AutoML: A Survey of the State-of-the-Art
Xin He, Kaiyong Zhao, Xiaowen Chu*
Department of Computer Science, Hong Kong Baptist University

Abstract
Deep-learning techniques have penetrated all aspects of our lives and brought us great convenience. However, the process of building a high-quality deep-learning system for a specific task is time-consuming, requires extensive resources and relies on human expertise, hindering the further development of deep learning applications in both industry and academia. To alleviate this problem, a growing number of research projects focus on automated machine learning (AutoML). In this paper, we provide a comprehensive and up-to-date study on the state-of-the-art (SOTA) in AutoML. First, we introduce the AutoML techniques in detail, in relation to the machine-learning pipeline. We then summarize existing research on neural architecture search (NAS), as this is one of the most popular topics in the field of AutoML. We also compare the performance of models generated by NAS algorithms with that of human-designed models. Finally, we present several open problems for future research.

Keywords: deep learning, automated machine learning (AutoML), neural architecture search (NAS)

1. Introduction
In recent years, deep learning has been applied in various fields and used to solve many challenging AI tasks, in areas such as image classification [1, 2], object detection [3], and language modeling [4, 5]. Specifically, since AlexNet [1] outperformed all other traditional manual methods in the 2012 ImageNet Large Scale Visual Recognition Challenge (ILSVRC) [4], increasingly complex and deep neural networks have been proposed. For example, VGG-16 [7] has more than 130 million parameters, occupies nearly 500 MB of memory space, and requires 15.3 billion floating-point operations to process an image. Notably, however, these models were all manually designed by experts by a trial-and-error process, which means that even experts require substantial resources and time to create well-performing models.

To reduce these onerous development costs, the novel concept of automating the entire pipeline of machine learning has emerged, i.e., developing automated machine learning (AutoML) methods. There are various definitions of AutoML. For example, according to [8], AutoML is designed to reduce the demand for data scientists and enable domain experts to automatically build machine learning applications without much requirement for statistical and machine learning knowledge. In [9], AutoML is defined as a combination of automation and machine learning. In a word, AutoML can be understood to involve the automated construction of a machine-learning pipeline on a limited computational budget.

With the exponential growth of computing power, AutoML has recently become a hot topic in both industry and academia. This is due to the ability of AutoML to enable a dynamic combination of various techniques to form an easy-to-use end-to-end machine-learning pipeline system (as shown in Figure [1]). Many AI companies have created and publicly shared such systems (e.g. Cloud AutoML [1] by Google) to help people with little or no machine-learning knowledge to build high-quality custom models. Zoph et al. [10] were one of the first to draw attention to AutoML, in which a recurrent network is trained by reinforcement learning to automatically search for the best-performing architecture. Since then, there has been an explosion of research interest in AutoML, with most focusing on NAS. The aim of NAS is to generate a robust and well-performing neural architecture by hyperparameter optimization (HPO). The most common NAS structure types are entire structures [10, 11, 12], cell-based structures [11, 13, 14, 15, 16], progressive structures [17] and morphism-based structures [18, 19, 20]. The most widely used HPO methods utilize reinforcement learning (RL) [10, 13, 21, 14, 11], evolution-based algorithm (EA) [22, 23, 24, 25, 26, 27, 28], and gradient descent (GD) [15, 29, 30], and Bayesian optimization (BO) [31, 32, 33, 34, 35, 36, 37]. In addition to NAS, AutoML also uses other well-established techniques, which we

Preprint submitted to Knowledge-Based Systems
classify into the following categories based on the machine-
learning pipeline (shown in Figure 1): data preparation,
feature engineering, model generation, and model evalua-
tion.

Notably, many sub-topics of AutoML are large enough
to have their own surveys. However, our goal is not to
conduct a thorough investigation of all AutoML sub-topics,
but to focus on the breadth of research in the field of
AutoML. Therefore, in the following sections, we select
some representative studies for discussion and analysis.
Moreover, as the boundaries between different sub-topics
are vague, this approach provides a good understanding of
the development of AutoML. For example, model selection
can also be considered a problem of HPO, because its main
purpose is to optimize the combination of primitive model
components. However, model selection in AutoML uses
some important techniques that HPO does not, making
it necessary to consider model selection separately from
HPO.

The contributions of this paper are as follows:

1. Although there are several surveys related to Au-
toML techniques (e.g., [38, 9, 39]), we cover a wider
range of AutoML techniques that are applied to the
pipeline (Figure 1) of machine learning, providing
beginners with a comprehensive and clear understand-
ing of AutoML. Specifically, we extend the process
of data collection to the pipeline, which may boost
the generality of the AutoML framework.
2. NAS is currently one of the most popular sub-topics
in AutoML. Therefore, in this study, we provide a
detailed comparison of various aspects of various
NAS algorithms, such as the performance of AutoML
on baseline datasets, its time and resource cost for
searching, and the size of the best-performing model.
3. In addition to summarizing the existing works, we
describe some of the current problems and propose
important areas for future work.

The rest of this paper is organized as follows. The
processes of data preparation, feature engineering, model
generation, and model evaluation are presented in Sections
2, 3, 4, 5, respectively. In Section 6, we give a detailed
summary of NAS algorithms and compare the performance
of the models generated by NAS and human design. In
Section 7 we describe several open problems in AutoML
and discuss important related areas for future work. We
conclude our survey in Section 8.

2. Data Preparation

The first step in the machine-learning (ML) pipeline is
data preparation. However, for many tasks, such as medical
image recognition, it is difficult to obtain enough data, or
enough good quality data. A robust AutoML system must
be able to deal with this problem. To explore this, we
divide data preparation into two steps: data collection and
data cleaning.

2.1. Data Collection

The deepening study of ML has led to a general consen-
sus that good data must be available; as a result, numerous
open datasets have emerged. In the early stages of the
study of ML, a handwritten digital dataset, i.e., MNIST
[40], was developed. After that, several larger datasets like
Canadian Institute for Advanced Research (CIFAR)-10 &
CIFAR-100 [41] and ImageNet [42] were also developed. A
variety of datasets can also be retrieved by entering the
requisite keywords into these websites: Kaggle 2 and Google

2https://www.kaggle.com
Dataset Search (GOODS)\cite{GOODS} and Elsevier Data Search\cite{ Elsevier Data Search}.

However, it is usually very difficult to find a proper dataset through the above approaches for special tasks, such as those related to medical care or other private matters. Two types of methods are proposed to solve this problem: data synthesis and data searching.

2.1.1. Data Synthesis

In light of the broad range of computer-vision problems that exist, only some representative approaches to generating synthetic data are discussed here. One of the most commonly used methods is augmenting the existing dataset. For image data, there are many augmentation operations, such as cropping, flipping, padding, rotation, and resizing. Python libraries such as torchvision\cite{tvision} and Augmentor\cite{Augmentor} perform these augmentation operations to generate more images. Cubuk and Zoph et al.\cite{FastAA} propose fast autoaugment (FastAA), which finds more effective augmentation policies via a more efficient search strategy based on density matching.

Wong et al.\cite{Wong} propose two approaches for creating additional training examples: data warping and synthetic over-sampling. The former generates additional samples by applying transformations to data-space, and the latter creates additional samples in feature-space. Text data can be augmented by synonym insertion or by first translating the text into a foreign language and then translating it back to the original language. In a recent study, Xie et al.\cite{Xie} propose a non-domain-specific data augmentation strategy that uses noise in RNNs, and this approach works well for natural language processing (NLP) tasks such as language modeling and machine translation. Yu et al.\cite{Yu} propose the use of back-translation for data augmentation to aid reading comprehension.

For some special tasks, such as autonomous driving, it is not possible to test and adjust a model in the real world during the research phase, due to safety hazards. Thus, a practical method of creating data for such tasks is to use a data simulator, which tries to match the real world as much as possible. For example, OpenAI Gym\cite{Gym} is a popular toolkit that provides various simulation environments, in which developers can concentrate on designing their algorithms, instead of struggling to generate data. Wang et al.\cite{Wang} use a famous game engine, Unreal Engine 4, to build a large synthetic indoor robotics stereo (IRS) dataset for disparity and surface normal estimation. Furthermore, a reinforcement learning-based method is applied in\cite{FastAA} for optimizing the parameters of a data simulator to control the distribution of the synthesized data.

Another novel technique is Generative Adversarial Network (GAN)\cite{GAN}, which can be used to generate images and text data. Figure\ref{fig:2} shows some human face images, which are generated by GAN in the work of Karras et al.\cite{Karras}. Instead of generating images, Eno et al.\cite{Eno} develop a synthetic data-definition language (SDDL) to create new data for the Iris dataset\cite{Iris}. Moreover, natural scene text can also be generated, as shown by\cite{Oh, Jaroensri}. Besides, Oh and Jaroensri et al.\cite{Jaroensri} build a synthetic dataset, which captures small motion for video-motion magnification.

2.1.2. Data Searching

As the Internet is an inexhaustible source of data, searching for Web data is an intuitive way to collect a dataset\cite{Web},\cite{Web},\cite{Web},\cite{Web}. However, there are some problems with using Web data.

First, the search results may not exactly match the keywords. To solve this problem, unrelated data can be filtered. For example, Krause et al.\cite{Krause} separate inaccurate results as cross-domain or cross-category noise, and remove any images that appear in search results for more than one category. Vo et al.\cite{Vo} re-rank relevant results and provide search results linearly, according to keywords.

Second, Web data may be incorrectly labeled, or even unlabeled. A learning-based self-labeling method is often used to solve this problem. For example, the active learning method\cite{active} selects the most “uncertain” unlabeled individual examples for labeling by a human, and then iteratively labels the remaining data. To completely remove the requirement for human labeling and further accelerate the process, many semi-supervised learning self-labeling methods are proposed. Roh et al.\cite{Roh} summarize the self-labeling methods into the following categories: self-training\cite{self}, co-training\cite{co}, and co-learning\cite{co}. Moreover, due to the complexity of Web images content, a single label cannot fully describe an image. Consequently, Yang et al.\cite{Yang} assign multiple labels to a Web image, i.e., if the confidence scores of these labels are very close or the label with the highest score is the same as the original label of the image, then this image will be set as a new training sample.

However, the distribution of Web data can be extremely different from that of the target dataset, which will increase...
the difficulty of training the model. A common solution is to fine-tune these Web data [74, 75]. Yang et al. [60] propose an iterative algorithm for model training and Web data-filtering. Dataset imbalance is another common problem because the number of Web data for some special classes is very limited. To solve this problem, the synthetic minority over-sampling technique (SMOTE) [76] is used to synthesize new minority samples between existing real minority samples, instead of simply up-sampling minority samples or down-sampling the majority samples. In another approach, Guo et al. [77] combine the boosting method with data generation to enhance the generalizability and robustness of the model against imbalanced data sets.

2.2. Data Cleaning

Once raw data have been collected, they must be pre-processed (i.e., cleaned) to remove many types of erroneous data, such as redundant, incomplete, or incorrect data. For example, the common error types in tabular data are missing values and incorrect data types. The typical operations used for data cleaning are standardization, scaling, binarization of quantitative characteristics, the one-hot encoding of qualitative characteristics, and replacing missing values with mean values.

In image datasets, an image may be assigned the wrong label. In such cases, techniques such as self-labeling are applicable. However, the data cleaning process usually needs to be manually defined in advance, because different methods may have different requirements, even for the same dataset. For example, a neural network can only deal with numerical data, while decision tree-based methods can deal with both numerical and categorical data. As an alternative, some studies propose possible automated data-cleaning processes [78, 79, 80, 81].

3. Feature Engineering

In industry, it is generally accepted that data and features determine the upper bound of machine learning, and that models and algorithms can only approximate this limit. In this context, the purpose of feature engineering is to maximize the extraction of features from raw data for use by algorithms and models. Feature engineering consists of three sub-topics: feature selection, feature extraction, and feature construction. Feature extraction and construction are variants of feature transformation, by which a new set of features is created [82]. In most cases, feature extraction aims to reduce the dimensionality of features by applying specific mapping functions, while feature construction is used to expand original feature spaces, and the purpose of feature selection is to reduce feature redundancy by selecting important features. Thus, the essence of automatic feature engineering is, to some degree, a dynamic combination of these three processes.

3.1. Feature Selection

Feature selection builds a feature subset based on the original feature set by reducing irrelevant or redundant features. This tends to simplify the model, hence avoiding overfitting and improving model performance. The selected features are usually divergent and highly correlated with object values. According to [83], there are four basic steps in a typical process of feature selection (see Figure 3), as follows:

![Figure 3: The iterative process of feature selection. A subset of features is selected, based on a search strategy, and then evaluated. Then, a validation procedure is implemented to determine whether the subset is valid. The above steps are repeated until the stop criterion is satisfied.](image)

The search strategy for feature selection involves three types of algorithm: complete search, heuristic search, and random search. Complete search comprises exhaustive and non-exhaustive searching; the latter can be further split into four methods: breadth-first search, branch and bound search, beam search, and best-first search. Heuristic search comprises sequential forward selection (SFS), sequential backward selection (SBS), and bidirectional search (BS). In SFS and SBS, the features are added from an empty set or removed from a full set, respectively, whereas BS uses both SFS and SBS to search until these two algorithms obtain the same subset. The most commonly used random search methods are simulated annealing (SA) and genetic algorithms (GAs).

Methods of subset evaluation can be divided into three different categories. The first is the filter method, which scores each feature according to its divergence or correlation and then selects features according to a threshold. Commonly used scoring criteria for each feature are variance, the correlation coefficient, the chi-square test, and mutual information. The second is the wrapper method, which classifies the sample set with the selected feature subset, after which the classification accuracy is used as the criterion to measure the quality of the feature subset. The third method is the embedded method, in which variable selection is performed as part of the learning procedure.
Regularization, decision tree, and deep learning are all embedded methods.

3.2. Feature Construction

Feature construction is a process that constructs new features from the basic feature space or raw data to enhance the robustness and generalizability of the model. Essentially, this is done to increase the representative ability of the original features. This process is traditionally highly dependent on human expertise, and one of the most commonly used methods is preprocessing transformation, such as standardization, normalization, or feature discretization. In addition, the transformation operations for different types of features may vary. For example, operations such as conjunctions, disjunctions and negation are typically used for Boolean features; operations such as minimum, maximum, addition, subtraction, mean are typically used for numerical features, and operations such as Cartesian product \[ P \] and M-of-N \[ M \] are commonly used for nominal features.

It is impossible to manually explore all possibilities. Hence, to further improve efficiency, some automatic feature-construction methods have been proposed and shown to achieve results as good as or superior to those achieved by human expertise. These algorithms are aimed to automate the process of searching and evaluating the operation combination. In terms of searching, algorithms such as decision tree-based methods \[ 86 \] and genetic algorithms \[ 87 \] require a pre-defined operation space, while annotation-based approaches do not, as the latter use domain knowledge (in the form of annotation), together with the training examples \[ 88 \]. Such methods can be traced back to the interactive feature-space construction protocol introduced by \[ 89 \]. Using this protocol, the learner identifies inadequate regions of feature space and, in coordination with a domain expert, adds descriptiveness using existing semantic resources. Then, after selecting possible operations and constructing a new feature, feature-selection techniques are applied to measure the new feature.

3.3. Feature Extraction

Feature extraction is a dimensionality-reduction process performed via some mapping functions. It extracts informative and non-redundant features according to certain metrics. Unlike feature selection, feature extraction alters the original features. The kernel of feature extraction is a mapping function, which can be implemented in many ways. The most prominent approaches are principal component analysis (PCA), independent component analysis, isomap, nonlinear dimensionality reduction, and linear discriminant analysis (LDA). Recently, the feed-forward neural networks approach has become popular; this uses the hidden units of a pretrained model as extracted features. Furthermore, many autoencoder-based algorithms are proposed; for example, Zeng et al. \[ 90 \] propose a relation autoencoder model that considers data features and their relationships, while an unsupervised feature-extraction method using autoencoder trees is proposed by \[ 91 \].

4. Model Generation

After generating the features, we need to generate a model and set its hyperparameters. As shown in Figure 1, model generation consists of two steps: model selection and hyperparameter optimization. There are two types of approaches to model selection: traditional model selection and neural architecture search (NAS). The former involves selecting the best-performing model from traditional machine-learning algorithms, such as support-vector machine (SVM), \( k \)-nearest neighbors (KNN), decision tree, and \( k \)-means. In this paper, we focus more on NAS, which aims to design a novel neural architecture without human assistance and is currently a very hot topic. To give readers a clear understanding of the NAS technique, we introduce two key aspects of NAS: the model structures and the algorithms used to optimize the parameters of the generated model (i.e., the hyperparameter optimization algorithms).

4.1. Model Structure

The model is generated by selecting and combining a set of primitive operations, which are predefined in the search space. The operations can be broadly divided into categories such as convolution, pooling, concatenation, elemental addition, and skip connection. Empirically, these
well-designed operations can help improve the performance of the generated model; therefore, many human-designed modules are used as operations, such as depth-wise separable convolution \cite{92}, dilated convolution\cite{93}, and Squeeze-and-Excitation (SE) Block \cite{94}. The parameters of these operations are also usually predefined empirically. For example, the kernel size of convolution is usually set as 3 \times 3 and 5 \times 5. The model structures are summarized as follows:

4.1.1. Entire Structure

The first and most intuitive way to create a model structure is to generate an entire chain-structured neural network \cite{10, 11}. Figure 4 presents two simplified examples of the generated entire chain-structured models, which are built by stacking a predefined number of nodes, where each node represents one layer and has a specified operation. The simplest structure is the left model in Figure 4, while the right model is more complex, as it permits arbitrary skip connections \cite{2} to exist between the ordered nodes, as these connections have been proven effective in practice \cite{10}. Although the entire structure is easy to implement, it has several disadvantages. For example, it is widely accepted that the deeper the model, the better the generalization ability, but searching for such a deep network is onerous and computationally expensive. Furthermore, the generated architecture lacks transferability: i.e., a model generated on a small dataset may not fit a larger dataset. This necessitates the generation of a new model for a larger dataset.

4.1.2. Cell-Based Structure

Based on the observation that many well-performing human-designed structures \cite{2, 96} are composed of a fixed number of repeating modules, several groups of researchers \cite{13, 14, 11} propose cell-based structures. These methods first learn a cell structure and then stack this cell a predefined number of times to generate a whole architecture. The major difference between such cell-based structures and the previous entire chain-structure is that each layer of the cell-based structure is not an operation but a structure, which is generated by multiple complex operations, hence the problem of searching for an entire structure is simplified into searching for an optimal cell structure. Figure 5 (left) presents an example of a cell-based convolutional neural network. The final model consists of two types of cells, namely normal cell and reduction cell. The output of the normal cell retains the same spatial dimension as the input and the number of normal cell repeats can be set manually according to the dataset. The reduction cell has half the spatial dimension of the normal cell and twice as many filters in its output than the normal cell. This design approach follows the common practice of manually designing neural networks. Unlike the entire structure, the cell-based structure can be expanded by simply adding more cells to form a larger model, without re-searching for the cell structure. Many approaches \cite{15, 11, 13} first learn a cell from a small dataset (such as the CIFAR-10), then transfer it to fit on a larger dataset (such as ImageNet). Thus, a cell-based structure can be easily transferred across datasets.

Most studies of the internal design of the cell refer to Zoph et al. \cite{13}, among the first to propose an exploration of cell-based models. Figure 5 (right) shows a normal cell discovered by Liu et al. \cite{15}. Each cell is a directed acyclic graph (DAG) containing B blocks (here B = 4), and each block has two nodes. One can see that each node in the block can be assigned different operations and can receive different inputs. The output of two nodes in the block can be combined by summing or concatenation; therefore, each block can be represented by a five-element tuple, i.e., (I_1, I_2, O_1, O_2, C), where I_1, I_2 \in \mathbb{I}_b indicates the inputs to the block, O_1, O_2 \in \mathbb{O} specifies the operation applied to each input, respectively, and C \in \mathbb{C} describes how to combine O_1 and O_2. As the blocks are ordered, the set of possible inputs, \mathbb{I}_b, is the output of the previous two cells plus the set of the outputs of all previous blocks in this cell. The first two inputs of the first cell of the whole model are by default set as the image data.

In the actual implementation, there are a few important details to be noted. First, the number of channels may be different for different inputs. To handle this problem, a calibration operation is added before each node operation to ensure that all inputs have the same number of channels. The calibration operation usually uses 1 \times 1 convolution filters. Second, as arbitrary skip-connections between ordered blocks in the cell are permitted, the output of all blocks in the cell must have the same spatial resolution. To this end, the stride of all convolution filters in a normal cell is set to 1. However, there are two ways this can be performed in a reduction cell: by adding a pooling layer or a convolution filter with a stride of 2 after the output of the cell, or by setting only the stride of the calibration operation to 2 and setting the stride of the remaining operations to 1.

Searching for a cell structure is more efficient than searching for an entire structure. To illustrate this, suppose that there are M predefined operations, the number of layers for both the entire and the cell-based structure is L, and the number of blocks in a cell is B. Then, the number of possible entire structures is

\[ N_{\text{entire}} = M^L \times 2 \frac{L \times (L-1)}{2} \]

(1)

The number of possible cells is \((M \times B)^2\). However, there are two types of cell (i.e., the normal cell and the reduction cell), so the final size of the cell-based structure is

\[ N_{\text{cell}} = (M^B \times B)^4 \]

(2)

Obviously, the complexity of searching for the entire structure grows exponentially with the number of layers. For example, assuming \(M = 5, L = 12, B = 5\), then \(N_{\text{entire}} = 1.8 \times 10^{28}\) is much larger than \(N_{\text{cell}} = 1.1 \times 10^{22}\).

All published studies \cite{11, 13, 23, 24, 21} follow a two-level hierarchy: the inner level is the cell level, which selects the operation and connection for each node in the
cell, and the outer layer is the network level, which controls the spatial-resolution changes. However, these approaches focus on the cell level and ignore the network level. As shown in Figure 5 whenever a fixed number of normal cells are stacked, the spatial dimension of feature maps is halved by adding a reduction cell. To jointly learn a good combination of repeatable cell and network structures, Liu et al. [15] define a general formulation for a network-level structure, depicted in Figure 6, from which many existing good network designs can be reproduced. In this way, we can more fully explore the number of channels and the size of feature maps of each layer in the network.

The common feature of the aforementioned networks is that they first search for a good cell structure on a proxy dataset, then build the final network by repeating this cell, and finally evaluate the network on a target dataset. ProxylessNAS [97] has made progress in these respects by using BinaryConnect [98], as this approach offers the following advantages. 1) Direct searching for the network on a large scale dataset without a proxy dataset. 2) The cell structure of each layer can be different, instead of simply comprising repeated stacking, thus creating a more diverse network structure.

4.1.3. Progressive Structure

Although the cell-based structure is more efficient and transferable than the entire structure, it also has several drawbacks.

First, the number of blocks ($B$) in a cell is usually predefined and thus fixed during the search stage. In other words, $B$ is a new hyperparameter that requires tuning by human input. To address this problem, Liu et al. [17] propose a novel hierarchical genetic representation scheme, in which the higher-level cell is generated by iteratively incorporating lower-level cells. As shown in Figure 7 the primitive operations, such as $1 \times 1$ and $3 \times 3$ convolution and $3 \times 3$ max-pooling in level-one, are the basic components of the level-two cells. Then, the level-two cells are used as primitive operations to generate the level-three cells. The highest-level cell is a single motif corresponding to...
the full architecture. In addition, a higher-level cell is defined by a learnable adjacency upper-triangular matrix $G$, where $G_{ij} = k$ means that the $k$-th operation $o_k$ is implemented between nodes $i$ and $j$. For example, the level-two cell in Figure 7(a) is defined by a matrix $G$, where $G_{01} = 2, G_{02} = 1, G_{12} = 0$ (the index starts from 0). This method can discover more types of network structures with more complex and flexible topologies than the cell-based structure. Similarly, Liu and Zoph et al. [16] also propose to search for the cell in a progressive manner, starting from the simplest model, i.e., the cell composed of only one block, and then expanding to a higher-level cell by adding all of the possible block structures. Moreover, Liu and Zoph et al. [16] increase the efficiency of the process of searching by using a surrogate model to predict the K-most promising blocks from the search space at each stage of cell construction.

However, although the above two methods optimize the approach of designing cell structures and explore more possible cell structures, there is a large gap between the search and evaluation stages. Specifically, due to the size limitation of the GPU memory, most of the cell-based methods have to search for the model in a shallow network and evaluate the model in a deeper network. For instance, in Differentiable ARchiTecture Search (DARTS) [15], a network of eight cells is built during the search stage, and an expanded network with 20 cells is then evaluated. Chen et al. [99] upgrade DARTS to a novel and efficient algorithm called Progressive DARTS (P-DARTS), which divides the search process into multiple stages and increases the depth of the searched networks gradually at the end of each stage, hence bridging the gap between search and evaluation. Figure 8 shows the difference between DARTS and P-DARTS: the latter method obtains a 2.50% error rate on the CIFAR-10 test dataset, outperforming the 2.83% error rate of the former method.

4.1.4. Morphism-Based Structure

Isaac Newton is reputed to have said that “if I have seen further, it is by standing on the shoulders of giants.” Similarly, several training tricks have been proposed, either to mimic the output of the parent network [100] or to fine-tune the pretrained model [101]. However, these methods do not directly modify the model structure. To this end, Chen et al. [18] propose the Net2Net technique to design new neural networks by inserting the function-preserving transformations between neural network layers; there two types of identity transformations (referred to as IdMorph): Net2WiderNet and Net2DeeperNet, which enables replacement of the original model with an equivalent model that is wider or deeper.

However, IdMorph is limited to width and depth changes, and can only modify width and depth separately, and the
which is similar to determining parameters such as the performance.

4.2. Hyperparameter Optimization

After defining the encoding scheme of model structure, we need to search for a well-performing architecture within a large search space. Such a process can be regarded as a hyperparameter optimization (HPO) problem of selecting the operations and connections for all nodes in the cell, which is similar to determining parameters such as the learning rate and batch size. We summarize the commonly used HPO algorithms as follows.

4.2.1. Grid & Random Search

Grid search and random search are the most widely used HPO strategies. Grid search divides the space of possible hyperparameters into regular intervals (i.e., creates a grid), trains the model for all values on this grid, and selects the best-performing model. In contrast, random search, as its name suggests, selects a set of hyperparameters at random. Grid search and random search are the most widely used HPO methods, as it is simple to implement in parallel and typically finds hyperparameters that are as good as or better than those revealed by manual search, and in the same amount of time. However, it also has several drawbacks. As can be seen in Figure 10, grid search can only test three distinct configurations for nine trials, whereas random search can test more possible hyperparameters. In [106], it is shown that it is not equally important to tune all hyperparameters, but grid search allocates too many trials to the exploration of unimportant hyperparameters. To exploit a well-performing region of hyperparameter space, Hsu et al. [110] propose to first inspect a coarse grid to find a good region, then implement a finer grid search on the identified region. Similarly, Hesterman et al. [111] propose a contracting-grid search algorithm, which first computes the likelihood of each point in the grid, and then generates a new grid centered on the maximum-likelihood value. The separation of points in the new grid is reduced to half of that on the old grid. Iterations of the above procedure are performed until the results converge to a local minimum.

Although Bergstra and Bengio [106] show empirically and theoretically that random search is more practical and efficient than grid search, it is still difficult to confirm whether the final generated hyperparameters are optimal. This means that more time and resources are required to
find the optimal hyperparameters. A trade-off between the performance of hyperparameters and resource budgets is detailed by Li and Jamieson et al. [112], who introduce a novel search algorithm, Hyperband, which allocates limited resources (such as time or CPUs) to only the most promising hyperparameters, by successively discarding the worst half of configuration settings long before the training process has finished.

### 4.2.2. Evolution-Based Algorithm

Evolution-based algorithm (EA) is a generic population-based metaheuristic optimization algorithm, which takes inspiration from biological evolution. Compared with traditional optimization algorithms such as calculus-based methods and exhaustive methods, an evolution-based algorithm is a mature global optimization method with high robustness and wide applicability. It can effectively deal with the complex problems that traditional optimization algorithms struggle to solve, without being limited by the nature of the problem.

Different EAs may use different types of encoding schemes for network representation, so the genetic operations vary from one approach to another. There are two types of encoding schemes: direct and indirect. Direct encoding is a widely used method that explicitly specifies the phenotype. For example, Genetic CNN [28] uses a binary encoding scheme to represent network structure, i.e., $I$ means that two nodes are connected, and vice versa. Although binary encoding can be performed easily, its computational space is about square of the number of nodes, and the number of nodes is usually limited and fixed. To represent variable-length network structures, Suganuma et al. [26] use Cartesian genetic programming (CGP) [113, 114] encoding scheme to represent the neural network as DAG. In [23], the neural architecture is also encoded as a graph, where vertices indicate rank-3 tensors or activations (ReLU) or plain linear units, and edges indicate identity morphism operators, hence the capacity of the child network in [23] to add a new structure without losing track of which gene is throughout a simulation.

#### Selection

This step involves selecting a portion of the networks from all the generated networks for crossover. There are three strategies for selecting networks. The first is fitness selection, in which the probability of a network being selected is proportional to its fitness value, i.e., $P(h_i) = \frac{\text{Fitness}(h_i)}{\sum_{j=1}^{N} \text{Fitness}(h_j)}$, where $h_i$ indicates the $i$-th network. The second is rank selection, which is similar to fitness selection, but with a network’s selection probability being proportional to its relative fitness rather than its absolute fitness. The third method is tournament selection [23, 25, 24, 17]. In each iteration, $k$ (tournament size) networks are randomly selected from the population and sorted according to their performance, and then the best network is selected with a probability of $p$, the second-best network has a probability of $p \times (1-p)$, and so on.

#### Crossover

After selection, every two networks are selected to generate a new offspring network, which inherits half of the genetic information of each of its parents. This is analogous to the genetic recombination that occurs during biological reproduction and crossover. The particular manner of crossover varies and depends on the encoding scheme. In binary encoding, networks are encoded as a linear string of bits, where each bit represents a unit, such that two parent networks can be combined via one-point or multiple-point crossover. However, the crossover of data arranged in such a fashion can sometimes lead to data damage. Thus Xie et al. [28] denote the basic unit in the crossover as a stage rather a bit, where a stage is a higher-level structure constructed by a binary string. For cellular encoding, a randomly selected sub-tree is cut from one parent tree and then used to replace a sub-tree cut from the other parent tree. In another approach, NEAT performs an artificial synapsis based on historical markings, allowing NEAT to add a new structure without losing track of which gene is throughout a simulation.

A typical evolution-based algorithm consists of the following steps: selection, crossover, mutation, and update (see Figure 11):

- **Selection**: This step involves selecting a portion of the networks from all the generated networks for crossover. There are three strategies for selecting networks. The first is fitness selection, in which the probability of a network being selected is proportional to its fitness value, i.e., $P(h_i) = \frac{\text{Fitness}(h_i)}{\sum_{j=1}^{N} \text{Fitness}(h_j)}$, where $h_i$ indicates the $i$-th network. The second is rank selection, which is similar to fitness selection, but with a network’s selection probability being proportional to its relative fitness rather than its absolute fitness. The third method is tournament selection [23, 25, 24, 17]. In each iteration, $k$ (tournament size) networks are randomly selected from the population and sorted according to their performance, and then the best network is selected with a probability of $p$, the second-best network has a probability of $p \times (1-p)$, and so on.

- **Crossover**: After selection, every two networks are selected to generate a new offspring network, which inherits half of the genetic information of each of its parents. This is analogous to the genetic recombination that occurs during biological reproduction and crossover. The particular manner of crossover varies and depends on the encoding scheme. In binary encoding, networks are encoded as a linear string of bits, where each bit represents a unit, such that two parent networks can be combined via one-point or multiple-point crossover. However, the crossover of data arranged in such a fashion can sometimes lead to data damage. Thus Xie et al. [28] denote the basic unit in the crossover as a stage rather a bit, where a stage is a higher-level structure constructed by a binary string. For cellular encoding, a randomly selected sub-tree is cut from one parent tree and then used to replace a sub-tree cut from the other parent tree. In another approach, NEAT performs an artificial synapsis based on historical markings, allowing NEAT to add a new structure without losing track of which gene is throughout a simulation.
- **Mutation**

As the genetic information of the parents is copied and inherited by the next generation, gene mutation also occurs. A point mutation [25, 26] is one of the most widely used operations, and consists of randomly and independently flipping each bit. Two types of mutations are described in [27]: one enables or disables a connection between two layers, and the other adds or removes skip connections between two nodes or layers. In another approach, Real and Moore et al. [23] redefine a set of mutation operators, such as those that alter the learning rate and filter size, and remove skin connections between nodes. By analogy with the biological process, although a mutation may look like a mistake that causes damage to the network structure and leads to a loss of functionality, the mutation also enables exploration of more novel structures and ensures diversity.

- **Update**

Many new networks are generated by completing the above steps, and in light of limitations on computational resources, some of these must be removed. In [23], a pair of networks is selected at random, and the worst-performing network of these two is immediately removed from the population. Alternatively, in [24, 25] the oldest networks are removed. Other methods [26, 27] discard all models at regular intervals. However, Liu et al. [17] do not remove any networks from the population; instead, they allow the network to grow with time.

4.2.3. **Bayesian Optimization**

Each trial that involves measuring the performance of a hyperparameter setting in a grid, random search or evolution-based algorithm is independent. In other words, poorly performing regions of search space are repeatedly tested. Bayesian optimization (BO) is a way around this problem, as it uses an algorithm to build a probability model of the objective function, and then uses this model to select the most promising hyperparameters. Finally, it evaluates the selected hyperparameters on the true objective function. Therefore, BO can iteratively update the probability model by keeping a record of past evaluation results. The probability model then mathematically maps hyperparameters to a score probability on the objective function.

Sequential model-based optimization (SMBO) is a succinct formalism of BO. The steps of SMBO are expressed in Algorithm 1 (from [119]). First, a probability model is randomly initialized using a small portion of samples from the search space $X$. $D$ is a dataset containing sample pairs $(x_i, y_i)$, where $y_i = f(x_i)$ is an expensive step. The model $M$ is then tuned to fit the dataset $D$, hence a new set of hyperparameters, which obey the distribution of $M$, are sequentially selected by a predefined acquisition function $S$. The acquisition function can be regarded as an inexpensive surrogate for the expensive objective function $f$. There are several types of acquisition functions, such as 1) improvement-based policies; 2) optimistic policies; 3) information-based policies; and 4) portfolios of acquisition functions. BO algorithms can be divided into three categories, according to the type of probability model they contain: Gaussian Processes (GP) [120, 121], Tree Parzen Estimators (TPE) [37], and Random Forests [33]. Several popular open-source software libraries for BO are summarized in Table 1, which shows that the GP-based BO algorithm is the most commonly used.

The BO algorithm can be effective even if the objective function is stochastic, non-convex, or even noncontinuous [119]. However, optimizing the parameters for deep neural networks is more challenging. In addition, although a bandit-based configuration optimization algorithm mentioned above, called Hyperband, can inexpensively search for promising hyperparameters using limited budgets, it is unable to rapidly converge to the best configuration. To solve this problem, Falkner and Klein et al. [36] propose the BO-based Hyperband (BOHB) algorithm, which combines the strengths of BO and Hyperband and outperforms other methods, such as reinforcement learning, on a wide range of problems.

of problem types. Furthermore, FABOLAS, a faster BO procedure, is introduced in [33], which maps the validation loss and training time as a function of dataset size, i.e., trains a generative model on a sub-dataset that gradually increases in size. As a result, FABOLAS is 10 to 100 times faster than other SOTA BO algorithms, and identifies the most promising hyperparameters.

4.2.4. Reinforcement Learning

![Figure 12: An overview of NAS using reinforcement learning.](image)

Zoph et al. [10] were one of the first to apply reinforcement learning (RL) for neural architecture search. Figure 12 presents an overview of an RL-based NAS algorithm. The agent is usually a recurrent neural network (RNN) that executes an action $A_t$ at each step $t$ to sample a new architecture from the search space, and receives an observation of the state $S_t$ together with a reward scalar $R_t$ from the environment to update the agent’s sampling strategy. Environment refers to the use of standard neural network training procedure to train and evaluate the network generated by the agent, after which the corresponding results (such as accuracy) are returned. Many follow-up approaches [21, 13, 14, 11] use this framework, but with different agent policies and neural-architecture encoding. Zoph et al. [10] first use the policy gradient algorithm [122] to train the agent, and sequentially sample a string to encode the entire neural architecture. In subsequent work [13], they use the Proximal Policy Optimization (PPO) algorithm [123] to update the agent, and propose the method shown in Figure 12 to build the cell-based neural architecture. MetaQNN [21] proposes a meta-modeling algorithm using Q-learning and a $\epsilon$-greedy exploration strategy and experience replay to sequentially search neural architectures.

Although the above RL-based algorithms have achieved SOTA results on CIFAR-10 and Penn Treebank (PTB) [124] datasets, they spend much time and computational resources. For instance, [10] took 28 days and 800 K40 GPUs to search for the best-performing architecture, and MetaQNN [21] also took 10 days and 10 GPUs to complete its search. This is clearly unaffordable for individual researchers, and perhaps even for companies. To improve efficiency, several improved RL-based algorithms are discussed.

4.2.5. Gradient Descent

The HPO methods above sample neural architectures discretely, a novel algorithm mentioned above, i.e. DARTS [15], searches for the neural architectures over the continuous and differentiable search space by using a softmax function to relax the discrete choice of hyperparameters, as outlined below:

$$\sigma^{(i,j)}(x) = \frac{\exp(\alpha^{(i,j)}_o)}{\sum_{o' \in O} \exp(\alpha^{(i,j)}_{o'}))} o(x)$$

where $o(x)$ indicates the operation performed on input $x$, $\alpha^{(i,j)}_o$ indicates the weight for the operation $o$ between a pair of nodes $(i,j)$, and $O$ is a set of predefined candidate operations. After the relaxation, the task of searching for architectures is transformed into a joint optimization of structural parameters $\alpha$ and model parameters $\theta$. These two types of parameters are optimized in an alternative way, suggestive of a bi-level optimization problem. To solve this problem, model parameters $\theta$ and structural parameters $\alpha$ are trained on the training set and validation set, respectively. The training and the validation loss are denoted by $\mathcal{L}_{\text{train}}$ and $\mathcal{L}_{\text{val}}$, respectively. Hence, the total loss function can be derived:

$$\min_{\alpha} \mathcal{L}_{\text{val}}(w^{*}(\alpha), \alpha) \quad \text{s.t.} \quad w^{*}(\alpha) = \arg\min_{\theta} \mathcal{L}_{\text{train}}(\theta, \alpha)$$

Figure 14 presents the process of searching for the neural architecture in DARTS. The cell is composed of $N$ (here $N = 4$) ordered nodes, and the node $z_i^k$ ($k$ starts from 0) is connected to the node $z_i^{k+1}$.
The operation on each edge $e_{i,j}$ is initially a mixture of candidate operations, each being of equal weight. After the structural parameters $\alpha$ are updated, the weights of all operations are also updated, and each edge will retain only the maximum-weight operation.

Although DARTS greatly reduces the search time, it can lead to several problems. First, the requirements of GPU memory increase linearly with the number of candidate operations. To reduce memory consumption, Xie et al. [125] propose an improvement to DARTS, namely stochastic neural architecture search (SNAS). In SNAS, the neural architecture is fully factorizable and modeled with a concrete distribution [126], such that the differentiability of the NAS pipeline is maintained. In addition, the search space is encoded in one-hot form and multiplied as a mask to select one operation at each edge; accordingly, only one path of the over-parameterized network is selected for training, thereby reducing GPU memory usage.

Similarly, a new path-level pruning method is introduced in [97]. First, an over-parameterized network containing all possible operations is trained, and then the redundant parts are gradually removed, resulting in only one single network requiring training. The architecture parameters are binarized using the BinaryConnect method [98] and hence only one path is activated at training time. Hundt et al. [127] propose SharpDARTS, which uses a general, balanced and consistent design, namely SharpConv Block. They also introduce differentiable hyperparameters grid search and hyperCuboid search space, leading to 50% faster performance than DARTS.

The second problem is that the skip-connect operation will dominate at later search stages, which will cause the network to be shallower and thus lead to a marked deterioration in performance [128, 99]. To solve this problem, DARTS+ [128] uses an additional early-stop criterion, such that when two or more skip-connects occur in a normal cell, the search process stops. In another example, the solution in P-DARTS [99] is to add search-space regularization, which executes operation-level dropout to control the proportion of skip-connect operations occurring during training and evaluation.

5. Model Estimation

Once a new neural network has been generated, its performance must be evaluated. An intuitive method is to train the network to convergence and then evaluate its performance. However, this method requires extensive time and computing resources. For example, [10] took 800 K40 GPUs and 28 days in total to search. Additionally, NASNet [13] and AmoebaNet [24] required 500 P100 GPUs and 450 K40 GPUs, respectively. Several algorithms have been proposed for accelerating the process of model evaluation, and are summarized as follows.

5.1. Low fidelity

As model training time is highly related to the dataset and model size, model evaluation can be accelerated in different ways. First, the number of images can be reduced, or the resolution of images (in terms of image-classification tasks) can be decreased. For example, FABOLAS [33] trains the model on a subset of the training set to accelerate model estimation. In [129], ImageNet64×64 and its variants 32×32, 16×16 are provided, while these lower resolution datasets can retain characteristics similar to those of the original ImageNet dataset. Second, low-fidelity model evaluation can be realized by reducing the model size, such as by training with fewer filters per layer [13, 24]. By analogy to ensemble learning, [130] proposes the Transfer Series Expansion (TSE), which constructs an ensemble estimator by linearly combining a series of basic low-fidelity estimators, hence avoiding the bias that can derive from using a single low-fidelity estimator. Furthermore, Zela et al. [32] empirically demonstrate that there is a weak correlation between performance after short or long training times, thus confirming that a prolonged search for network configurations is unnecessary (see Figure 15).
5.2. Weight sharing

In [10], once a network has been evaluated, it is dropped. Hence, the technique of weight sharing is used to accelerate the process of NAS. For example, Wong and Lu et al. [131] propose Transfer Neural AutoML, which uses knowledge from prior tasks to accelerate the process of network design. ENAS [11] shares parameters among child networks, leading to a thousand-fold faster network design than [10]. Network morphism based algorithms [18, 19] can also inherit the weights of previous architectures, and single-path NAS [132] uses a single-path over-parameterized ConvNet to encode all architectural decisions with shared convolutional kernel parameters.

5.3. Surrogate

A surrogate-based method [133, 134, 135] is another powerful tool that approximates to the black-box function. In general, once a good approximation has been obtained, it is trivial to find the configurations that directly optimize the original expensive objective. For example, Progressive Neural Architecture Search (PNAS) [16] introduces a surrogate model to control the method of searching. Although ENAS has been proven to be very efficient, PNAS is even more efficient, as the number of models evaluated by PNAS is over five times that evaluated by ENAS, and PNAS is eight times faster in terms of total computational speed. However, when the optimization space is too large and hard to quantify, and the evaluation of each configuration is extremely expensive [136], a surrogate-based method is not applicable.

5.4. Early stopping

Early stopping was first used to prevent overfitting in classical machine learning. It is used in several recent studies [137, 138, 139] to accelerate model evaluation by stopping evaluations that are predicted to perform poorly on the validation set. For example, [139] propose a learning-curve model that is a weighted combination of a set of parametric curve models selected from the literature, thereby enabling the performance of the network to be predicted. Furthermore, [140] presents a novel approach for early stopping based on fast-to-compute local statistics of the computed gradients, which no longer relies on the validation set and allows the optimizer to make full use of all of the training data.

5.5. Resource-aware

Most of the abovementioned studies [10, 13, 24] pay more attention to searching for neural architectures that achieve higher performance (e.g., classification accuracy), regardless of the associated resource consumption (i.e., the number of GPUs and time required). Therefore, many follow-up studies investigate resource-aware algorithms to trade off performance against the resource budget. To do so, these algorithms add computational cost to the loss function, as a resource constraint. These algorithms differ in the type of computational cost, which may be 1) the parameter size; 2) the number of Multiply-ACcumulate (MAC) operations; 3) the number of float-point operations (FLOPs); or 4) the real latency. For example, MONAS [141] considers MAC as the constraint, and as MONAS uses a policy-based reinforcement-learning algorithm to search, the constraint can be directly added to the reward function. In terms of a differentiable neural architecture search (DNAS) framework, the constraint should be differentiable before being added to the loss. To do so, MnasNet [142] uses a customized weighted product to approximate a Pareto optimal solution and thereby render the constraint differentiable. Another DNAS method, called FBNet [143], uses a latency lookup-table model to estimate the overall latency of a network based on the runtime of each operator and differentiate the latency of candidate operations. In SNAS [125], the cost of time for the generated child network is linear with respect to the one-hot random variables, such that the derivability of the resource constraint is ensured.

6. NAS Performance Summary

As the model of [10] has achieved better results than previous human-designed SOTA models on CIFAR-10, much research focuses on further improving its performance. It is, therefore, necessary to summarize and compare different algorithms to give readers a comprehensive understanding of the range of NAS methods. Most studies contain several different model variants, with each variant designed for different scenarios (e.g., building a small-scale model on a mobile device), so we compare the best results of each scenario. To ensure a valid comparison, we consider both the top-1 accuracy on the CIFAR-10 test set and the algorithm efficiency of a model. However, as the number of GPUs used in each algorithm is different, it is not valid to evaluate algorithm efficiency only in terms of search time. Thus we use GPU Days to measure the efficiency, which is defined as:

\[ \text{GPU Days} = N \times D \]  

(5)

where \( N \) represents the number of GPUs, and \( D \) represents the number of days spent searching. The performance of different algorithms on CIFAR-10 is summarized in Table 2. It can be seen from the table that the evolution-based algorithm is time-consuming and not applicable in practice because it consumes too many GPUs. ENAS [11] greatly improves the efficiency of reinforcement learning-based methods by using a parameter-sharing strategy, and gradient descent-based methods can achieve SOTA results with more rapidly and with fewer resources. Interestingly, random search-based methods can also obtain comparable results. The authors of [145] further demonstrate that random search with weight-sharing can outperform a series of powerful methods such as ENAS and DARTS, achieving SOTA results on PTB and a highly competitive result.

Table 2: The performance of different NAS algorithms on CIFAR-10. The dash indicates that the corresponding information is not provided in the original paper. RL, EA, GD, RS indicate reinforcement learning, evolution-based algorithm, gradient descent, and random search, respectively.

on CIFAR-10. This raises the question of what the advantages and significance of the previous HPO algorithms are compared with such a well-performing random-search method.

We further compare the performance of models generated by NAS algorithms and human-designed models on CIFAR-10 and PTB datasets, as these two datasets are the most commonly used baseline datasets for classification and language modeling tasks, respectively. We refer the reader to the online data[6] and Figure 16, where Figure (a) presents currently top-performing models on CIFAR-10. The top seven models, ranked by the final classification results they achieve, are BiT-L [146], GPIPE [147], EfficientNet [105], FastAA [46], ProxylessNAS [97], Squeeze-and-Excitation Network (SENet) [94], and AmoebaNet [24]. Although the top two best-performing models are both manually designed models, the gap between the manually and NAS algorithm-designed models is very small. However, in terms of language-modeling ability, there is still a large gap between the performance of automatically generated models and that of models designed by experts. As Figure 16 (b) shows, the top four best-performing language-modeling models are all manually designed, i.e., GPT-2 [148], FRAG AWD-LSTM-Mos [4], adversarial AWD-LSTM-Mos [149] and Transformer-XL [5]. Therefore, the NAS community needs to greatly improve the language-modeling performance of its models to make them competitive with manually designed models.

7. Open Problems and Future Work

In this paper, we summarize a series of approaches to improving the automated machine-learning pipeline, shown in Figure 1. These methods have various strengths, but many theoretical and practical problems remain to be solved. We summarize these problems below.

---

7.3. Reproducibility

It is well known that a major problem with machine learning is its inability to reproduce many methods. AutoML is no exception, especially NAS, because the source code of the algorithm is either not publicly available or the results are random and non-repeatable. Even if the source code is provided, it is difficult to reproduce results because some approaches require months of search time, e.g., [10].

In this context, NASBench [152] is a pioneering work to alleviate the problem of non-reproducibility. It provides a tabular dataset that contains 423,624 unique neural networks. These networks are generated and evaluated from a fixed graph-based search space and mapped to their trained and evaluated performance on CIFAR-10. Thus, NASBench enables reproducible NAS experiments to be performed within seconds. Hence, developing analogous reproducibility for all processes of the AutoML pipeline is invaluable.

7.4. Encoding Scheme

A primary difference between various NAS algorithms is their structure-encoding scheme. The existing NAS literature shows that all of the primitive operations and encoding schemes are still manually designed. Thus, it is currently unlikely that a new primitive operation (such as convolution or pooling) or a novel network architecture (such as transformer [3]) can be generated in a wholly automated manner (without any human assistance). Therefore, a more general and flexible encoding scheme that allows the algorithm to construct various types of network structures would be advantageous.

7.5. Application of NAS to More Areas

As described in Section 7.3, NAS algorithms have achieved SOTA results in image classification tasks. Therefore, NAS has also been applied to many other computer vision tasks, such as object detection [153, 154, 155], semantic segmentation [150, 157], image restoration [158], GAN [159], graph neural network (GNN) [160]. Furthermore, many approaches have been proposed to compress the neural networks into more efficient forms [161, 162, 163]. However, there is much room for improvement in the NAS-based processing of text-based tasks. Therefore, exploring more areas to which NAS can be applied will be an important part of future work.

7.6. Lifelong Learning

Last, most AutoML algorithms focus only on solving a specific task on some fixed datasets, e.g., image classification on CIFAR-10 and ImageNet. However, a high-quality AutoML system should be capable of lifelong learning, and this can be illustrated from two different perspectives. Fundamentally, the system should be capable of re-using prior knowledge to solve new tasks (i.e., learning to learn). For example, a child can quickly identify tigers, rabbits, and elephants after seeing several pictures of these animals, but
current machine-learning algorithms must be trained on a large number of images before they are capable of such an identification task.

A hot topic in this area is meta-learning, which is also a hot research topic that aims to design models for new tasks using previous experience. It is based on the work of [164], published in 1976, and the unified framework of Smith-Miles [165] (2009), which generalizes the meta-learning concept to cross-disciplinary studies, exposing the similarities and differences between these approaches. Several recent studies use the meta-learning technique to accelerate the process of searching for neural architectures and find a network in only one shot [166, 12].

In addition, an AutoML system must be able to constantly acquire and learn from new data, while also preserving the learnings from old data. However, when we use new datasets to train the current model, the performance of the model on the previous data sets is greatly reduced. Incremental learning may alleviate this problem. For example, Li and Hoiem [167] propose the learning without forgetting (LwF) method, which trains the model using only new data, while preserving its original capabilities. In addition, iCaRL [168] is a new training strategy based on LwF, which uses only a small part of old data for pretraining, and then gradually increases the proportion of a new class of data that is used to train the model.

8. Conclusions

In this paper, we provide a detailed and systematic review of the studies of AutoML according to the machine-learning pipeline (see Figure 1), ranging from data preparation to model estimation. Additionally, we summarize the performance and efficiency of existing NAS algorithms on the CIFAR-10 dataset, and compare the performance of NAS-based models and human-designed models on the CIFAR-10 and PTB datasets. These performance comparisons show that NAS can identify well-performing neural architecture, but that much improvement to this method is required.

We also describe several interesting and important open problems and discuss some important future research directions. Although research on AutoML is in its infancy, we believe that future researchers will effectively solve these problems. In this context, this review provides a comprehensive and clear understanding of AutoML for the benefit of those new to this area, and will thus assist with their future research endeavors.
