_\alpha$ is the compression of $\Delta^W$ onto a $(|V| - |V_0|)$-subspace.

The previous operations of arc and vertex virtualization will be used to localize the spectrum of intermediate DMLs. Before summarizing the technique in the next theorem, we need to introduce the following notion of vertex neighborhood of a family of arcs.

**Definition 3.4.** Let $G$ a graph and $E_0 \subset E(G)$. We say that a vertex subset $V_0 \subset V(G)$ is in the neighborhood of $E_0$ if $E_0 \subset \bigcup_{v \in V_0} E(v)$, i.e., if $\partial_+ e \in V_0$ or $\partial_- e \in V_0$ for all $e \in E_0$.

Later on $E_0$ will be the set of connecting arcs of a covering graph, and we will choose $V_0$ to be as small as possible to guarantee the existence of spectral gaps (this set is in general not unique).
Theorem 3.5. Let \( W = (G, m) \) be a finite MW-graph with magnetic potential \( \alpha \) and \( E_0 \subset E(G) \). Then, for any subset of vertices \( V_0 \) in a neighborhood of \( E_0 \) we have

\[
W^- \preceq W \preceq W^+, \tag{3.2}
\]

where \( W^- = (G^-, m^-) \) with \( G^- = G - E_0 \) and \( W^+ = (G^+, m^+) \) with \( G^+ = G - V_0 \). In particular, we have the spectral localizing inclusion

\[
\sigma(\Delta,W^\alpha) \subset J := J(W^-, W^+) = \cup_{k=1}^{V(G)} [\lambda_k(\Delta,W^-),\lambda_k(\Delta,W^+)]. \tag{3.3}
\]

Observe that, in fact, the bracketing \( J = J(\alpha) \) depends on the magnetic potential \( \alpha \). In Section 5 we show in some examples how the localization intervals \( J_k \) change under the variation of the magnetic potential (see, e.g., Figure 3). However, if the magnetic potential \( \alpha \) has support on the virtualized arcs \( E_0 \), then \( J \) will not depend on \( \alpha \) because \( \alpha^\pm \sim 0 \).

Next we make precise several notions in relation to spectral gaps that will be need when we study covering graphs. Recall that \( \sigma(\Delta G^\alpha) \subset [0,2\rho_\infty] \), where \( \rho_\infty \) denotes the supremum of the relative weight, (cf., Eq. (2.3)).

Definition 3.6. Let \( W = (G, m) \) be a weighted graph.

(a) The spectral gaps set of \( W \) is defined by

\[
S_W = [0,2\rho_\infty] \setminus \sigma(\Delta W) = [0,2\rho_\infty] \cap \rho(\Delta W),
\]

where \( \rho(\Delta W) \) denotes the resolvent set of the operator \( \Delta W \).

(b) The magnetic spectral gaps set of \( W \) is defined by

\[
MS_W = [0,2\rho_\infty] \setminus \bigcup_{\alpha \in A(G)} \sigma(\Delta W^\alpha) = \bigcap_{\alpha \in A(G)} \rho(\Delta W^\alpha) \cap [0,2\rho_\infty].
\]

where the union is taken over all the magnetic potential \( \alpha \) acting on \( G \).

The following elementary properties follow directly from the definition: \( MS_W \subseteq S_W \). In particular, if \( S_W = \emptyset \), then \( MS_W = \emptyset \) or, equivalently, if \( MS_W \neq \emptyset \), then \( S_W \neq \emptyset \). Moreover, if \( G \) is a tree, then \( MS_W = S_W \), as all DMLs are unitary equivalent with the usual Laplacian \( \Delta W \).

Up to now we have seen that arc/vertex virtualization will produce graphs \( W^\pm \) that allow to localize the spectrum of the DML of any intermediate MW-graph \( W \) satisfying

\[
W^- \preceq W \preceq W^+.
\]

4. Periodic graphs and spectral gaps

In this section, we will study the spectrum of the DML of an infinite covering graph with periodic magnetic potential in terms of its Floquet decomposition. In Proposition 4.6 we will identify the Floquet parameter of the covering graph with a suitable set of magnetic potentials \( \alpha \) on the quotient (cf., Definition 4.5). This approach generalizes results in [FLP18, Section 5] to include Laplacians on the infinite covering graph with a periodic magnetic potential \( \beta \). Finally in Theorem 4.7 we state a bracketing technique to localize the spectrum.

4.1. Periodic graphs and fundamental domains. Let \( \Gamma \) be an (Abelian) lattice group and consider the \( \Gamma \)-covering (or \( \Gamma \)-periodic) graph

\[
\tau: \tilde{G} \to G = \tilde{G}/\Gamma.
\]

We assume that \( \Gamma \) acts freely and transitively on the connected graph \( \tilde{G} \) with finite quotient \( G = \tilde{G}/\Gamma \) (see also [Sun13, Chapters 5 and 6] or [Sun08, FLP18]). This action (which we write multiplicatively) is orientation preserving, i.e., \( \Gamma \) acts both on \( \tilde{V} \) and \( \tilde{E} \) such that

\[
\partial_+(\gamma e) = \gamma(\partial_+ e) \quad \text{and} \quad \partial_-(\gamma e) = \gamma(\partial_- e) \quad \text{for all} \ \gamma \in \Gamma \ \text{and} \ e \in \tilde{E}.
\]

In particular, we have \( \tilde{E}_{\gamma v} = \gamma \tilde{E}_{v}, \gamma \in \Gamma, v \in \tilde{V} \).

In addition, we will study weighted covering graphs with a periodic weight \( \tilde{m} \) and periodic magnetic potential \( \tilde{\beta} \), i.e., we consider \( W = (\tilde{G}, \tilde{m}, \tilde{\beta}) \) a MW-graph such that for any \( \gamma \in \Gamma \) we have

\[
\tilde{m}(\gamma v) = \tilde{m}(v), \ v \in \tilde{V}, \ \tilde{m}_{\gamma e} = \tilde{m}_e, \ e \in \tilde{E} \quad \text{and} \quad \tilde{\beta}_{\gamma e} = \tilde{\beta}_e, \ e \in \tilde{E}.
\]
Note that, by definition, the standard or combinatorial weights on a covering graph satisfy the invariance conditions on the weights. A \( \Gamma \)-covering weighted graph \( \overline{W} = (\overline{G}, \overline{m}) \) naturally induces a weight \( m \) and a magnetic potential \( \beta \) on the quotient graph \( G = \overline{G}/\Gamma \), given by \( m = \overline{m} \circ \pi^{-1} \) and \( \beta = \overline{\beta} \circ \pi^{-1} \).

We define next some useful notions in relation to covering graphs (see, e.g., \[FLP18\] Section 5) as well as \[KSL14\] Subsections 1.2 and 1.3 and \[LP08D\]).

**Definition 4.1.** Let \( \tilde{G} = (\tilde{V}, \tilde{E}, \tilde{\partial}) \) be a \( \Gamma \)-covering graph.

(a) A vertex, respectively arc fundamental domain on a \( \Gamma \)-covering graph is given by two subsets \( D^V \subset \tilde{V} \) and \( D^E \subset \tilde{E} \) satisfying

\[
\tilde{V} = \bigcup_{\gamma \in \Gamma} \gamma D^V \quad \text{and} \quad \gamma_1 D^V \cap \gamma_2 D^V = \emptyset \quad \text{if} \quad \gamma_1 \neq \gamma_2,
\]

\[
\tilde{E} = \bigcup_{\gamma \in \Gamma} \gamma D^E \quad \text{and} \quad \gamma_1 D^E \cap \gamma_2 D^E = \emptyset \quad \text{if} \quad \gamma_1 \neq \gamma_2
\]

with \( D^E \cap E(\tilde{V} \setminus D^V) = \emptyset \) (i.e., an arc in \( D^E \) has at least one endpoint in \( D^V \)). We often simply write \( D \) for a fundamental domain, where \( D \) stands either for \( D^V \) or \( D^E \).

(b) A (graph) fundamental domain of a covering graph \( \tilde{G} \) is a partial subgraph (cf., Definition 2.1)

\[
H = (D^V, D^E, \partial |_{D^E}),
\]

where \( D^V \) and \( D^E \) are vertex and arc fundamental domains, respectively. We call

\[
B(H, \tilde{G}) := E(D^V, \tilde{V} \setminus D^V)
\]

the set of connecting arcs of the fundamental domain \( H \) in \( \tilde{G} \).

**Remark 4.2.**

(a) Fixing a fundamental domain on the covering graph and the group \( \Gamma \) will be used to give coordinates (to the arcs and vertices) on the covering graph \( \tilde{G} \).

In fact, given a specific \( D^V \) in a \( \Gamma \)-covering graph \( G \), we can write any \( v \in V(\tilde{G}) \) uniquely as \( v = \xi(v)v_0 \) for a unique pair \( (\xi(v),v_0) \in \Gamma \times D^V \). This follows from the fact that the action is free and transitive. We call \( \xi(v) \) the \( \Gamma \)-coordinate of \( v \) (with respect to the fundamental domain \( D^V \)). Similarly, we can define the coordinates for the arcs: any \( e \in E(\tilde{G}) \) can be written as \( e = \xi(e)e_0 \) for a unique pair \( (\xi(e),e_0) \in \Gamma \times D^E \). In particular, we have

\[
\xi(\gamma v) = \gamma \xi(v) \quad \text{and} \quad \xi(\gamma e) = \gamma \xi(e), \quad \text{for all} \quad \gamma \in \Gamma.
\]

(b) Once we have chosen a fundamental domain \( H = (D^V, D^E, \partial) \), we can embed \( H \) into the quotient \( G = \overline{G}/\Gamma \) of the covering \( \pi : \overline{G} \to G \) by

\[
D^V \to V(G) = V/\Gamma, \quad v \mapsto [v] \quad \text{and} \quad D^E \to E(G) = E/\Gamma, \quad e \mapsto [e],
\]

where \([v]\) and \([e]\) denote the \( \Gamma \)-orbits of \( v \) and \( e \), respectively. By definition of a fundamental domain, these maps are bijective. Moreover, if \( \partial_{\pm} e = v \) in \( H \), then also \( \partial_{\pm}([e]) = [v] \) in \( G \), i.e., the embedding is a (partial) graph homomorphism.

**Definition 4.3.** Let \( \tilde{G} = (\tilde{V}, \tilde{E}, \tilde{\partial}) \) be a \( \Gamma \)-covering graph with fundamental graph \( H = (D^V, D^E, \partial) \).

We define the index of an arc \( e \in \tilde{E} \) as

\[
\text{ind}_{H}(e) := \xi(\partial_{+} e) (\xi(\partial_{-} e))^{-1} \in \Gamma.
\]

In particular, we have \( \text{ind}_{H} : \tilde{E} \to \Gamma \), and \( \text{ind}_{H}(e) \neq 1_{\Gamma} \) iff \( e \in \bigcup_{\gamma \in \Gamma} \gamma B(H, \tilde{G}) \), i.e., the index is only non-trivial on the (translates of the) connecting arcs. Moreover, the set of indices and its inverses generate the group \( \Gamma \).

Since the index fulfills \( \text{ind}_{H}(\gamma e) = \text{ind}_{H}(e) \) for all \( \gamma \in \Gamma \) by Remark 4.2, we can extend the definition to the quotient \( G = \overline{G}/\Gamma \) by setting \( \text{ind}_{G}([e]) = \text{ind}_{H}(e) \) for all \( e \in E(G) \). We denote also \( B(H, \tilde{G}) := \{[e] \mid e \in B(H, \tilde{G})\} \).
4.2. Discrete Floquet theory. Let $W = (\tilde{V}, \tilde{E}, \tilde{\partial}, \tilde{m})$ be a weighted $\Gamma$-covering graph and fundamental domain $H = (D^V, D^E, \partial)$ with corresponding weights inherited from $\tilde{W}$. In this context one has the natural Hilbert space identifications

$$\ell_2(\tilde{V}, \tilde{m}) \cong \ell_2(\Gamma) \otimes \ell_2(D^V, m) \cong \ell_2\left(\Gamma, \ell_2(D^V, m)\right).$$

Floquet theory uses a partial Fourier transformation on the Abelian group that can be understood as putting coordinates on the periodic structure and allows to decompose the corresponding operators as direct integrals. Concretely, we consider

$$F: \ell_2(\Gamma) \to L_2(\hat{\Gamma}), \quad (Fa)(\chi) := \sum_{\gamma \in \Gamma} \overline{\chi(\gamma)} a_\gamma$$

for $a = \{a_\gamma\}_{\gamma \in \Gamma} \subset \ell_2(\Gamma)$ and where $\hat{\Gamma}$ denotes the character group of $\Gamma$. We adapt to the discrete context of graphs with periodic magnetic potential $\tilde{\beta}$ the main results concerning Floquet theory needed later. See, e.g., [LP07, Section 3] or [KSL14] for details, additional motivation and references.

For any character $\chi \in \hat{\Gamma}$ consider the space of equivariant functions on vertices and arcs

$$\ell_2^E(V, m) := \{g: V \to \mathbb{C} \mid g(\gamma v) = \chi(\gamma) g(v) \text{ for all } v \in V \text{ and } \gamma \in \Gamma\},$$

$$\ell_2^E(E, m) := \{\eta: E \to \mathbb{C} \mid \eta_{\gamma e} = \chi(\gamma) \eta_e \text{ for all } e \in E \text{ and } \gamma \in \Gamma\}.$$

These spaces have the natural inner product defined on the fundamental domains $D^V$ and $D^E$:

$$\langle g_1, g_2 \rangle := \sum_{v \in D^V} g_1(v) \overline{g_2(v)} m(v) \quad \text{and} \quad \langle \eta_1, \eta_2 \rangle := \sum_{e \in D^E} \eta_1(e) \overline{\eta_2(e)} m_e.$$

Note that the definition of the inner product is independent of the choice of fundamental domain (due to the equivariance). We extend the standard decomposition to the case of the DML with periodic magnetic potential (see, for example, [KSL14] or [HS99]).

**Proposition 4.4.** Let $W = (\tilde{G}, \tilde{m})$ be a covering weighted graph where $\tilde{G} = (\tilde{V}, \tilde{E}, \tilde{\partial})$ and $\tilde{\beta}$ is a periodic magnetic potential. Then there are unitary transformations

$$\Phi: \ell_2(\tilde{V}) \to \int_{\hat{\Gamma}} ^{\oplus} \ell_2^{\tilde{E}}(\tilde{V}, \tilde{m}) d\chi \quad \text{given by} \quad (\Phi f)(\chi)(v) = \sum_{\gamma \in \Gamma} \overline{\chi(\gamma)} f(\gamma v),$$

$$\Phi: \ell_2(\tilde{E}) \to \int_{\hat{\Gamma}} ^{\oplus} \ell_2^{\tilde{E}}(\tilde{E}, \tilde{m}) d\chi \quad \text{given by} \quad (\Phi \eta)(\chi)(v) = \sum_{\gamma \in \Gamma} \overline{\chi(\gamma)} \eta_{\gamma e},$$

such that

$$\sigma\left(\Delta_{\tilde{W}}^{\tilde{\beta}}\right) = \bigcup_{\chi \in \hat{\Gamma}} \sigma\left(\Delta_{\tilde{W}}^{\tilde{\beta}}(\chi)\right),$$

where equivariant Laplacian (fiber operators) are defined as $\Delta_{\tilde{W}}^{\tilde{\beta}}(\chi) := \Delta_{\tilde{W}}(\chi) |_{\ell_2^{\tilde{V}}(\tilde{V})}.$

**Proof.** Consider the twisted derivative $d_{\tilde{\beta}}^{\tilde{\partial}}: \ell_2^{\tilde{E}}(\tilde{V}) \to \ell_2^{\tilde{E}}(\tilde{E})$ specified in Eq. (2.4) and the equivariant twisted derivative on the fiber spaces defined by $d_{\tilde{\beta}}^{\chi}: \ell_2^{\tilde{V}}(\tilde{V}) \to \ell_2^{\tilde{E}}(\tilde{E})$

$$(d_{\tilde{\beta}}^{\chi})_e := e^{i\tilde{\beta} e/2} g(\partial_+ e) - e^{-i\tilde{\beta} e/2} g(\partial_- e), \quad g \in \ell_2^{\tilde{V}}(\tilde{V}).$$

It is straightforward to check that if $g \in \ell_2^{\tilde{E}}(\tilde{V})$, then $d_{\tilde{\beta}}^{\chi} g \in \ell_2^{\tilde{E}}(\tilde{E})$ and that $\Delta_{\tilde{W}}^{\tilde{\beta}}(\chi) = (d_{\tilde{\beta}}^{\chi})^* d_{\tilde{\beta}}^{\chi}$. Moreover, we will show that the unitary transformations $\Phi$ intertwine these two first order operators, i.e.,

$$\Phi d_{\tilde{\beta}}^{\chi} f = \int_{\hat{\Gamma}} ^{\oplus} d_{\tilde{\beta}}^{\chi}(\Phi f)(\chi) d\chi, \quad f \in \ell_2^{\tilde{V}}(\tilde{V}).$$
In fact, this is a consequence of the following computation that uses the invariance of the magnetic potential. For any \( f \in \ell^2(\hat{V}) \) and \( \chi \in \hat{\Gamma} \)
\[
\left( \Phi \left( d_{\beta}f \right) \right)_{\chi,e} = \sum_{\gamma \in \hat{\Gamma}} \chi(\gamma) \left( d_{\beta}f \right)_{\gamma,e} = \sum_{\gamma \in \hat{\Gamma}} \chi(\gamma) \left[ e^{i\tilde{\beta}_e/2} f(\partial_+ \gamma e) - e^{-i\tilde{\beta}_e/2} f(\partial_- \gamma e) \right] \\
= \sum_{\gamma \in \hat{\Gamma}} \chi(\gamma) \left[ e^{i\tilde{\beta}_e/2} f(\gamma \partial_+ e) - e^{-i\tilde{\beta}_e/2} f(\gamma \partial_- e) \right] \\
= \left( d_{\beta}^{\chi}(\Phi f)_{\chi} \right)_e.
\]
This shows that
\[
\Delta_{\beta}^{\chi} = \int_{\hat{\Gamma}} \Delta_{\beta}^{\chi} (\chi) \, d\chi
\]
and, hence, \( \sigma(\Delta_{\beta}^{\chi}) = \bigcup_{\chi \in \hat{\Gamma}} \sigma(\Delta_{\alpha}^{\chi}) \).

### 4.3. Vector potential as a Floquet parameter.

The following result shows that in the case of Abelian groups \( \Gamma \) we can interpret the magnetic potential \( \alpha \) on the quotient graph partially as a Floquet parameter for the covering graph \( \hat{G} \to G \) (see Remark 4.2 (b)). Moreover, recalling the definition of coordinate giving in Remark 4.2 (b) we can define the following unitary maps (see also [KOS89] for a similar definition in the context of manifolds):

\[
U^V : \ell_2(\hat{V}, m) \to \ell_2^\chi(\hat{V}, \hat{m}), \quad \left( U^V f \right)(v) = \chi(\xi(v)) f([v]),
\]
\[
U^E : \ell_2(\hat{E}, m) \to \ell_2^\chi(\hat{E}, \hat{m}), \quad \left( U^E \eta \right)_e = \chi(\xi(e)) \eta_{\hat{e}}.
\]

It is straightforward to check that \( U^V \) and \( U^E \) are well defined and unitary.

**Definition 4.5.** Let \( \Gamma \)-covering graph \( \pi : \hat{W} \to W \) with periodic weights \( \hat{m} \), periodic magnetic potential \( \hat{\beta} \) and fundamental domain \( H \). We denote by \( \alpha \) a magnetic potential acting on the quotient \( G = G/\Gamma \). We say that \( \alpha \) has the lifting property if there exists \( \chi \in \hat{\Gamma} \) such that:

\[
e^{i\alpha[e]} = \chi(\text{ind}_H(e)) e^{i\tilde{\beta}[e]} \quad \text{for all} \quad e \in E. \tag{4.1}
\]

We denote the set of all the magnetic potentials with the lifting property as \( A_H \).

**Proposition 4.6.** Consider a \( \Gamma \)-covering graph \( \pi : \hat{W} \to W \) with periodic magnetic potential \( \hat{\beta} \), where \( \hat{W} = (\hat{G}, \hat{m}) \), \( W = (G, m) \) and \( H \) is a fundamental domain. Then

\[
\sigma(\Delta_{\beta}^{\chi}) = \bigcup_{\alpha \in A_H} \sigma(\Delta_{\alpha}^{\chi}) \subset [0, 2p_{\infty}] \setminus MS^W. \tag{4.2}
\]

**Proof.** By Proposition 4.4, it is enough to show
\[
\bigcup_{\chi \in \hat{\Gamma}} \sigma(\Delta_{\beta}^{\chi}(\chi)) = \bigcup_{\alpha \in A_H} \sigma(\Delta_{\alpha}^{\chi}).
\]
To show the inclusion “\( \subset \)” consider a character \( \chi \in \hat{\Gamma} \) and define a magnetic potential on \( G \) as follows
\[
e^{i\alpha[e]} := \chi(\text{ind}_H(e)) e^{i\tilde{\beta}[e]}, \quad e \in E. \tag{4.3}
\]
Then we have
\[
\left( d_{\beta}^{\chi}(U^V f) \right)_e = e^{i\tilde{\beta}_e/2} (U^V f)(\partial_+ e) - e^{-i\tilde{\beta}_e/2} (U^V f)(\partial_- e) = e^{i\tilde{\beta}_e/2} \chi(\xi(\partial_+ e)) f([\partial_+ e]) - e^{-i\tilde{\beta}_e/2} \chi(\xi(\partial_- e)) f([\partial_- e]).
\]

On the other hand, we have
\[
\left( U^E d_{\alpha} f \right)_e = \chi(\xi(e)) \left( e^{i\alpha[e]/2} f([\partial_+ e]) - e^{-i\alpha[e]/2} f([\partial_- e]) \right).
\]
Therefore, the intertwining equation \( d_{\beta}^{\chi} U = U^E d_{\alpha} \) holds if
\[
e^{i\tilde{\beta}_e/2} \chi(\xi(\partial_+ e)) = \chi(\xi(e)) e^{i\alpha[e]/2} \quad \text{and} \quad e^{-i\tilde{\beta}_e/2} \chi(\xi(\partial_- e)) = \chi(\xi(e)) e^{-i\alpha[e]/2}.
\]
or, equivalently, if
\[ e^{i\alpha[e]} = \chi(\xi(\partial_+ e))\chi(\xi(\partial_- e))^{-1} e^{i\tilde{\beta}[e]} = \chi(\text{ind}_H(e)) e^{i\tilde{\beta}[e]} . \]

But this equation is true by definition of the magnetic potential on $G$ given in Eq. [4.3]. Finally, since $\Delta_{W}^{\beta}(\chi) = (d\beta)^*d\beta$ and $\Delta_{W}^{\alpha} = d^*d$ it is clear that these Laplacians are unitary equivalent.

To show the reverse inclusion “−” let $\alpha \in \mathcal{A}_H$ and $E_H \subset E(G)$ is such that $\{\text{ind}_H(e) \mid [e] \in E_H\}$ is a basis of the group $\Gamma$. Then define
\[ \chi(\text{ind}_H(e)) := e^{i\alpha[e]} e^{-i\tilde{\beta}[e]} , \quad e \in E_H \]
and we can extend $\chi$ to all $\Gamma$ multiplicatively, so that $\chi \in \hat{\Gamma}$. As before, we can show then $\sigma(\Delta_{W}^{\beta}(\chi)) = \sigma(\Delta_{W}^{\alpha}(\chi))$ and the proof is concluded. \hfill \Box

4.4. Spectral localization for the DML on a covering graph. We apply now the technique stated in Theorem 3.5 to covering graphs.

**Theorem 4.7.** Let $\tilde{W} = (\tilde{G}, \tilde{m})$ be a $\Gamma$-covering graph and $\tilde{\beta}$ a periodic magnetic potential. Consider a fundamental domain $H = (D^V, D^E, \partial)$ and $W = (G, m)$ with magnetic potential $\beta$, where $G = \tilde{G}/\Gamma$. The functions $m$ and $\beta$ are induced by $\tilde{m}$ and $\tilde{\beta}$ respectively. Let
\[ E_0 := [B(H, \tilde{\beta})] \]
be the image of the connectivity arcs on the quotient and $V_0$ in the neighborhood of $E_0$. Define by
\[ W^- := W - E_0 \quad \text{and} \quad W^+ := W - V_0. \]
the corresponding arc and vertex virtualized graphs, respectively. Then
\[ \sigma(\Delta_{W}^{\tilde{\beta}}(\chi)) \subset \bigcup_{k=1}^{\left|V(G)\right|} [\lambda_k(\Delta_{\beta}^{W^-}), \lambda_k(\Delta_{\beta}^{W^+})] \]
where the eigenvalues of $\sigma(\Delta_{W}^{\beta}(-))$ and $\sigma(\Delta_{W}^{\beta}(+))$ are written in ascending order and repeated according to their multiplicities.

**Proof.** By Proposition 4.6 we have
\[ \sigma(\Delta_{W}^{\tilde{\beta}}(\chi)) = \bigcup_{\alpha \in \mathcal{A}_H} \sigma(\Delta_{W}^{\alpha}(\chi)). \]

Now, by the bracketing technique of Theorem 3.5 we have for any potential with the lifting property $\alpha \in \mathcal{A}_H$ (cf., Definition 3.4):
\[ \lambda_k(\Delta_{\alpha}^{W^-}) \leq \lambda_k(\Delta_{\alpha}^{W}) \leq \lambda_k(\Delta_{\alpha}^{W^+}) \quad \text{for all} \quad k = 1, \ldots, \left|V(G)\right|. \]
Therefore, by Eq. (3.3)
\[ \sigma(\Delta_{W}^{\tilde{\beta}}(\chi)) \subset \bigcup_{\alpha \in \mathcal{A}_H} \bigcup_{k=1}^{\left|V(G)\right|} [\lambda_k(\Delta_{\alpha}^{W^-}), \lambda_k(\Delta_{\alpha}^{W^+})] ; \]
since $\alpha$ has the lifting property, Eq. (4.1) implies that there exists $\chi \in \hat{\Gamma}$ such that:
\[ e^{i\alpha[e]} = \chi(\text{ind}_H(e)) e^{i\tilde{\beta}[e]} \quad \text{for all} \quad e \in E. \]
But for all $e \in E \setminus E_0 = E \setminus [B(H, \tilde{\beta})]$ the index is trivial, i.e., $\text{ind}_H(e) = 1_\Gamma$ (see Remark 4.2). Thus by $\Gamma$-periodicity we obtain that $\beta_e = \alpha_e$ for all arcs $e \in E \setminus E_0$. Since $\alpha$ and $\beta$ are magnetic potentials acting on $G$, and $G^- = G - E_0$ then $\alpha^- = \beta^-$. Similarly, for $G^+ = G - V_0$ with $V_0$ in the neighborhood of $E_0$, we have that $\alpha^+ = \beta^+$. We obtain finally
\[ \sigma(\Delta_{W}^{\tilde{\beta}}(\chi)) \subset \bigcup_{\alpha \in \mathcal{A}_H} \bigcup_{k=1}^{\left|V(G)\right|} [\lambda_k(\Delta_{\beta}^{W^-}), \lambda_k(\Delta_{\beta}^{W^+})] . \]

Note that the last union does not depend anymore of $\alpha$ and this fact concludes the proof. \hfill \Box
Note that the bracketing intervals $J_k$ depend on the fundamental domain $H$. A good choice is one where the set of connecting arcs is as small as possible providing high contrast between the interior of the fundamental domain and its boundary. In this case, we have a good chance that the localizing intervals $J_k$ do not cover the full interval $[0, 2\rho_\infty]$. This is a discrete geometrical version of a “thin–thick” decomposition as described in [LP08a], where a fundamental domain of the metric and discrete graph has only a few connections to its complement.

The next theorem gives a simple geometric condition on an MW-graph $W$ for the existence of gaps in the spectrum of the DML on the $\Gamma$-covering graph. We will specify which arcs and vertices should be virtualized in $W$ to guarantee the existence of spectral gaps. This result generalizes the Theorem 4.4 in [FLP18].

**Theorem 4.8.** Let $\tilde{W} = (\tilde{G}, \tilde{m})$ be a $\Gamma$-covering graph with a $\Gamma$-periodic magnetic potential $\tilde{\beta}$. Denote by $W = (G, m)$ the quotient graph with induced magnetic potential $\beta$ and induced weights $m$, respectively.

The spectrum of the DML has spectral gaps, i.e., $\sigma(\Delta^{\tilde{W}}_\beta) \neq [0, 2\rho_\infty]$, if the following condition holds: there exists a vertex $v_0 \in V(G)$ and a fundamental domain $H$ such that the connecting arcs $[B(H, \tilde{G})]$ contain no loops, $[B(H, \tilde{G})] \subset E_{v_0}$ and

$$\delta := \rho(v_0) - \sum_{e \in [B(H, \tilde{G})]} \frac{m_e}{m((v_0)_e)} - \frac{m([B(H, \tilde{G})])}{m(v_0)} - \lambda_1(\Delta^{\tilde{W}}_{\beta^-}) > 0,$$

(4.5)

where $\rho(v_0) = m(E_{v_0})/m(v_0)$ is the relative weight at $v_0$ and $W^- = (G^-, m^-)$ with $G^- = G - [B(H, \tilde{G})]$.

**Proof.** Consider the following arc and vertex virtualized weighted graphs:

$$W^- := W - [B(H, \tilde{G})] \quad \text{and} \quad W^+ := W - \{v_0\}.$$

Then by Theorem 4.7 we obtain

$$\sigma(\Delta^{\tilde{W}}_\beta) \subset \bigcup_{k=0}^{\lfloor |V(G)| / |B(H, \tilde{G})| \rfloor} [\lambda_k(\Delta^{\tilde{W}}_{\beta^-}), \lambda_k(\Delta^{\tilde{W}}_{\beta^+})] = J \subset [0, 2\rho_\infty].$$

To prove that $\sigma(\Delta^{\tilde{W}}_\beta) \neq [0, 2\rho_\infty]$ it is enough to show that the measure of $[0, 2\rho_\infty] \setminus J$ is positive and it can be estimate from below by:

$$\sum_{k=1}^{n-1} (\lambda_{k+1}(\Delta^{\tilde{W}}_{\beta^-}) - \lambda_k(\Delta^{\tilde{W}}_{\beta^+})) = \sum_{k=1}^{n} \lambda_k(\Delta^{\tilde{W}}_{\beta^-}) - \sum_{k=1}^{n-1} \lambda_k(\Delta^{\tilde{W}}_{\beta^+})$$

$$= \text{Tr}(\Delta^{\tilde{W}}_{\beta^-}) - \text{Tr}(\Delta^{\tilde{W}}_{\beta^+}) - \lambda_1(\Delta^{\tilde{W}}_{\beta^-}).$$

(4.6)

Therefore it is enough to calculate $\text{Tr}(\Delta^{\tilde{W}}_{\beta^+})$ and $\text{Tr}(\Delta^{\tilde{W}}_{\beta^-})$ (see [FLP18] Proposition 3.3).

**Step 1: Trace of $\Delta^{\tilde{W}}_{\beta^-}$.** We define $W^- = (G^-, m^-)$ where $G^- = G - [B(H, \tilde{G})]$. Recall that $V(G^-) = V(G) \setminus [B(H, \tilde{G})]$; the weights on $V(G^-)$ and $E(G^-)$ coincide with the corresponding weights on $W$. The relative weights of $W^-$ are

$$\rho^-(v) = \begin{cases} \rho_W(v) - \frac{m([B(H, \tilde{G})])}{m(v)}, & \text{if } v = v_0, \\ \rho_W(v) - \frac{m([B(H, \tilde{G})] \cap E_v)}{m(v)}, & \text{if } v \in B_{v_0}, \\ \rho_W(v), & \text{otherwise}, \end{cases}$$

where $B_{v_0} = \{v \in V(G) \mid v = (v_0)_e \text{ for some } e \in [B(H, \tilde{G})] \text{ with } v \neq v_0\}$. 

The trace of $\Delta^{G^{-}}_{\beta}$ is now

$$\text{Tr}(\Delta^{G^{-}}_{\beta}) = \sum_{k=1}^{n} \lambda_k(\Delta^{G^{-}}_{\beta}) = \sum_{v \in V(G)} \rho(v)$$

$$= \sum_{v \in V(G)} \rho^{W}(v) - m(\frac{[B(H, \tilde{G})]}{m(v)}) - \sum_{v \in B_{v_{0}}} m(\frac{[B(H, \tilde{G})] \cap E_{v}}{m(v)}) . \quad (4.7)$$

**Step 2: Trace of $\Delta^{W^{+}}_{\beta}$.** Let $W^{+} = (G^{+}, m^{+})$, then the trace of $\Delta^{W^{+}}_{\beta}$ is given by

$$\text{Tr}(\Delta^{W^{+}}_{\beta}) = \sum_{k=1}^{n} \lambda_k(\Delta^{W}_{\beta}) = \sum_{v \in V(G)} \rho^{W}(v). \quad (4.8)$$

Combining Eqs. (4.6), (4.7) and (4.8) we obtain

$$\text{Tr}(\Delta^{W^{-}}_{\beta}) - \text{Tr}(\Delta^{W^{+}}_{\beta}) - \lambda_{1}(\Delta^{W^{-}}_{\beta}) = \rho^{W}(v_{0}) - m(\frac{[B(H, \tilde{G})]}{m(v_{0})}) - \sum_{v \in B_{v_{0}}} m(\frac{[B(H, \tilde{G})] \cap E_{v}}{m(v)}) - \lambda_{1}(\Delta^{W^{-}}_{\beta})$$

$$= \rho^{W}(v_{0}) - m(\frac{[B(H, \tilde{G})]}{m(v_{0})}) - \sum_{e \in [B(H, \tilde{G})]} m e - \lambda_{1}(\Delta^{W^{-}}_{\beta}) = \delta$$

as defined in Eq. (4.5). This shows that if $\delta > 0$, then the spectrum of the DML is not the full interval. □

**Remark 4.9.**

(a) If the graph has the standard weights, the condition becomes:

$$\delta = 1 \sum_{e \in [B(H, \tilde{G})]} \frac{1}{\deg((v_{0})e)} - \frac{[B(H, \tilde{G})]}{\deg(v_{0})} - \lambda_{1}(\Delta^{W^{-}}_{\beta}) > 0 , \quad (4.9)$$

where $[[B(H, \tilde{G})]]$ denote the cardinality of the set $[B(H, \tilde{G})]$.  

(b) If we have the combinatorial weights, the condition becomes simply:

$$\delta = \deg(v_{0}) - 2[[B(H, \tilde{G})]] - \lambda_{1}(\Delta^{W^{-}}_{\beta}) > 0 . \quad (4.10)$$

5. **Examples.**

In this final section, we show some examples of graphs with standard weights that are used as models of important chemical compounds, as the polyacetylene and the graphene nanoribbons. We use the bracketing technique developed before to localize the spectrum and the gaps of these infinite covering graphs under the action of a periodic magnetic potential $\beta$. In particular, we will show in these examples the dependence of the spectral gaps on $\beta$.

Given $\tilde{W} = (\tilde{G}, \tilde{m})$ a periodic weighted graph, we consider for simplicity in this section only periodic magnetic potentials $\beta$ with the property that the flux through all cycle on $\tilde{G}$ is constant and equal to $s$ for some $s \in [0, 2\pi)$. Since two magnetic potentials are cohomologous iff they induce the same flux through all the cycles on the graph, all periodic magnetic potentials are constant in this sense and are determined by the value $s$. That is to say even if $\beta$ is a function on the arcs, we can identify it with one value in $\mathbb{T}$. We call this choice a constant magnetic field. A similar analysis can be done for non-constant magnetic potentials.

5.1. **Polyacetylene with magnetic field.** For the first illustration of the existence of spectral gaps for covering graphs with periodic magnetic potential, we study the graph modeling polyacetylene, an organic polymer that consists of a chain of carbon atoms (white circles) with alternating single and double bonds between them, each with one hydrogen atom (black vertex). We denote this MW-graph as $\tilde{W} = (\tilde{G}, \tilde{m})$, where $\tilde{G}$ is in Figure 2a and $\tilde{m}$ are the standard weights. The polyacetylene belongs to the family of polymers, a chemical compound in long repeated chains that can be naturally modeled by covering graphs. The polymers have important electrical properties (see, e.g., [Chi12, Shi01] and references therein). In particular, the polyacetylene is a simple polymer with good electric conductance.
Fact 1. Let \( \bar{m} \) be the standard weights and \( \bar{\beta} \) a constant periodic magnetic potential. We show how to apply the bracketing technique to localize the spectrum for a specific value of the magnetic potential (equal to \( \pi/2 \)) and then we show how the bracketing intervals change as a function of \( \bar{\beta} \). We will show the existence of spectral gaps.

Fact 2. Let \( \bar{m} \) be the combinatorial weights and \( \bar{\beta} \) a periodic magnetic potential (not necessarily constant). Using the condition on \( \delta \) in Eq. 4.10 we show the existence of spectral gaps.

Fact 3. Let \( \bar{m} \) be the standard weights, we show the existence of periodic magnetic spectral gaps, i.e., a spectral gap which is stable under any perturbation by the constant periodic magnetic field.

We define a periodic magnetic potential \( \tilde{\beta} \) acting as in Figure 2a i.e., the potential acts only on the cycles defined by the double bonds. Observe that the action of any constant magnetic field on the polymer can be represented by putting a suitable value \( s \) on the cycles defined by the double bonds. Observe that the action of any constant magnetic field on the polymer can be represented by putting a suitable value \( s \) on the cycles defined by the double bonds.

\[ W \]

Figure 2b. This graph is bipartite and has Betti number 2. In this case, if \( \sigma \) is the spectrum of the Laplacian in the infinite polyacetylene graph (cf., [EKN10]). In [FLP18] we study the spectrum of the Laplacian in the infinite polyacetylene graph under the action of a periodic magnetic potential, in particular, \( W \)

\[ \sigma(\Delta W) \]

as in Figure 2c. The induced weights \( m^- \) is defined as in 3.2 and \( m^+ \) as in 3.3. Using the notation of the Theorem 3.5 and Theorem 4.7 we get \( \sigma(\Delta G) \subset J \subset [0,2] \), where \( J \) is the union of the localizing intervals \( J_k \) (see Figure 2d for the case of \( s = \pi/2 \)). Since \( G \) is bipartite we have the symmetry of spectrum under the function \( \kappa(\lambda) = 2 - \lambda \) (cf., [LP08a, Proposition 2.3]), hence we also have \( \sigma(\Delta G) \subset \kappa(J) \). Therefore, the intersection gives a finer localization of the spectrum, i.e., we obtain finally \( \sigma(\Delta G \beta) \subset J \cap \kappa(J) \). In this example our method works almost perfectly, since we are able to determine almost precisely the spectrum:

\[ J \cap \kappa(J) \setminus \{1\} = \sigma(\Delta G \beta) \]

In conclusion, given a covering graph \( \bar{W} \) with a periodic magnetic potential \( \tilde{\beta} \) (see Figure 2 for \( s = \pi/2 \)), we were able to almost determine \( \sigma(\Delta G \beta) \) just by specifying the localization of the spectrum given by \( J \cap \kappa(J) \) (and without computing explicitly the spectrum). Obviously, \( J \) depends on \( \tilde{\beta} \) and therefore of the value of \( s \). Therefore for each value of \( \tilde{\beta} \) we can construct a bracketing \( \kappa(J) \) of intervals for the spectrum of \( \Delta G \beta \) and, since in this case we have the reflection symmetry specified by \( \kappa \) and an additional interlacing property of \( W^- \) due to Cauchy’s theorem (to be shown in [FLP19]), we are able to give a much finer localization of the spectrum. In Figure 3 we plot the spectrum \( \sigma(\Delta G \beta) \) of the DML as a function of the periodic magnetic potential \( \tilde{\beta} \) varying within the interval \([0,2\pi]\). Here one can appreciate how the size of the gaps and their localization within the interval \([0,2\pi]\) changes as a function of the external magnetic field.
magnetic potential. Let $G^-$ as in Fact 1, but now $m^-$ are also the combinatorial weights. First, we observe that $\lambda_1(\Delta_{\beta}^{-}) < 2$, then we calculate $\delta$ from condition in Eq. 4.10, i.e.,

$$\delta = \text{deg}(v_1) - 2 \|B(H, \tilde{G})\| - \lambda_1(\Delta_{\beta}^{-}) > 4 - 2 - 2 = 0,$$

then by Theorem 4.8 we have spectral gaps. Observe we do this without compute explicitly any eigenvalue.

Fact 3. Our method of virtualizing suitable arcs and vertices allows to proceed also alternatively. Define now $E_1 := \{e_1, e_2\}$ and $V_1 := \{v_1\}$ so that $V_1$ is a neighborhood of $E_1$ (see Definition 3.4). We construct as usual the MW-graphs $W_1^+$ and $W_1^-$ setting $G_1^+ = G - E_1$ and $G_1^- = G - V_1$ as in Figure 4 and inducing the weights as in Definition 3.2 and 3.3 (observe that in this case $W_1^+ = W^+$). Using the notation of the Theorem 3.5 and Proposition 4.6 we observe now that the spectral localization intervals do not depend on the periodic magnetic potential. In fact, using the same idea that before we obtain

$$\sigma(\Delta_{\tilde{\beta}}^{-}) \subset [0, 3/4] \cup [5/4, 2]$$

for all periodic constant magnetic potential $\tilde{\beta}$, in particular, $(3/4, 5/4)$ is a spectral gap which is stable under any perturbation by the magnetic field. Finally, we note that if the magnetic potential has a constant value equal to $\pi$ then the spectrum degenerates to four eigenvalues with infinity multiplicity, i.e., the gaps consist of the whole interval $[0, 2]$ except for the four eigenvalues. In this case, the polyacetylene becomes essentially an insulator under the influence of this particular value of the magnetic field.

5.2. Graphene nanoribbons. In this subsection, we will apply our method to study the example of the graphene nanoribbons (GNRs), also known as nano-graphene ribbons or nano-graphite
The horizontal axis represents the values of the magnetic potential $\tilde{\beta} \in [0, 2\pi)$ acting on the polyacetylene polymer with standard weights. For any fixed $\tilde{\beta}$ we obtain the intervals $J$ given by the bracketing technique as we did in the case $\tilde{\beta} = \pi/2$ in the Figure 2 (and also using the symmetry given by the bipartiteness). In the vertical axis we represent the spectral bands and gaps for each constant value $\tilde{\beta}$.

Using this graph $G_1^-$ and $G_1^+$, we can find spectral gaps in common for all periodic magnetic potential $\tilde{\beta}$ acting on the polyethylene, represented by the covering graph $G$.

Two structures of the graphene nanoribbons: armchair and zigzag. These structures are covering graphs only in one direction.

(i) The first variant is called armchair nanoribbon with width equal to $N_a$ and denoted as $N_a$-aGNR (see Figure 5). Consider for example the case of a 3-aGNR which has similar structure as the poly-para-phenylene (PPP), one of the most important conductive polymers. Let $W = (\tilde{G}, \tilde{m})$ the MW-graph with standard weights where $\tilde{G}$ the $\mathbb{Z}$-covering graph representing the 3-aGNR and $\tilde{\beta}$ a constant (periodic) magnetic potential, the idea will be use the bracketing
technique to localize $\sigma(\Delta_{\beta} \tilde{W})$ and we proceed as in the previous examples. Figure 6a is the finite quotient graph $G = \tilde{G}/\mathbb{Z}$. Define in this case $E_1 = \{e_1\}$ and $V_1 = \{v_1\}$ so that $V_1$ is a neighborhood of $E_1$ (see Definition 3.4). We construct $W^+_1$ and $W^-_1$ as before: $G^+_1 = G - E_1$ and $G^-_1 = G - V_1$ (cf., Figure 6b). The weights are induced as in Definitions 3.2 and 3.3. Using again the notation of the Theorem 3.5 and Proposition 4.6 we obtain now a spectral localization $J$ that depends on $\tilde{\beta}$. Finally, in Figure 6c we plot the spectral bands and gaps specified by $J$ for the different values of the magnetic field within the interval $[0, 2\pi]$. Observe that in this case we don’t have a spectral gaps common to all values of $\tilde{\beta}$ (as we had for the polyacetylene).

![Diagram](a) The quotient graph $G$ of 3-aGRN.

![Diagram](b) The graph $G^-$ and the graph $G^+$.

![Diagram](c) Spectral bands and gaps as a function of the constant (periodic) magnetic potential $\tilde{\beta}$.

**Figure 6.** Spectral gaps of $3$-aGNR for a constant magnetic potential $\tilde{\beta} = s$. Here, $J$ is the spectral localization of the pair $G - \{e_1\}$ and $G - \{v_1\}$, bipartitness (and interlacing) gives again the bracketing $J$ as localization set.

Similar analysis could be done for any $N_z$-aGNR under the action of any periodic magnetic potential, and the bracketing technique will give good estimates of the intervals where the spectrum lies.

Also, observe that for the combinatorial weights, we can show the existence of spectral gaps using the condition of Eq. 4.10 as in Fact 2 in the polyacetylene example. We have in this case,

$$\delta = \deg(v_1) - 2 \|B(H, \tilde{G})\| - \lambda_1(\Delta_{\beta} W^-) > 3 - 2 - 1 = 0.$$  

(ii) The second variant is the so-called zigzag nanoribbon with width equal to $N_z$ are denoted as $N_z$-zGNR (see Figure 5). Consider $W = (\tilde{G}, \tilde{m})$ the MW-graph with standard weights and $\tilde{G}$ is the graph given by the zigzag nanoribbons for a fixed $N_z$, and $\tilde{\beta} \sim 0$ acting on $\tilde{G}$. In this
Our spectral localization method does not specify spectral gaps (i.e., the spectral bands overlap). The reason is that for any width $N$, the spectrum of the zigzag nanoribbons satisfy $\sigma(\Delta_{zW}) = [0, 2]$, i.e., in this case there are no spectral gaps. This fact is confirmed also by our method.
