Abstract.

We show how Cooper-pair-assisted transport, which describes the stimulated transport of electrons in the presence of Cooper-pairs, can be engineered and controlled with cold atoms, in regimes that are difficult to access for condensed matter systems. Our model is a channel connecting two cold atomic gases, and the mechanism to generate such transport relies on the coupling of the channel to a molecular BEC, with diatomic molecules of fermionic atoms. To show this, we use an open-system framework we derived recently \cite{1}, which allows for an exact treatment of the interaction between atoms in the channel. We explore, in particular, the impact of the coupling to the BEC and the interaction between atoms in the junction on its transport properties, revealing non-trivial dependence of the produced particle current. We also study the effects of finite temperatures of the reservoirs and the robustness of the current against additional dissipation acting on the junction. Our work is experimentally relevant and has potential applications to dissipation engineering of transport with cold atoms, studies of thermoelectric effects, quantum heat engines, and Floquet Majorana fermions.

Keywords: cold atoms, quantum transport, open system, Andreev reflection

1. Introduction

Transport measurements between reservoirs connected by a channel are well-known tools to understand and study the static and dynamical properties of condensed matter systems. In this context, the development of cold atom platforms has offered possibilities to explore phenomena with strongly-interacting particles in transport setups. A key feature of these setups is that they can be described by microscopic models derived from first principles under well-controlled approximations \cite{2}. Such setups allow for the simulation of novel phenomena and exploration of the fundamental mechanisms since they allow for tuning of the microscopic parameters such as interaction and potential. Examples include the observation of quantised transport of neutral atoms in a junction.
Reservoir engineering of Cooper-pair-assisted transport with cold atoms

Connecting cold gas reservoirs [3], or the investigation of the role of interaction and temperature on transport in quantum point contacts [4] or lattices [5].

In addition to connecting to well-known phenomena of solid state physics, cold atom platforms offer the possibility to investigate new paradigms of transport, via continuous measurements [6] or dissipation engineering. Indeed, the atomic motion occurs on sufficiently long timescales that the transient dynamics can be measured and controlled in real time. These tools have been long applied in few-body systems in quantum optics [7, 8], and in that context form the basis for standard techniques such as laser cooling and trapping [9]. The coupling to reservoirs is well-understood microscopically under well-controlled approximations, and can be engineered experimentally. In the transport channel, particle losses, which naturally occur via collisions with a background gas, can be engineered via the use of an electron beam [10] or light scattering through a quantum gas microscope with single-site resolution [11, 12, 13]. Dephasing can also be realized via light scattering or noise sources [14, 15, 16, 17, 18].

Taking advantage of the level of microscopic control offered by cold atoms, we study here transport of fermionic atoms between reservoirs weakly connected by a single site junction, a system that resembles a quantum dot junction connecting leads. In particular, we explore the possibility to control transport based on Andreev reflection, i.e., transport of electrons assisted by exchange of Cooper-pairs [19, 20, 21], via reservoir engineering. In contrast with [4], the junction we consider is a weakly-connected single site – not a quantum point contact – and our reservoirs are non-interacting. Such a system naturally produces sequential tunnelling of atoms, yielding a quantised particle current. We show here how to engineer the transport between the reservoirs by coupling the junction to a molecular BEC [22], mimicking Cooper-pair assisted transport of electrons in the solid-state, and yielding a rich peak structure in the current-bias characteristics. We then study the effects of finite temperature of the reservoirs and interaction between atoms in the junction on the produced current, and also determine its robustness against the effects of particle losses acting on the channel.

Our results are obtained using an open-system framework that we recently derived [1], which goes beyond standard GSKL master equations [23, 24, 25], capturing the complex interplay between the dissipation – coming from the coupling with the reservoirs or additional particle losses acting on the junction – and the driving – coming from the molecular BEC – on the transport processes, while treating the interaction in the junction exactly.

Our results demonstrate the possibility to engineer transport based on Andreev reflection in an unconventional setup – without the need for interactions in the source and drain reservoirs – and in regimes that are hard to access with other methods. Our work also provides a framework to diagnose the impact on transport of many effects that could be engineer experimentally, such as controlled interaction and dissipation. We also analyse realistic experimental conditions, including finite temperatures in the reservoirs.

The paper is organised as follow. In Sec. II, we detail our model and summarise
the main steps of the derivation of the master equation used to calculate the transport properties of the junction. In Sec. III, we present our results for the particle current, with and without coupling with the molecular BEC. We study the effects of finite temperature of reservoirs, interaction between atoms and particle losses acting on the junction. In Sec. IV, we summarise and provide an outlook. We use in the remainder of this paper natural units in which $\hbar = k_B = 1$.

2. Model

In this section, we summarise our model for a tunnel junction connecting two cold atom reservoirs. Figure 1 (A) shows a setup where two ultracold fermionic gases are connected together by a small junction. We consider two different spin states, labelled with $s \in \{\downarrow, \uparrow\}$. Transport of atoms through the junction is generated by preparing an initial chemical potential imbalance between the two reservoirs. We propose here to control the transport properties of the junction by immersing it into a molecular BEC and coupling them via radiofrequency fields, as explained below.

2.1. Hamiltonian

We consider a “system-bath” decomposition where the “system” corresponds to the junction and the “bath” to the cold atom reservoirs. This is described by the total Hamiltonian $H_{\text{tot}} = H^\text{eff}_S(t) + H_B + H_I$ with

$$H^\text{eff}_S(t) = H_S + H_{\text{BEC}}(t) = \omega \sum_{s=\downarrow,\uparrow} c_s^\dagger c_s + U c_\uparrow^\dagger c_\uparrow^\dagger c_\downarrow c_\downarrow + \sum_{\ell} (g_\ell e^{i\delta_\ell t} c_\uparrow^\dagger c_\downarrow + \text{h.c.}),$$

$$H_B = \sum_{\ell=L,R} \sum_{k,s=\downarrow,\uparrow} \omega_k b_{\ellks}^\dagger b_{\ellks},$$

$$H_I = \sum_{\ell=L,R} \kappa_\ell \sum_{k,s=\downarrow,\uparrow} (b_{\ellks}^\dagger c_s + \text{h.c.}).$$
where $H_S(t)$ is the effective Hamiltonian of the junction including the influence of the molecular BEC, $H_B$ the sum of the Hamiltonian of the left (L) and right (R) reservoirs, and $H_I$ the tunnelling Hamiltonian between the junction and both reservoirs, where $\kappa_\ell$ is the tunnelling amplitude of atoms between the reservoir $\ell$ ($\ell = L, R$) and the junction.

In Eq. (1), $H_S = \omega \sum_s c_s^\dagger c_s + U c_\uparrow^\dagger c_\uparrow^\dagger c_\downarrow^\dagger c_\downarrow$ corresponds to a single-site Hubbard model (Anderson impurity model) for fermionic atoms of energy $\omega$, spin $s \in \{\downarrow, \uparrow\}$, and interaction $U$. We consider for the sake of simplicity the same energy $\omega$ for both spin $s \in \{\downarrow, \uparrow\}$, even though such assumption can be relaxed without any difficulty. Hence, the bare junction is an effective system of dimension $d_S = 4$ spanned by the non-occupied, single occupied, and double-occupied states $\{|0\rangle, |\downarrow\rangle, |\uparrow\rangle, |\downarrow\uparrow\rangle\}$. The corresponding potential geometry could be achieved as proposed in [26] by using two laser beams with adjusted detunings, beam waists, and positions, but also more generally with acousto-optical deflectors [27] or holographic mask techniques [28]. The interaction $U$ between atoms can for its part be tuned using a magnetic field via Feshbach resonance.

The last term of Eq. (1), $H_{\text{BEC}}(t) = \sum_\ell (g_\ell e^{i\delta_\ell t} c_\downarrow^\dagger c_\uparrow + \text{h.c.})$, describes the effects of the coupling of the fermions of the junction to the background molecular BEC [29, 30, 31, 32]. Such coupling could be realized using one [22] or multiple fields $\ell$ of radio-frequencies $\omega_\ell$ and detunings $\delta_\ell = \omega_\ell - \epsilon$, where $\epsilon$ is the frequency related to the transition between the molecular BEC and the pair states, i.e., $|\text{BEC}\rangle \leftrightarrow |\uparrow\downarrow\rangle$ illustrated in Fig. 1 (C). Note that we work in the rotating-frame associated to $\epsilon$, absorbed in the definition of $\omega$ to not burden the notations. The coupling strength $g_\ell = \langle S \rangle \Omega_\ell$ of each field is determined by the macroscopic ground state occupation $\langle S \rangle$ of the BEC and the Rabi frequency $\Omega_\ell$, which can be tuned independently through different field amplitudes. It turns out that the Hamiltonian $H_{\text{BEC}}(t)$ well-represents the so-called proximity effects induced by $s$-wave superconductors of chemical potentials $\delta_\ell/2$ and Cooper-pair tunnelling amplitudes $g_\ell$, when their superconducting gap is larger than the junction frequency scales [21, 1]. For this reason, we consider in the following only two driving fields whose detunings are adjusted to the chemical potential of the fermionic reservoirs, i.e.,

$$\delta_\ell \equiv 2\mu_\ell \quad \text{with} \quad \ell = L, R,$$

(4)

even though, in principle, any frequencies could be chosen. This choice is motivated to resemble the case of a quantum dot tunnelling junction connecting two superconducting leads, where the Cooper-pair condensates have energies related to an applied bias voltage.

In Eq. (2), $b_{\ell k s}$ is the annihilation operator of a fermion of energy $\omega_\ell$, spin $s$ and momentum $k$ in the $\ell$ reservoir ($\ell = L, R$). We consider both reservoirs initially prepared in thermal states $\rho_\ell$ defined as

$$\rho_\ell = \frac{e^{-\beta_\ell (H_B - \mu_\ell N_\ell)}}{\text{Tr} \left[ e^{-\beta_\ell (H_B - \mu_\ell N_\ell)} \right]};$$

(5)

with chemical potential $\mu_\ell$, temperature $T_\ell = 1/(k_B \beta_\ell)$, and where $N_\ell = \sum_k b_{\ell k s}^\dagger b_{\ell k s}$. Various techniques have been realised to implement initial imbalance between atomic
reservoirs, as summarised in [2].

2.2. Master equation for the driven junction

We treat the coupling of the driven junction with the left and right reservoirs in the weak-coupling regime. This justifies our “system+bath” decomposition and motivates the use of an open system approach. As in [1], we derive a Floquet-Born-Markov master equation, i.e., a Born-Markov master equation for the periodic time-dependent system [33, 34, 35, 36] – which corresponds to the driven junction in our case. In contrast with [1] where the reservoirs were in a gapped phase, we consider them in a normal, non-interacting phase. This allows us to show that Cooper-pair-assisted transport can be achieved between the drain and source reservoirs even if these latter do not contain any pairs. We present below the key assumptions of the derivation of the master equation (all details can be found in Appendix A).

2.2.1. Born and Markov approximations. The first key approximation is the Born approximation, which supposes that the total system-bath density matrix $\rho^{I}_{\text{tot}}(t)$ in interaction picture with respect to $H_0(t) \equiv H_S^{\text{eff}}(t) + H_\text{B}$ can be written in the separable form

$$\rho^{I}_{\text{tot}}(t) \approx \rho^{I}(t) \otimes \rho_L \otimes \rho_R,$$

where $\rho^{I}$ is density matrix of the driven junction in interaction picture and where $\rho_L$ are the thermal states given by Eq. (5). This approximation amounts in considering that the initial states of the bath are sufficient to determine the whole evolution of the system during a timescale $\tau_R \propto 1/\kappa^2_\ell$, the typical time scale needed for the junction to reach a non-equilibrium steady state. Note that this present model cannot describe the complete relaxation of the whole “junction+reservoir” system towards a common equilibrium, which occurs on a time scale larger than $\tau_R$ [37].

Using the ansatz (6) and tracing over the bath degrees of freedom, the equation for $\rho^{I}(t)$ in second-order in $H_1(t)$ reads

$$\dot{\rho}(t) =$$

$$- \sum_{\ell,s} \int_0^t \left\{ \left[ \langle B^{\dagger}_{\ell s}(t)B_{\ell s}(t-t') \rangle_B \left( c_s(t)c^\dagger_s(t-t')\rho(t-t') - c^\dagger_s(t-t')\rho(t-t')c_s(t) \right) + \text{h.c.} \right] \right.$$  

$$\left. + \left[ \langle B_{\ell s}(t)B^{\dagger}_{\ell s}(t-t') \rangle_B \left( c^\dagger_s(t)c_s(t-t')\rho(t-t') - c_s(t-t')\rho(t-t')c^\dagger_s(t) \right) + \text{h.c.} \right] \right\} dt',$$  

(7)

where we removed the superscript $^{I}$ to simplify the notation, and where $\langle B^{\dagger}_{\ell s}(t_1)B_{\ell s}(t_2) \rangle_B \equiv \text{Tr}_B \left( B^{\dagger}_{\ell s}(t_1)B_{\ell s}(t_2)\rho_B \right)$ is the bath correlation function with $B_{\ell s}(t) = \kappa_\ell \sum_k e^{-i\omega_k t} b_{\ell ks}$. The Markov approximation consists of setting $\rho(t-t') \approx \rho(t)$ and extending the upper limit of integration to infinity. This amounts to neglect the memory effects, in the sense that this transforms the integro-differential equation into a time-local differential equation.
Both the Born and Markov approximations are justified for $\tau_R \gg \tau_B$, where $\tau_B$ is the decay time of the bath correlation function $\langle B_{t_1}^\dagger(t_1)B_{t_2}(t_2) \rangle$. Such condition can in general be fulfilled in different ways. In the present case, this is due to the large size of the bath, which yields an infinite summation over destructively-interfering modes in the expression of the bath correlation function, making them decaying quickly \[38,39\].

2.2.2. Final form of the master equation To obtain the final form of the master equation from (7), we need to evaluate the time-dependence of the system operators $c_s(t) = U(t)\dagger c_s U(t)$ where $U(t) = T e^{-i \int_0^t H_{\text{eff}}(\tau')d\tau'}$ is the system propagator with $T$ the time-ordering operator, before performing the time-integration. We use for this purpose the Floquet theory, assuming that the driving is periodic of period $T = 2\pi/\Delta \mu$, where $\Delta \mu = \mu_L - \mu_R$ corresponds to the chemical potential bias between the reservoirs. We consider for simplicity $\mu_L = -\mu_R = \Delta \mu/2$. All details are given in Appendix B. The resulting master equation for the density matrix elements $\rho^{ab}(t) = \langle \phi_a(t)|\rho(t)|\phi_b(t) \rangle$ in the basis of the periodic Floquet modes $|\phi_a(t)\rangle = |\phi_a(t+T)\rangle$ labelled by indices $a = 1, \cdots, d_S$ reads, in the Schrödinger picture,

$$\dot{\rho}^{ab}(t) = -i(E_a - E_b)\rho^{ab}(t) + \sum_{\ell} (\mathcal{L}_{\ell}[\rho(t)])^{ab},$$

where $E_a$ are the quasienergies corresponding to the Floquet modes $|\phi_a(t)\rangle$ and

$$(\mathcal{L}_{\ell}[\rho(t)])^{ab} = -\sum_s \sum_{k,k'\in \mathbb{Z}} \sum_{c,d} \left\{ e^{i(k+k')\Delta \mu t} \left( e_s^{\text{ack}} e_s^{\text{cdk}'} \Gamma_{\ell+}(-\Delta_{cdk'}) + e_s^{\text{ack}'} e_s^{\text{cdk}'} \Gamma_{\ell-}(-\Delta_{cdk'}) \right) \rho^{db}(t) - e^{i(k+k')\Delta \mu t} \left( e_s^{\text{ack}} e_s^{\text{dbk}'} \Gamma_{\ell-}(-\Delta_{ack}) + e_s^{\text{ack}'} e_s^{\text{dbk}'} \Gamma_{\ell+}(-\Delta_{ack}) \right) \rho^{cd}(t) \right\} + \text{h.c.}$$

is the Liouvillian. This latter is written in terms of Fourier components $e_s^{\text{ack}} = \frac{1}{T} \int_0^T e^{-ik\Delta \mu t} \langle \phi_a(t)|c_s|\phi_b(t) \rangle dt$ and complex rates

$$\Gamma_{\ell\pm}(E) = \int_0^\infty dt' f_{\ell\pm}(t') e^{iEt'} = \gamma_{\ell\pm}(E) + i\Omega_{\ell\pm}(E)$$

evaluated at energies $\Delta_{abk} = E_a - E_b + k\Delta \mu$ ($k \in \mathbb{Z}$) with

$$\gamma_{\ell\pm}(E) = \gamma_{\ell} \left[ 1 - n_{\ell}(E \pm \mu_{\ell}) \right],$$

$$\Omega_{\ell\pm}(E) = \frac{\gamma_{\ell}}{\pi} \text{ P.V.} \int_{-\infty}^\infty d\omega \frac{n_{\ell}(\omega)}{E + \omega \pm \mu_{\ell}},$$

where $\gamma_{\ell} \propto \kappa_{\ell}^2$ is the tunnelling rate, $n_{\ell}(E) = 1/(1 + e^{\beta_{\ell}E})$ the Fermi distribution, and where P.V. denotes the principal value. Hence, while for a standard Born-Markov master equation the rates (10) are evaluated at transition between bare system energies, our Floquet-Born-Markov theory captures transition between quasienergies of the driven system up to multiple of $\Delta \mu$. This quantity corresponds to the energy difference obtained
Reservoir engineering of Cooper-pair-assisted transport with cold atoms

from the conversion of a molecule into a pair via the field of detuning $\mu_L$ which is then reconverted into a molecule via the other field of detuning $2\mu_R$, i.e., the process [see Fig. 1 (C)]

$$|\text{BEC}\rangle \xrightarrow{2\mu_L} |\uparrow\downarrow\rangle \xrightarrow{2\mu_R} |\text{BEC}\rangle.$$  \hfill (12)

Hence, our theory describes the assisted transport of atoms thanks to the energy provided by molecular conversions. In solid-state systems, such assistance would correspond to transfers of Cooper-pairs between superconductors: currents based on multiple Andreev reflections.

3. Transport properties

Solving the master equation (8) allows us to compute the transport properties of the driven junction. We focus here on the steady state current of atoms leaving the junction to reach the right reservoir, which is defined as

$$\langle I_R \rangle = -\sum_{s=\uparrow,\downarrow} \text{Tr} \left[ c_s^\dagger c_s L_R [\rho_{SS}] \right],$$

where $L_R[\cdot]$ is the Liouvillian (9) for the right reservoir and $\rho_{SS}$ the steady state density matrix (see Appendix B for details and expressions of other currents, such as the current of molecules in the BEC). We investigate below the “current-voltage” characteristics of the junction, where the voltage corresponds to the chemical potential bias $\Delta \mu$. For the sake of simplicity, we consider in the reminder of this paper identical left and right tunnelling rates $\gamma_L = \gamma_R = \gamma$ and reservoir temperatures $T_L = T_R = T$.

3.1. Without coupling to the molecular BEC

When the junction is not coupled to the molecular BEC ($g_\ell = 0 \ \forall \ell = L, R$), the system Hamiltonian is time-independent and the Floquet-Born-Markov master equation reduces to a standard Born-Markov master equation that can be solved analytically. The steady state current in the right reservoir reads

$$\langle I_R \rangle = 4\gamma \frac{n_R(\omega - \mu_R) (n_L(U + \omega - \mu_L) - 1) - n_L(\omega - \mu_L) (n_R(U + \omega - \mu_R) - 1)}{n_L(\omega - \mu_L) - n_L(U + \omega - \mu_L) + n_R(\omega - \mu_R) - n_R(U + \omega - \mu_R) + 2}.$$

We focus in the following on the particle-hole symmetric case, for which the double occupied state $|\downarrow\uparrow\rangle$ of the junction has the same energy than the non-occupied state $|0\rangle$, i.e., when $U + 2\omega = 0$. This simplifies the analysis – giving rise to a single parameter $U$ to characterise the bare junction energy – and corresponds to the situation where the driving of the transition $|0\rangle \leftrightarrow |\downarrow\uparrow\rangle$ gives maximal effects. In that case, the current (15) becomes

$$\langle I_R \rangle = 2\gamma \frac{\sinh \left( \frac{\Delta \mu}{2T} \right)}{\cosh \left( \frac{U}{2T} \right) + \cosh \left( \frac{\Delta \mu}{2T} \right)}.$$
Reservoir engineering of Cooper-pair-assisted transport with cold atoms

which corresponds to a smooth step function. For $2T \ll \Delta \mu$, the quantization of the current becomes more obvious, since we have

$$\langle I_R \rangle \approx 2\gamma \frac{1}{e^{\frac{|U| - \Delta \mu}{2T}} + 1},$$

(16)

where we see that for $|(|U| - \Delta \mu)| \gg 2T$, the current goes to 0 at small bias $\Delta \mu < |U|$ and to $2\gamma$ at large bias $\Delta \mu > |U|$.

3.2. With coupling to the molecular BEC

Coupling the atoms to the BEC drastically changes the transport properties of the junction, since the sequential tunnelling of atoms can in that case be assisted by molecular conversions. Figure 2 (A) shows the steady state current of atoms reaching the right reservoir for different coupling $g_\ell \equiv g$ – taken identical for both RF fields –, fixed value of (attractive) interaction $U < 0$, and zero temperature. Peaks of currents appear at chemical potential bias

$$\Delta \mu = \frac{|U|}{2k + 1}, \quad k \in \mathbb{N},$$

(17)

as can be obtained from the resonant condition

$$\mu_L + k\Delta \mu = \frac{|U|}{2},$$

(18)

where $|U|/2$ is the energy of the transitions $|0\rangle \leftrightarrow |s\rangle$ and $|s\rangle \leftrightarrow |\downarrow\uparrow\rangle$. Equation (18) means that the maximal energy of an incoming atom (from the left reservoir) combined with multiple of the energy provided by the molecular conversion process (12) must be at least equal to the junction transition energy to generate transport. This explains why a non-zero current appears for lower bias values compared to the uncoupled case $g = 0$ [see dashed black line in Fig. 2 (A), corresponding to Eq.(15)]. These peaks can be interpreted as transport based on Andreev reflections of order $k$, where the energy of $k$ Cooper-pairs are required to generate transport. Increasing $g$ cranks up the amplitude of the Andreev peaks.

Finite temperature of the reservoirs smears out the peaks, as can be seen in Fig. 2 (B). For low bias, the current decreases as a polynomial as a function of the chemical potential bias. For moderate temperature, signatures of Andreev transport can still be observed. However, For large temperature, thermal effects dominate and the effect of the driving becomes indistinct.

3.3. Effects of interaction $U$

In this section, we analyse the effects of the interaction $U$ in the channel on the produced transport. Figure 3 shows the current (13) for a fixed value of $g$, zero temperature $T = 0$, and different $U$, still focusing on the particle-hole symmetric case by adjusting $\omega = -U/2$
Reservoir engineering of Cooper-pair-assisted transport with cold atoms

Figure 2. Current-bias characteristics of the junction for different driving amplitudes $g$ at zero temperature $T = 0$ (A) and for different temperatures $T$ for fixed driving amplitude $g = 0.5$ (solid lines) and $g = 0$ (dashed lines) (B). Other parameters are $\omega = -U/2$ and $U = -2$, in units chosen so that $\gamma = 10^{-2}$. A: For $g = 0$, the current exhibits a step at $\Delta \mu = |U|$ (dashed black line). When $g$ increases, current peaks appear at $\Delta \mu = |U|/(2k + 1)$ with $k \in \mathbb{N}$. B: Increasing the temperature smears out the peaks. In addition, for large temperature, the differences between the cases with and without driving fade.

so that we always have $U + 2\omega = 0$. In order to compare the curves appropriately, we rescaled the chemical potential bias $\Delta \mu$ of each curve by $|U|$, which makes the peaks overlap. Otherwise, a smaller interaction $|U|$ requires a smaller chemical bias $\Delta \mu$ to generate transport. Such methodology allows us to compare the shape and the size of the Andreev current peaks for different interaction strengths.

The system exhibits two different regimes of transport. For $|U|/3 \leq g$ [Fig. 3 (A)], the current is characterised by small oscillations, whose the period and amplitude increase for increasing $|U|$. These oscillations are fragmented in sections

$$\Delta \mu \in \left[ \frac{|U|}{2(k + 1) + 1}, \frac{|U|}{2k + 1} \right]$$

separating the different order $k$ of multiple Andreev reflections. Around $|U|/3 \sim g$, the oscillations are no more visible and leave the place to well-resolved peaks. The amplitudes of the peaks are maximum in this regime. For $|U|/3 > g$ [Fig. 3 (B)], the amplitudes of the peaks decrease as $|U|$ increases. We thus recover the fact that Andreev reflection is suppressed for large interaction $U$. However, while it is commonly assumed that interaction has always a detrimental effects on current based on Andreev reflection in quantum dot junction [21], it seems there exists an optimal value of $|U|$, i.e., $|U|/3 \sim g$, for observing large and well-resolved current peaks. We confirmed this behaviour by considering different values of $g$ (not shown) [40].

3.4. Effects of particle losses in the channel

We finally investigate the effects of the presence of additional particle losses acting on the junction. A diagnostic of such effects is important, since particle losses are inherent in
Reservoir engineering of Cooper-pair-assisted transport with cold atoms

Figure 3. Current-bias characteristics of the junction for different interaction strengths in the regime $|U|/3g < 1$ (A) and $|U|/3g > 1$ (B). Other parameters are $g = 0.5$, and $T = 0$, in units chosen so that $\gamma = 10^{-3}$. A: When the driving dominates, the current is characterized by fragmented oscillations. B: By contrast, when the interaction starts to dominate, clear Andreev peaks appear. However, for strong interactions, i.e., $|U|/3g \gg 1$, Andreev transport is suppressed and the current goes to its value without driving [i.e., Eq. (15)].

We incorporate these effects into our master equation through an additional dissipator of the Lindblad form $\mathcal{D}_I(\rho) = \gamma_I \left( 2L \rho L^\dagger - \{ L^\dagger L, \rho \} \right)$, where $\gamma_I$ is the rate of the incoherent process and $L$ the corresponding Lindblad operator (see Appendix C). Such dissipator corresponds to the effect of a structureless bath. We consider in the following atom losses, where $L = c_s \ (s \in \{\downarrow, \uparrow\})$. Figure 4 shows the atomic current in the right lead as a function of the bias potential for different loss rates $\gamma_I$ of only one of the atomic species (A) and of both atomic species (B), i.e., with one dissipator of the form above for each $s \in \{\downarrow, \uparrow\}$. For $\Delta \mu > |U|$, we observe a decrease of the current of atoms reaching the drain reservoir, since some of the atoms are lost in the additional decay channel. Surprisingly, the current assisted by molecular conversions (for $\Delta \mu < |U|$) seems to be only slightly affected by the losses, even for loss rate $\gamma_I$ of the order of magnitude of the tunnelling rate $\gamma$ with the reservoirs. This is because the dissipation processes coming from the additional particle losses do not account for the driving. Hence, while the standard tunnelling processes (for $\Delta \mu > |U|$) are significantly altered by atom losses, the Cooper-pair assisted current seems resilient against them, even at higher order (i.e., at lower bias).
Reservoir engineering of Cooper-pair-assisted transport with cold atoms

4. Conclusion

We showed how transport of fermionic atoms through a junction connecting two cold gases can be assisted by molecular conversion with a BEC. We described such reservoir engineering using an open-system framework that we recently derived, which is able to capture the effects of finite temperature of the reservoirs, strong interaction and presence of additional dissipation in the junction. This allowed us to explore with cold atoms the physics of Andreev reflection – a well-known paradigm in condensed-matter – in new parameter regimes. As a main result, we showed that there exists an optimal range of interaction yielding well-resolved, maximal peaks of assisted particle current. We showed that increasing the temperature of the reservoirs smears out the peaks, whereas these latter are robust against additional particle losses acting on the junction.

Our framework describes naturally dissipative processes and could be generalized to include the effects of measurements [6] and feedback loops, to potentially engineer and uncover new phenomena in quantum transport. In addition, it could be used to study spin-polarised [41] or thermoelectric [42, 43] transport properties of an engineered junction, starting from initial spin or temperature imbalances. Finally, since our method is suited to describe the interplay between driving and dissipation, it could be applied in the context of quantum heat engine or Floquet Majorana fermions [44, 45, 22].

Figure 4. Current-bias characteristics of the junction for different particle loss rates $\gamma$ of spin down ($s=\downarrow$) atom only (A) and both spin up ($s=\uparrow$) and down ($s=\downarrow$) atoms (B). Other parameters are $\omega = -U/2$, $U = -2$, $T = 0$, in units chosen so that $\gamma = 10^{-2}$. In both cases, the current assisted by molecular conversion is relatively robust against atom losses.
Appendix A: Derivation of the master equation

Our starting point is the usual Liouville-Von Neumann equation \[25\]
\[
\dot{\rho}_{\text{tot}}^I(t) = -i \left[ H_1^I(t), \rho_{\text{tot}}^I(t) \right]
\]
for the total density matrix \( \rho_{\text{tot}}^I(t) \) in interaction picture with respect to \( H_0(t) \equiv H_{S}^{\text{eff}}(t) + H_B \), where \( H_1^I(t) = \sum_\ell \kappa_\ell \sum_k (b_{\ell s}^I(t) c_{s}^I(t) + \text{h.c.}) \) with
\[
c_{s}^I(t) = U(t)^\dagger c_s U(t),
\]
\[
b_{\ell k s}^I(t) = e^{iH_0 t} b_{\ell k s} e^{-iH_0 t} = e^{-i\omega \ell t} b_{\ell k s},
\]
where the propagator \( U(t) \) is defined as
\[
U(t) = \mathcal{T} e^{-i \int_0^t H_{S}^{\text{eff}}(t') dt'},
\]
with \( \mathcal{T} \) the time-ordering operator.

4.1. Born and Markov approximations

Under the Born approximation, the total system-bath density matrix \( \rho_{\text{tot}}^I(t) \) can be written in the separable form
\[
\rho_{\text{tot}}^I(t) \approx \rho^I(t) \otimes \rho_L \otimes \rho_R,
\]
where \( \rho^I(t) \) is the junction density matrix in interaction picture and where \( \rho_\ell \) are the thermal states given by Eq. \([5]\). Expanding Eq. \([20]\) up to the second order in \( H_I \), using the Born approximation \([24]\) and tracing over the bath degrees of freedom yields
\[
\dot{\rho}^I(t) = - \int_0^t dt' \text{Tr}_B \left( \left[ H_1^I(t), [H_1^I(t - t'), \rho^I(t - t') \otimes \rho_L \otimes \rho_R] \right] \right),
\]
where we neglected the first order term \([25]\). After performing the Markov approximation by setting \( \rho^I(t - \tau) \approx \rho^I(t) \) and extending the upper limit of integration to infinity, the expansion of the double commutator yields
\[
\dot{\rho}(t) =
\]
\[
- \sum_\ell \sum_s \int_0^t \left\{ \left[ B_{\ell s}^I(t) B_{\ell s}(t - t') \right] \left( c_s(t)c_s^I(t - t')\rho(t) - c_s^I(t - t')\rho(t)c_s(t) + \text{h.c.} \right) \right.
\]
\[
+ \left[ B_{\ell s}(t) B_{\ell s}^I(t - t') \right] \left( c_s^I(t)c_s(t - t')\rho(t) - c_s(t - t')\rho(t)c_s^I(t) + \text{h.c.} \right) \left. \right\} dt',
\]
where we removed the superscript \(^I\) to not burden the notation and where \( \langle B_{\ell s}^I(t_1) B_{\ell s}(t_2) \rangle_B \equiv \text{Tr}_B \left( B_{\ell s}^I(t_1) B_{\ell s}(t_2) \rho_\ell \right) \) are the bath correlations with \( B_{\ell s}(t) = \kappa_\ell \sum_k b_{\ell k s}(t) \). Since for reservoirs in thermal states we have
\[
\langle b_{\ell k s}^I b_{\ell k's'} \rangle_B = \delta_{k k'} \delta_{s s'} n_\ell (\omega_k - \mu_\ell),
\]
\[
\langle b_{\ell k s} b_{\ell k's'} \rangle_B = \delta_{k k'} \delta_{s s'} (1 - n_\ell (\omega_k - \mu_\ell)),
\]
\[
\langle b_{\ell k s} b_{\ell k's'} \rangle_B = \langle b_{\ell k s}^I b_{\ell k's'}^I \rangle_B = 0,
\]
for reservoirs in thermal states with \( n_\ell = \frac{1}{\text{e}^{\beta \omega_\ell} + 1} \).
where \( n_\ell(E) = 1/(1 + e^{\beta_\ell E}) \) is the Fermi occupation number, the bath correlation functions can be rewritten as

\[
\begin{align*}
\Delta^\ell_{c} & = \frac{\gamma_\ell}{\pi} \int_{-\infty}^{\infty} d\omega \, e^{i\omega t'} n_\ell(\omega) - \mu_\ell) \]
\end{align*}
\]

In order to perform the time-integration in Eq. (26), we now evaluate the time dependence of the system operators \( c_a^\dagger(t) \) given by Eq. (21) using the Floquet theory. For that purpose, we suppose in the following that \( \mu_L = -\mu_R = \Delta \mu/2 \), so that effective system Hamiltonian \( H_S^{\text{eff}}(t) \) is periodic of period \( T = 2\pi/\Delta \mu \). If it was not the case, one could simply work in the rotating-frame with respect to one of the driving frequency \( 2\mu_\ell \), let say \( 2\mu_L \). This would provide a periodic Hamiltonian of period \( \delta = 2(\mu_R - \mu_L) \), and the same theory would apply.

Since \( H_S^{\text{eff}}(t) \) is periodic, the system wavefunction \( |\psi(t)\rangle \) satisfying the Schrödinger equation

\[
i \frac{d}{dt} |\psi(t)\rangle = H_S(t)|\psi(t)\rangle
\]

(29)
can be written as

\[
|\psi(t)\rangle = \sum_a d_a |\psi_a(t)\rangle = \sum_a d_a e^{-iE_a t} |\phi_a(t)\rangle,
\]

(30)
where \( |\psi_a(t)\rangle = e^{-iE_a t} |\phi_a(t)\rangle \) are the Floquet states with the periodic Floquet modes \( |\phi_a(t + T)\rangle = |\phi_a(t)\rangle \), quasi-energies \( E_a \), and \( d_a = \langle \phi_a(0) | \psi(0) \rangle \). By definition of the propagator, we have

\[
|\psi_a(T)\rangle = U(T)|\psi_a(0)\rangle \leftrightarrow e^{-iE_a T} |\phi_a(0)\rangle = U(T)|\phi_a(0)\rangle,
\]

(31)
showing that \( e^{-iE_a T} \) are the eigenvalues of \( U(T) \), which can be numerically computed using \( U(T) \approx \prod_{n=0}^{N-1} e^{-iH_S^{\text{eff}}(nt) dt} \) with \( N = T/dt - 1 \). Solving the eigenvalue problem, we obtain \( E_{a,k} = E_a + k^2 \pi^2 T^2 \) with \( k \in \mathbb{Z} \), and consider the values of \( E_{a,k} \) lying in the first Brillouin zone \([-\pi/T, \pi/T]\) to define the quasienergies \( E_a \). The eigenvectors correspond to the Floquet modes at initial time \( |\phi_a(0)\rangle \). The Floquet modes at all times \( t \) are obtained from these latter using

\[
|\phi_a(t)\rangle = e^{iE_a t} U(t)|\phi_a(0)\rangle.
\]

(32)
4.3. Master equation in the Floquet basis

We now decompose the density matrix in the Floquet mode basis \( \{|\phi_a(0)\rangle\} \), i.e.

\[
\rho(t) = \sum_{a,b} \rho^{I,ab}(t) |\phi_a(0)\rangle \langle \phi_b(0)|,
\]

(33)

and derive below the equations of motion for the density matrix element \( \rho^{I,ab}(t) \equiv \langle \phi_a(0)|\rho(t)|\phi_b(0)\rangle \) from Eq. (26).

In this basis, the matrix elements of the system operator \( c_s(t) \) reads

\[
\langle \phi_a(0)|c_s(t)|\phi_b(0)\rangle = \langle \phi_a(t)|c_s|\phi_b(t)\rangle e^{i(E_a-E_b)t}.
\]

(34)

Since \( |\phi_a(t)\rangle \) is periodic of period \( T \), we can rewrite \( \langle \phi_a(t)|c_s|\phi_b(t)\rangle \) in the Fourier space as

\[
\langle \phi_a(t)|c_s|\phi_b(t)\rangle = \sum_{k \in \mathbb{Z}} e^{ik\Delta \mu t} c_{sk}^{abk},
\]

(35)

which yields

\[
\langle \phi_a(0)|c_s(t)|\phi_b(0)\rangle = \langle \phi_a(t)|c_s|\phi_b(t)\rangle e^{i(E_a-E_b)t} = \sum_{k \in \mathbb{Z}} e^{ik\Delta \mu t} c_{sk}^{abk},
\]

(36)

where \( \Delta_{abk} = E_a - E_b + k\Delta \mu \) and

\[
c_{sk}^{abk} = \frac{1}{T} \int_0^T e^{-ik\Delta \mu t} \langle \phi_a(t)|c_s|\phi_b(t)\rangle dt.
\]

(37)

Expanding all operators of the first term of the right-hand side of the master equation (26) in the the Floquet basis yields

\[
\langle \phi_a(0)| \left( \int_0^\infty dt' f_{\ell^+}(t') c_s(t') c_s^\dagger(t - t') \rho(t) \right) |\phi_b(0)\rangle
\]

\[
= \sum_{c,d} \sum_{k,k'} e^{i(\Delta_{ckk'} + \Delta_{dck'})} c_{sk}^{ckk'} c_{sk'}^{dck'} \rho_{skd}^{f,db}(t) \int_0^\infty dt' f_{\ell^+}(t') e^{-i\Delta_{ckk'} t'},
\]

(38)

and all other terms can be written in the same way. Hence, we see that the master equation involves complex rates

\[
\Gamma_{\ell^\pm}(E) = \int_0^\infty dt' f_{\ell^\pm}(t') e^{iEt'} = \gamma_{\ell^\pm}(E) + i\Omega_{\ell^\pm}(E),
\]

(39)

where \( E \) corresponds to system transition energies and where \( \gamma_{\ell^\pm} \) and \( \Omega_{\ell^\pm} \) are the real and imaginary parts of \( \Gamma_{\ell^\pm} \) which explicitly read

\[
\gamma_{\ell^\pm}(E) = \gamma_{\ell}[1 - n_{\ell}(E \pm \mu_{\ell})],
\]

\[
\Omega_{\ell^\pm}(E) = \frac{\gamma_{\ell}}{\pi} \text{P.V.} \int_{-\infty}^{\infty} d\omega \frac{n_{\ell}(\omega)}{E + \omega \pm \mu_{\ell}},
\]

(40)
Reservoir engineering of Cooper-pair-assisted transport with cold atoms

where P.V. denotes the principal value. Note that the integrands appearing in the expressions of the shifts \( \Omega_{\ell \pm} \) do not converge for \( \omega \to \pm \infty \), and one has to introduce a cutoff frequency \( \omega_c \) in the integration domain to obtain finite values for the shifts.

All together, the master equation (26) written in the Floquet basis gives us the following set of equations for the matrix elements \( \rho^{I,ab}(t) \equiv \langle \phi_a(0)|\rho^I(t)|\phi_b(0) \rangle \), i.e. the non-secular Floquet-Born-Markov master equation

\[
\dot{\rho}^{I,ab}(t) = \sum_\ell \mathcal{L}_\ell [\rho^I(t)]^{ab} \\
= -\sum_\ell \sum_{s,k,k'} \sum_{c,d} \left\{ e^{i(\Delta_{cdk'} + \Delta_{ack})t} \left( e_s^{ack} c_s^{cdk'} \Gamma_{\ell+} (-\Delta_{cdk'}) + e_s^{ack} c_s^{cdk'} \Gamma_{\ell-} (-\Delta_{cdk'}) \right) \rho^{I,db}(t) \right. \\
- e^{i(\Delta_{dk'k} + \Delta_{ack})t} \left( e_s^{ack} c_s^{dk'} \Gamma_{\ell-} (-\Delta_{ack}) + e_s^{ack} c_s^{dk'} \Gamma_{\ell+} (-\Delta_{ack}) \right) \rho^{I,cd}(t) \bigg\} + h.c. \right). \tag{41}
\]

The master equation for the matrix elements in Schrödinger picture \( \rho^{ab}(t) \) can be obtained from Eq. (41) by making the replacement \( \rho^{I,ab}(t) = e^{i(E_a - E_b)t} \rho^{ab}(t) \). In doing so, one can see that all terms \( e^{i(\Delta_{cdk'} + \Delta_{ack})t} \) reduces to \( e^{i(k'k + \Delta \mu)t} \) [see Eq.(8)], showing that the master equation exhibits the same periodicity than the system Hamiltonian \( H_{S}^{\text{eff}}(t) \). This implies that the steady state of the master equation is also periodic with the same period \( T = 2\pi/\Delta \mu \) \[46\].

Note that we did not proceed with the secular approximation, so that we have a Redfield-like master equation, for which the steady state properties match the ones of the equivalent non-Markovian master equation for time-independent system. Hence, while non-Markovian effects might potentially be present in the transient dynamics of our system, we do not expect significant memory effects in its steady state properties. The investigation of the interplay between potential non-Markovian effects and Floquet dynamics will be investigated in a further work.

Appendix B: Solution of the master equation and particle currents

We present here two methods to solve the master equation (41) that exploits its periodicity. Note that since the steady state density matrix and any expectation value of system operators obtained from it are in principle periodic (or constant), we always present in the main text time-averaged values of these quantities over one period of oscillation \( T = 2\pi/\Delta \mu \).

The master equation in Schrödinger picture (8) can be vectorized in the form

\[
|\dot{\rho}^{S}(t)\rangle = L(t)|\rho^{S}(t)\rangle \tag{42}
\]

where \( |\rho^{S}(t)\rangle = (\rho^{S,11}(t), \rho^{S,12}(t), \ldots, \rho^{S,44}(t)) \) is the vectorized density matrix and \( L(t) \) is a periodic time-dependent matrix of period \( T \).
4.4. Solving the master equation in Fourier space

We can express the steady state density matrix $\rho_{SS}^S(t)$ and the matrix $L(t)$ as

$$\rho_{SS}^S(t) = \sum_k e^{-ik\Delta \mu} \rho_k; \quad \rho_k = \frac{1}{T} \int_0^T e^{-ik\Delta \mu} \rho_{SS}^S(t) dt$$

$$L(t) = \sum_k e^{-ik\Delta \mu} L_k; \quad L_k = \frac{1}{T} \int_0^T e^{-ik\Delta \mu} L(t) dt. \quad (43)$$

Inserting these decompositions into the vectorized form (42), we get

$$\sum_k -ik Ve^{-ik\Delta \mu} |\rho_k\rangle = \sum_{k,k'} e^{-i(k+k')\Delta \mu} L_{k'} |\rho_k\rangle \quad (44)$$

Applying then $(1/T) \int_0^T \cdot e^{ik'' \Delta \mu}$ on both sides yields

$$0 = -ik''V \mathbb{1} |\rho_{k''}\rangle + \sum_k L_k |\rho_{k'-k}\rangle \quad (45)$$

which can be written in matrix form as

$$\begin{pmatrix}
\vdots \\
0 \\
0 \\
\vdots \\
\end{pmatrix} = \begin{pmatrix}
-ik \Delta \mu + L_0 & L_1 & L_2 \\
L_{-1} & -ik \Delta \mu + L_0 & L_1 \\
L_{-2} & L_{-1} & -i(k-1) \Delta \mu + L_0 \\
\vdots & & \ddots \\
\end{pmatrix} \begin{pmatrix}
\vdots \\
|\rho_{k+1}\rangle \\
|\rho_k\rangle \\
|\rho_{k-1}\rangle \\
\vdots \\
\end{pmatrix} \quad (46)$$

This linear system of equations for the Fourier components can be efficiently solved numerically after truncation, i.e., by introducing a cutoff $k_{\text{max}}$ in the summation over $k$ of the Fourier series (35). The off-diagonal blocks $L_k$ in Eq. (46) describe the coupling between different Fourier components. A block $L_k$ corresponds to a molecular conversion process of the form (12).

4.5. Solving the master equation in real space

The vectorized master equation (42) is of the same form than the time-dependent Schrödinger equation (29). We can thus apply again the Floquet theory and write the solution as

$$|\rho^S(t)\rangle = \sum_a d_a e^{i\alpha t} |\rho^{S,a}(t)\rangle \quad (47)$$

where $|\rho^{S,a}(t)\rangle = |\rho^{S,a}(t+T)\rangle$ are periodic functions of period $T$ and where $d_a = \langle \rho^{S,a}(0)|\rho^S(0)\rangle$. Hence, solving the entire problem in this case consists in applying twice the Floquet theory: once to write the Floquet-Born-Markov master equation (41) and once to solve it.
4.6. Currents

From the solution of the master equation \(^{(41)}\) for the matrix elements \(\rho_{I,ab}(t)\), one can evaluate the expectation values of any system operator \(O\) through

\[
\langle O \rangle = \text{Tr} \left[ U^\dagger(t)O U(t)\rho_I(t) \right] = \sum_{j=0,\downarrow,\uparrow\uparrow} \sum_{ab} \rho_{I,ab}(t)e^{-i(E_a-E_b)t} \langle j|O|\phi_a(t)\rangle \langle \phi_b(t)|j \rangle.
\]

(48)

We derive here the expressions of the particle currents \(I_S\), \(I_\ell\) and \(I_{\text{mol}}\) respectively in the junction, the reservoirs and the molecular BEC. For the sake of clarity, we introduce an annihilation operator \(S\) for the BEC that interacts with the junction with an Hamiltonian of the form \(H_{\text{BEC}}(t) = \sum_\ell (\Omega_\ell S c_\downarrow^\dagger c_\uparrow^\dagger e^{2i\mu_\ell t} + \text{h.c.})\). The currents \(I_S\), \(I_\ell\) and \(I_{\text{mol}}\) are then defined as

\[
I_S = \frac{d}{dt} \sum_s c_\downarrow^s c_\downarrow^s = -i\kappa_\ell \sum_{ks} \left( c_\downarrow^s b_{\ell ks} - \text{h.c.} \right) - 2i \sum_\ell \left( g_\ell^* e^{-2i\mu_\ell t} c_\uparrow^\dagger c_\downarrow^\dagger - \text{h.c.} \right),
\]

\[
I_\ell = \frac{d}{dt} \sum_{ks} b_{\ell ks}^\dagger b_{\ell ks} = i\kappa_\ell \sum_{ks} \left( c_\downarrow^s b_{\ell ks} - \text{h.c.} \right),
\]

\[
I_{\text{mol}} = \frac{d}{dt} S^\dagger S = i \sum_\ell \left( g_\ell^* e^{-2i\mu_\ell t} c_\uparrow^\dagger c_\downarrow^\dagger - \text{h.c.} \right),
\]

(49)

(50)

where we replaced the operator \(S\) by the macroscopic fraction \(\langle S \rangle\) and where we used the Langevin equations for \(c_s\), \(b_{\ell ks}\) and \(S\). Note that the total number of particles is conserved, i.e.,

\[
I_S + \sum_\ell I_\ell + 2I_{\text{mol}} = 0,
\]

(52)

where the factor 2 is front of \(I_{\text{mol}}\) denotes the fact that a molecule is made of two atoms.

The expectation value of the particles current in the junction is obtained from the solutions of the master equation and Eq. \(^{(48)}\), that is

\[
\langle I_S \rangle = \sum_s \frac{d}{dt} \langle c_\downarrow^s c_\downarrow^s \rangle = \sum_s \frac{d}{dt} \text{Tr} \left[ U^\dagger(t)c_\downarrow^s U(t)\rho_I(t) \right].
\]

(53)

Due to the conservation of the number of particles \(^{(52)}\), it can be related to the particle current in the reservoirs, as shown below. Applying the derivative and using the fact that \(dU(t)/dt = -iH_{\text{eff}}^S(t)U(t)\), we get

\[
\langle I_S \rangle = i \sum_s \text{Tr} \left[ U^\dagger(t)H_{\text{eff}}^S(t)c_\uparrow^s c_\downarrow^s U(t)\rho_I(t) \right] - i \sum_s \text{Tr} \left[ U^\dagger(t)c_\downarrow^s H_{\text{eff}}^S(t)U(t)\rho_I(t) \right] + \sum_s \text{Tr} \left[ U^\dagger(t)c_\downarrow^s U(t) \frac{d\rho_I(t)}{dt} \right].
\]

(54)
The two first terms on the right-hand-side can be rewritten as

\[
i \sum_s \langle H_S^{\text{eff}}(t)t_s^a c_s \rangle - i \sum_s \langle c_s^{\dagger} H_S^{\text{eff}}(t)t_s \rangle = 2i \sum_\ell g_\ell e^{2i\mu_\ell t} \langle c_\ell^a c_\ell^a \rangle - 2i \sum_\ell g_\ell^* e^{-2i\mu_\ell t} \langle c_\ell^a c_\ell^a \rangle = -2\langle I_{\text{mol}} \rangle
\]

where [see Eq. (50)]

\[
\langle I_{\text{mol}} \rangle = i \sum_\ell \left( g_\ell^* e^{-2i\mu_\ell t} \langle c_\ell^a c_\ell^a \rangle - \text{h.c.} \right)
\]

Finally, replacing the derivative in Eq. (54) by the right-hand-side of the master equation (41) yields

\[
\langle I_S \rangle = -2\langle I_{\text{mol}} \rangle + \sum_\ell \text{Tr} \left[ U(t) c_\ell^a c_\ell^a U(t) \left( \mathcal{L}_\ell \left[ \rho(t) \right] \right) \right] = -2\langle I_{\text{mol}} \rangle - \sum_\ell \langle I_\ell \rangle,
\]

with

\[
\langle I_\ell \rangle = - \sum_{ab} \left( \mathcal{L}_\ell \left[ \rho(t) \right] \right)^{ab} e^{-i(E_a - E_b)t} \left( \sum_j \sum_s \langle j | c_s^a \phi_a(t) \rangle \langle \phi_b(t) | j \rangle \right).
\]

In the main text, we always present time-averaged values of the current over one period of oscillation \(T = 2\pi/\Delta \mu\).

5. Appendix C: Adding dissipation on the channel

Additional dissipation acting on the channel can be accounted for by adding to Eq. (41) a dissipator of the form

\[
D_1[\rho(t)] = \gamma_t \left( 2L_\rho(t) L_\rho(t) - L_\rho(t) L_\rho(t) - \rho(t)L_\rho(t) \right)
\]

In the Floquet basis, this dissipator reads

\[
(D_1[\rho(t)])^{ab} = \gamma_t \sum_{cd} \sum_{kk'} \left[ 2 \left( e^{i(\Delta_{dk} + \Delta_{ak})t} L_{ak}^c L_{dk}^d \right) \rho_{cd}(t) - \left( e^{i(\Delta_{dk} + \Delta_{ak})t} L_{dk}^c L_{ak}^d \right) \rho_{dc}(t) - \left( e^{i(\Delta_{dk} + \Delta_{ak})t} L_{ak}^c L_{dk}^d \right) \rho_{cd}(t) - \left( e^{i(\Delta_{dk} + \Delta_{ak})t} L_{ak}^c L_{dk}^d \right) \rho_{dc}(t) \right]
\]

By solving the master equation (41) after adding on its right-hand-side the dissipator (60), we can then calculate the associated particle current

\[
\langle I_1(t) \rangle = - \sum_{ab} \left( D_1[\rho(t)] \right)^{ab} e^{-i(E_a - E_b)t} \left( \sum_j \sum_s \langle j | c_s^a \phi_a(t) \rangle \langle \phi_b(t) | j \rangle \right).
\]

Reservoir engineering of Cooper-pair-assisted transport with cold atoms

Reservoir engineering of Cooper-pair-assisted transport with cold atoms

In cold atom experiments, the initial imbalance between the reservoirs is usually not maintained during the transport measurements. This is in contrast with the solid-state where the bias between the leads that act as reservoirs can easily be conserved through the use of bias voltages.

The condition \( \tau_R \gg \tau_B \) can also be fulfilled for single-mode environment that are damped by other means, as it is the case for an atomic system trapped in a single-mode lossy cavity [39].

Note that we observed a slower numerical convergence of the transport properties of the junction when decreasing the interaction strength \( |U| \), in the sense that a higher cutoff \( k_{\text{max}} \) of the Fourier series appearing in (9) was required in this regime. This can be understood by the fact that for smaller interaction \( |U| \) compared to a fixed pair-tunnelling \( g \), higher-order multiple Andreev reflections must be accounted for, requiring then higher \( k_{\text{max}} \).
