ON REEB GRAPHS INDUCED FROM SMOOTH FUNCTIONS ON CLOSED OR OPEN MANIFOLDS

NAOKI KITAZAWA

Abstract. For a smooth function on a smooth manifold of a suitable class, the space of all connected components of preimages is the graph and called the Reeb graph. Reeb graphs are fundamental tools in the algebraic and differential topological theory of Morse functions and more general functions which are not so wild.

In this paper, we study whether we can construct a smooth function with good geometric properties inducing a given graph as the Reeb graph. This problem has been essentially launched by Sharko in 2000s and various answers have been given by Masumoto, Michalak, Saeki, and so on. Recently the author set a new explicit problem and gave an answer. In the studies before the result of the author, considered functions are smooth functions on closed surfaces or Morse functions such that preimages of regular values are disjoint unions of standard spheres. On the other hand, the author constructed a smooth function on a suitable 3-dimensional closed, connected and orientable manifold inducing the Reeb graph isomorphic to the given graph such that preimages of regular values are arbitrary closed surfaces. Based on this result and method of the author, with several new ideas, we will consider smooth functions on surfaces and manifolds which may be non-closed and give answers to the problem.

1. Introduction and some terminologies and notation

For a graph, the vertex set is the set of all vertices throughout this paper.

The Reeb graph or a Kronrod-Reeb graph of a smooth function of a suitable class on a smooth manifold is the graph obtained as the space of all connected components of level sets such that the vertex set coincides with the set of all connected components of level sets including singular points (see [10] and [12] for example). A singular point of a smooth map is a point at which the rank of the differential drops. For Morse functions, functions with finitely many singular points on closed manifolds and functions of several suitable classes, the spaces are graphs. Reeb graphs are fundamental and important tools in the algebraic and differential topological theory of Morse functions and their generalizations.

In this paper, we attack the following fundamental, natural and important problem.

Problem 1. Can we construct a smooth function with good geometric properties inducing a given graph as the Reeb graph?

2010 Mathematics Subject Classification. Primary 57R45. Secondary 57N15.

Key words and phrases. Singularities of differentiable maps; generic maps. Differential topology. Reeb spaces.
This problem has been first considered by Sharko ([12]). Related to this pioneering work, several works have been done: the work of J. Martinez-Alfaro, I. S. Meza-Sarmiento and R. Oliveira ([6]), the work of Masumoto and Saeki ([7]) and recent works such as [1], [8] and [9]. In these studies, explicit smooth functions inducing the given graphs as the Reeb graphs have been constructed. Most of the functions are ones on closed surfaces or Morse functions on closed manifolds such that preimages of regular values are disjoint unions of circles or standard spheres.

The author has obtained a related result of a new type in [5]. [4] is also closely related to [5]. We introduce several terminologies and introduce the result.

**Definition 1.** Let a smooth manifold $X$ and a function $c : X \to \mathbb{R}$ given. Let $\sim_c$ be the equivalence relation on $X$ defined by the following rule: $x_1 \sim_c x_2$ holds if and only if they are in a same connected component of a level set $c^{-1}(y)$. We call the quotient space $W_c := X/\sim_c$ the **Reeb space** of $c$. Let $V \subset W_c$ be the set of all points representing connected components of level sets of $c$ which contain some singular points of $c$. If $W_c$ is regarded as the graph whose vertex set is $V$, then the graph $W_c$ is called the **Reeb graph** of $c$.

In the definition, we denote the natural quotient map by $q_c : X \to W_c$ and by $\bar{c}$ the map satisfying the relation $c = \bar{c} \circ q_c$. For a connected finite graph without loops which is not a single point or empty, a **good function** is a continuous real-valued function on the graph such that the restriction map to each edge is injective. Note that the graph is canonically topologized as a 1-dimensional polyhedron.

We can give an orientation to each edge compatible with the good function so that the following hold. The **starting point** of an edge is a vertex from which the edge originates. The **ending point** of an edge is a vertex in which the edge terminates.

1. The starting point of an edge is the vertex at which the (restriction of the) given good function has the minimum.
2. The ending point of an edge is the vertex at which the (restriction of the) given good function has the maximum.

The **singular set** of a smooth map is defined as the set of all singular points of the map. A **singular value** is a point such that the preimage contains a singular point. The **singular value set** is the image of the singular set. A point in the complement of the singular value set of the map is called a **regular value**.

A **Morse-Bott** function is a function at each singular point which is represented as a composition of a submersion and a Morse function ([2]). A **fold** map is a smooth map such that at each singular point, the map is represented as a product of a Morse function and the identity map on an open ball (the singular set is a smooth closed submanifold of a source manifold and the restriction to the singular set of the original map is a smooth immersion whose codimension is 1).

More strictly, a smooth map $f$ is represented as another smooth map $g$ means that $f$ is $C^\infty$ equivalent to $g$: there exists a pair of a diffeomorphism $\Phi$ between the source manifolds and a diffeomorphism $\phi$ between the target ones satisfying the relation $\phi \circ f = g \circ \Phi$.

For singularities of smooth maps, see also [3] for example.

The following is the main theorem of [5].

**Theorem 1** ([5]). For a finite and connected graph $G$ such that a non-negative integer is assigned to each edge and a good function $h : G \to \mathbb{R}$ is given, we can...
construct a smooth function $f$ of a suitable 3-dimensional closed, connected and orientable manifold $M$ satisfying the following properties.

1. The Reeb graph $W_f$ is isomorphic to the given graph $G$: we set an isomorphism between the graphs by $\phi : W_f \to G$.

2. If we consider the natural quotient map $q_f$ onto the Reeb graph $W_f$ and a point $p \in W_f$ such that $\phi(p)$ is in the interior of an edge of $G$ $q \geq 0$ is assigned to, then the preimage $q_f^{-1}(p)$ is a closed, connected and orientable surface of genus $q \geq 0$.

3. For a point $p \in M$ mapped by the quotient map $q_f$ to a vertex $v$, $f(p) = h(\phi(v))$.

4. At each singular point of $f$, the function is a Morse function, a Morse-Bott function or represented as a composition of two fold maps.

We introduce several terminologies on graphs. Two graphs are isomorphic if there exists a homeomorphism mapping the vertex set of a graph onto the vertex set of another graph and this homeomorphism is called an isomorphism between the graphs.

A main theorem or Theorem 2 of the present paper is for smooth functions on closed or open surfaces and similar to Theorem 1 in considerable parts. One of the new ingredients is that the resulting function may have non-closed preimages of regular values. We prove this and a higher dimensional version (Theorem 3) in the next section. In the last two sections we prove further results related to these results.

The author is a member of the project Grant-in-Aid for Scientific Research (S) (17H06128 Principal Investigator: Osamu Saeki) ”Innovative research of geometric topology and singularities of differentiable mappings” (https://kaken.nii.ac.jp/en/grant/KAKENHI-PROJECT-17H06128/) and supported by this project. The author would like to thank Osamu Saeki and colleagues supporting this project for motivating the author to produce the present study through discussions on [5].

2. A MAIN THEOREM AND ITS PROOF

Theorem 2. Let $G$ be a finite and connected graph with a good function $h : G \to \mathbb{R}$ such that an integer $0$ or $1$ is assigned to each edge satisfying the following conditions.

1. For a vertex at which the good function $h$ does not have a local extremum, the number of edges $1$’s are assigned to and containing the vertex as the starting points and that of edges $1$’s are assigned to and containing the vertex as the ending points agree. Moreover, if the number of edges $1$’s are assigned to and having the vertex as the starting points is $1$, then there exists an edge $0$ is assigned to and containing the vertex as the starting point or ending point.

2. For a vertex at which the good function $h$ has a local extremum, the number of edges $1$’s are assigned to and containing the vertex as the starting points are even.

Then there exists a connected surface $M$ and a smooth function $f : M \to \mathbb{R}$ satisfying the following properties.
(1) The Reeb graph $W_f$ is isomorphic to $G$: we denote an isomorphism by $\phi : W_f \to G$.

(2) If we consider the natural quotient map onto the Reeb graph $W_f$ and a point $p \in W_f$ such that $\phi(p)$ is in the interior of an edge of $G$ an integer $q = 0, 1$ is assigned to, then the preimage is diffeomorphic to a circle ($q = 0$) or a line ($q = 1$).

(3) For a point $p \in M$ mapped by the quotient map $q_f$ to a vertex $v$, $f(p) = h(\phi(v))$.

(4) Around each singular point at which the function $f$ does not have a local extremum, the function is a Morse function.

(5) Around each singular at which $f$ has a local extremum, the function is a Morse function, a Morse-Bott function, or represented as a composition of two Morse functions.

The outline of the proof is similar to that of Theorem 1. We prove this.

**Proof of Theorem 2.** STEP 1 Construction around a vertex at which the good function $h$ does not have a local extremum.

Let $a$ be the number of edges 1’s are assigned and containing the vertex as the starting (ending) points (these numbers agree by the assumption on the numbers assigned to edges). Let $b$ and $c$ be the numbers of edges 0’s are assigned to and containing the vertex as the ending points and the starting points, respectively. We construct a desired function as a Morse function. We apply well-known fundamental correspondence of the handles in a family of handles attached to a boundary of a manifold and singular points of a Morse function on the manifold produced by the handles. We abuse several terminologies omitting the definitions such as the index $k$ of a handle or a $k$-handle.

Let $a$, $b$ and $c$ defined before be arbitrary non-negative integers satisfying

$$(a, b, c) \neq (1, 0, 0), (0, 1, 0), (0, 0, 1), (0, 0, 0).$$

FIGURE 1 shows handle attachments producing a surface whose boundary is the disjoint union of two 1-dimensional manifolds which may not be connected. We attach $a - 1 + b + c$ 1-handles to the product of a 1-dimensional manifold $F$, consisting of $a$ copies of a line and $b$ copies of a circle, and the closed interval $[0, 1]$. More precisely, we attach them to $F \times \{0\} \subset F \times [0, 1]$. If $a > 0$, then we attach handles as the following explanation.

1. We attach $a - 1$ 1-handles to connect $a$ copies of a line,
2. We attach $b - 1$ 1-handles to connect $b$ copies of a circle if $b > 0$. We attach a 1-handle to a line to connect the $b$ copies of a circle.
3. We attach $c$ 1-handles to a line. We may attach $c$ 1-handles to a circle if it exists, not a line.

If $a = 0$ and $(b, c) \neq (1, 1)$, then we attach 1-handles according to the following explanation.

1. We attach $b - 1$ 1-handles to connect $b$ copies of a circle $(b > 0)$.
2. We attach $c - 1$ 1-handles to one of the $b$ circles $(c > 0)$.

If $a = 0$ and $(b, c) = (1, 1)$, then we attach 1-handles according to the following explanation.

1. We choose four disjoint closed intervals in the circle $F(F \times \{0\})$. 
1-handles

Figure 1. Handle attachments to obtain a connected and orientable surface and a desired local Morse function on this in STEP 1 for $a > 0$: attaching $a - 1$ 1-handles to connect $a$ copies of a line, $b$ 1-handles to connect $b$ copies of a circle and a line and $c$ 1-handles to a line.

(2) We choose two of the four closed intervals which are not adjacent.
(3) We attach a 1-handle to the two closed intervals.
(4) We attach another 1-handle to the remaining two closed intervals.

As a result, we obtain a 2-dimensional connected and orientable manifold whose boundary is the disjoint union of two 1-dimensional manifolds. One of the 1-dimensional manifolds is the 1-dimensional manifold $F \times \{1\}$, consisting of $a$ copies of a line and $b$ copies of a circle. The other is the disjoint union of $a$ copies of a line and $c$ copies of a circle.

We obtain a desired local Morse function satisfying the first four properties around the vertex for any $(a, b, c)$. For the first property, this means that a small regular neighborhood of the vertex in the given graph and the Reeb graph is homeomorphic and that there exists a homeomorphism mapping a vertex onto a point representing the level set containing some singular points: in the present paper, situations like this appear in the proceeding theorems and proofs. Note that handles can be attached simultaneously and that this gives a Morse function with exactly one singular value on the 2-dimensional manifold.

STEP 2 Construction around a vertex at which the good function $h$ has a local extremum.
Case 1 The case where the vertex is of degree 1.
It is sufficient to consider the case where the label assigned to the edge including the vertex is 0 by the assumption. A natural height function on a 2-dimensional unit disc, which is a Morse function with exactly one singular point in the interior or in the center, is a desired local function. Note that this is generalized to arbitrary dimensional cases and this is a key in proving Theorem 3 later and in various situations of the present paper.

Case 2 The case where the vertex is of degree larger than 1.
We show the case where at the vertex the good function has a local maximum. For the case where at the vertex the good function has a local minimum, we can do similarly. We first construct a local function as in STEP 1 and embed the image
into the plane as the set \( \{(x, y) \in \mathbb{R}^2 \mid -1 \leq x \leq 1, y = x^2\} \) sending the singular value to the origin. See FIGURE 2: \( F_1 \) and \( F_2 \) represent the preimages of \((-t, t^2)\) and \((t, t^2)\) \((t > 0)\), respectively. \( F_1 \sqcup F_2 \) is the preimage of a regular value of the resulting local function.

We construct a desired local function as in STEP 1 first so that \( F_1 \) is diffeomorphic to the disjoint union of \( a \) copies of a line and \( b \) copies of a circle and that \( F_2 \) is diffeomorphic to the disjoint union of \( a \) copies of a line and \( c \) copies of a circle where \( a, b \) and \( c \) are arbitrary non-negative integers satisfying \((a, b, c) \neq (1, 0, 0), (0, 1, 0), (0, 0, 1), (0, 0, 0)\): we consider a case where the vertex is contained in exactly \( 2a \) edges 1’s are assigned to and contained in exactly \( b + c \) edges 0’s are assigned to.

We compose the projection \( p(x, y) := y \) to the map into the plane in FIGURE 2 and we have a desired local smooth function. By the construction, at each singular point, the function is a Morse-Bott function or represented as a composition of two Morse functions. As a result, we obtain a local function satisfying the first, second, third and fifth properties around the vertex.

In the case \((a, b, c) = (1, 0, 0), (0, 1, 1)\), we construct a trivial smooth bundle whose fiber is connected and diffeomorphic to \( S^1 \) or \( \mathbb{R} \) instead of a Morse function before embedding the image into the plane. In this case, at the singular points, the function is Morse-Bott.

This completes STEP 2 for any \((a, b, c)\).

STEP 3 Completing the construction.

Last, we construct functions around remaining parts. We can construct these functions as trivial smooth bundles. Gluing the local functions together on the 1-dimensional manifolds in boundaries gives a desired function on a surface. To make the resulting surface orientable, we must use the diffeomorphisms for the gluing carefully one after another.

This completes the proof. \(\square\)

We can show a higher dimensional version of Theorem 2 or Theorem 3 similarly by virtue of Remark 1 in the following.

**Remark 1.** Let \( n > 1 \) be an integer. Let \( a, b \) and \( c \) be non-negative integers satisfying
\[
(a, b, c) \neq (1, 0, 0), (0, 1, 0), (0, 0, 1), (0, 0, 0).
\]
Consider the disjoint union \( F \) of \( a \) copies of \( \mathbb{R}^n \) and \( b \) copies of \( S^n \) and \( F \times [0, 1] \). We can attach 1-handles to \( F \times \{0\} \) and \( n \)-handles to this. As a result, for an arbitrary
positive integer $c$, we obtain an $(n + 1)$-dimensional connected and orientable manifold whose boundary is the disjoint union of two $n$-dimensional manifolds. One is the disjoint union of $a$ copies of $\mathbb{R}^n$ and $b$ copies of $S^n$ or $F \times \{1\}$. The other is the disjoint union of $a$ copies of $\mathbb{R}^n$ and $c$ copies of $S^n$.

Figure 3 represents the attachments of $1$-handles and $n$-handles to the disjoint union of the manifolds diffeomorphic to $\mathbb{R}^n$ in $F \times \{0\}$ for $a > 0$: we attach $a - 1$ $1$-handles to connect $a$ copies of $\mathbb{R}^n$, an $n$-handle to each copy of $\mathbb{R}^n$ in the figure. We also need to attach $b$ $1$-handles to connect $b$ copies of $S^n$ and a copy of $\mathbb{R}^n$ in $F \times \{0\}$. In addition, we also need to attach $c$ $n$-handles to a copy of $\mathbb{R}^n$ in $F \times \{0\}$. If $a = 0$ and $(b, c) \neq (1, 1)$, then we attach $b$ $1$-handles to connect $b$ copies of $S^n$ and $c - 1$ $n$-handles to a copy of $S^n$ in $F \times \{0\}$. If $a = 0$ and $(b, c) = (1, 1)$, then we attach a $1$-handle and an $n$-handle to the standard $n$-dimensional sphere in $F \times \{0\}$ to obtain a desired $(n + 1)$-dimensional manifold.

Note that the handles are attached simultaneously in these cases. This yields STEP 1 of the proof of Theorem 2 in the proof of Theorem 3.

We finish this section by presenting the higher dimensional version or Theorem 3. The rigorous proof is left to readers.

**Theorem 3.** Let $n$ be a positive integer. Let $G$ be a finite and connected graph with a good function $h : G \to \mathbb{R}$ such that an integer 0 or 1 is assigned to each edge satisfying the following conditions.

1. For a vertex at which the good function does not have a local extremum, the number of edges 1’s are assigned to and containing the vertex as the starting points and that of edges 1’s are assigned to and containing the vertex as the ending points agree. Moreover, if the number of edges 1’s are assigned to and containing the vertex as the starting points is 1, then there exists an edge 0 is assigned to and containing the vertex as the starting point or ending point.
(2) For a vertex at which the good function has a local extremum, the number of edges 1's are assigned to are even.

Then there exists an \((n+1)\)-dimensional connected and orientable manifold and a smooth function \(f : M \to \mathbb{R}\) satisfying the following properties.

1. The Reeb graph \(W_f\) is isomorphic to \(G\): we denote an isomorphism by \(\phi : W_f \to G\).
2. If we consider the natural quotient map onto the Reeb graph \(W_f\) and a point \(p \in W_f\) such that \(\phi(p)\) is in the interior of an edge of \(G\) an integer \(q = 0, 1\) is assigned to, then the preimage is diffeomorphic to \(S^n\) \((q = 0)\) or \(\mathbb{R}^n\) \((q = 1)\).
3. For a point \(p \in M\) mapped by the quotient map \(q_f\) to a vertex \(v\), \(f(p) = h(\phi(v))\).
4. At each singular point at which the function \(f\) does not have a local extremum, the function is a Morse function.
5. At each singular point at which the function \(f\) has a local extremum, the function is a Morse function, Morse-Bott function, or represented as a composition of two Morse functions.

3. Modifications of Theorems 2 and 3 when the original assumptions do not hold

**Theorem 4.** Let \(G\) be a finite and connected graph having a good function \(h\) such that an integer 0 or 1 is assigned to each edge. We assume that the original assumption as in Theorem 2 does not hold.

Then there exists a connected surface \(M\) and a smooth function \(f : M \to \mathbb{R}\) satisfying the following properties.

1. The Reeb graph \(W_f\) is isomorphic to \(G\): we denote an isomorphism by \(\phi : W_f \to G\).
2. If we consider the natural quotient map onto the graph and for each point that is not a vertex and that is in an edge an integer \(p = 0, 1\) is assigned to, then the preimage is diffeomorphic to a circle \((p = 0)\) or a line \((p = 1)\).
3. For a point \(p \in M\) mapped by the quotient map \(q_f\) to a vertex \(v\), \(f(p) = h(\phi(v))\).
4. At each singular point at which the function \(f\) does not have a local extremum, except finitely many ones, the functions are Morse functions or Morse-Bott functions.
5. At each singular point at which the function \(f\) has a local extremum, except finitely many ones, the functions are Morse functions, Morse-Bott functions, or represented as a composition of two Morse functions or a composition of a Morse-Bott function with a Morse function.

**Proof.** The proof is similar to that of Theorem 2 in considerable parts. However, there are several new ingredients.

**STEP 1** Construction around a vertex at which the good function \(h\) does not have a local extremum.

Let \(a\) \((d)\) be the number of edges 1's are assigned to and containing the vertex as the (starting) points. Let \(b\) and \(c\) be the numbers of edges 0's are assigned to and containing the vertex as the ending points and the starting points, respectively.
By the assumption, the assumption of Theorem 2 does not hold. This means that either of the following holds.

(1) $a \neq d$ and either of the following hold.
   (a) $a \neq 0$ and $d \neq 0$.
   (b) $a = 0$ and $b > 0$.
   (c) $d = 0$ and $c > 0$.

(2) $a = d = 1$ and $(b, c) = (0, 0)$.

CASE 1-A $a = d = 1$ and $(b, c) = (0, 0)$ hold. Let $p_0 > 0$ Let $g_0$ be a $C^\infty$ function on $\mathbb{R}$ such that $g_0(x) = 0$ for $x \geq p_0$ and $g_0(x_1) - g_0(x_2) > 0$ for any $x_1 < x_2 \leq p_0$. We introduce several points and subsets in the plane. Set $A_0 := \{(t, 0) \mid t > p_0\}$ and $B_0 := \{(t, g_0(t)) \mid p_0 - 1 < t < p_0\}$. We also set $-A_0 := \{-a \mid a \in A_0\}$ and $-B_0 := \{-b \mid b \in B_0\}$.

We can construct a smooth map $F_0$ from a surface into the plane satisfying the following properties.

(1) $F_0$ is a fold map from an open surface into the plane such that the interior of the image is one of the domains bounded by the union of the following sets and that the image of the composition of $F_0$ with the projection $p(x, y) := y$ is $(-g_0(p_0 - 1), g_0(p_0 - 1)) \subset \mathbb{R}$.
   (a) $A_0$.
   (b) $\{(p_0, 0)\}$.
   (c) $B_0$.
   (d) $-A_0$.
   (e) $\{(-p_0, 0)\}$.
   (f) $-B_0$.
   (g) $\{(t, g_0(p_0 - 1)) \mid t \leq p_0 - 1\}$.
   (h) $\{(t, g_0(p_0 - 1)) \mid t \geq 1 - p_0\}$.

(2) Let us denote the domain before by $D_0$. The image of $F_0$ is the disjoint union of $D_0$ and the first six sets before. Moreover, the union of the first six set is the singular value set of the fold map $F_0$ and the restriction of $F_0$ to the singular set is an embedding.

(3) Let $\epsilon_0 > 0$ be a small number. $L_{0.1} := D_0 \cap \{(t, g_0(t) - \epsilon_0) \mid t \in \mathbb{R}\}$. Over the union of the domain $U_1$ between the union $A_0 \cup \{(p_0, 0)\} \cup B_0 \subset D_0$ and $L_{0.1} \subset D_0$ and the union $A_0 \cup \{(p_0, 0)\} \cup B_0$, $F_0$ is represented as a product of a Morse function on an interval with exactly one singular point in the interior and the identity map on the union $A_0 \cup \{(p_0, 0)\} \cup B_0$, which is a line: note that the graph of the Morse function on an interval is a parabola as in FIGURE 2.

(4) $L_{0.2} := D_0 \cap \{(t, -g_0(t) + \epsilon_0) \mid t \in \mathbb{R}\}$. Over the union of the domain $U_2$ between the union $-A_0 \cup \{(-p_0, 0)\} \cup B_0 \subset D_0$ and $L_{0.2} \subset D_0$ and the union $-A_0 \cup \{(-p_0, 0)\} \cup B_0$, $F_0$ is represented as a product of a Morse function on a closed interval with exactly one singular point in the interior and the identity map on the union $-A_0 \cup \{(-p_0, 0)\} \cup B_0$, which is a line: note that the graph of the Morse function on an interval is a parabola as in FIGURE 2.

(5) Over the complement of the union of $U_1 \cup U_2$ of the two domains in the previous two properties in $D_0$, $F_0$ is represented as a trivial smooth bundle whose fiber is a disjoint union of two points.
Figure 4. The image of a smooth map $\tilde{F}$ into the plane and the composition of the map with the projection $p$: the dot on the line in the right is the singular value.

(6) Canonically, we can extend $F_0$ to a smooth map $\tilde{F}_0$ from a surface which is not closed or open. More precisely, this satisfies the following conditions.

(a) The image of $\tilde{F}_0$ is the closure of $D_0$.

(b) The preimages of $(p_0 - 1, g_0(p_0 - 1))$ and $(1 - p_0, g_0(p_0 - 1))$ are single points.

(c) The preimages of points in the complement of the union of the image of $F_0$ and $\{(p_0 - 1, g_0(p_0 - 1)), (1 - p_0, g_0(p_0 - 1))\}$ in the image of $\tilde{F}_0$ consist of two points.

We can define the composition of $\tilde{F}_0$ with the projection $p(x, y) := y$. The singular value set is $\{0\}$. See also FIGURE 4. After scaling, we can obtain a desired local function satisfying the first, second, third and fourth conditions in the statement. By the construction, at each singular point, except finitely many ones, the function is a Morse-Bott function. More precisely, the preimage of points in $A_0$ and $-A_0$ by $\tilde{F}_0$ are single points and singular points at which the functions are Morse-Bott functions.

CASE 1-B Either of the following holds.

1. $a \neq d$, $a \neq 0$ and $d \neq 0$ hold.

2. $a \neq d$, $b > 0$, $c > 0$ hold and either $a = 0$ or $d = 0$ holds.

Suppose $d > a$.

First, we construct a local Morse function as in Theorem 2 where "a", "b" and "c" in the proof of Theorem 2 are $a$, $b$ and $c$ here respectively except the case $(a, b, c) = (1, 0, 0), (0, 1, 1)$, a local smooth function in CASE 1-A for the case $(a, b, c) = (1, 0, 0)$, and a trivial smooth $S^1$-bundle over a closed or open interval for the case $(a, b, c) = (0, 1, 1)$. By fundamental properties on structures of these functions, we can construct a local function so that we can find disjoint $d - a$ copies of small smooth trivial bundles whose fibers are intervals over the image and that the projections of the bundles are regarded as the restrictions of the original function here. To obtain a desired function, we change these $d - a$ functions to new smooth functions. We construct the function.

Let $g$ be a $C^\infty$ function on $\mathbb{R}$ such that $g(x) = 0$ for $x \leq 0$ and $g(x_2) - g(x_1) > 0$ for any $0 \leq x_1 < x_2$ (set $g(x) = e^{-\frac{x}{x}}$ for $x > 0$ for example). Let $p_1$ and $p_2$
be positive numbers. Let \( p_3 < p_4 \) be positive numbers satisfying \( p_3 > p_2 \). We introduce several points and subsets in the plane. Set \( A := \{(t, 0) \mid t < 0\} \), \( B := \{(t, -g(t)) \mid 0 < t < p_1\} \), \( C := \{(t, (t - p_2)^2) \mid 0 \leq (t - p_2)^2 < (p_3 - p_2)^2\} \) and \( O := (0, 0) \).

We can construct a smooth map \( F \) from a surface into the plane satisfying the following properties.

1. \( F \) is a fold map from an open surface into the plane such that the interior of the image is one of the domains bounded by the union of the following sets and that the image of the composition of \( F \) with the projection \( p(x, y) := y \) is \((-g(p_1), (p_3 - p_2)^2) \subset \mathbb{R}\).
   a. \( A \).
   b. \( \{O\} \).
   c. \( B \).
   d. \( \{(t, -g(p_1)) \mid p_1 \leq t \leq p_4\} \).
   e. \( \{(p_4, t) \mid -g(p_1) \leq t \leq (p_3 - p_2)^2\} \).
   f. \( \{(t, (p_3 - p_2)^2) \mid p_3 \leq t \leq p_4\} \).
   g. \( C \).
   h. \( \{(t, (p_3 - p_2)^2) \mid t \leq p_2 - (p_3 - p_2)\} \).

2. Let us denote the domain before by \( D \). The image of \( F \) is the disjoint union of \( A, \{O\}, B \) and \( C \). Moreover, the union \( A \cup \{O\} \cup B \cup C \) is the singular value set of the fold map \( F \) and the restriction of \( F \) to the singular set is an embedding.

3. Let \( \epsilon > 0 \) be a small number. \( L_1 := D \cap \{(t, -g(t) + \epsilon) \mid t \in \mathbb{R}\} \). Over the union of the domain \( U_3 \) between the union of \( A \cup \{O\} \cup B \subset D \) and \( L_1 \subset D \) and the union of \( A \cup \{O\} \cup B \), \( F \) is represented as a product of a Morse function on an interval with exactly one singular point and the identity map on the union of \( A \cup \{O\} \cup B \), which is a line: note that the graph of the Morse function on an interval is a parabola as in FIGURE 2.

4. Let \( L_2 := D \cap \{(t, (t - p_2)^2 - \epsilon) \mid t \in \mathbb{R}\} \). Over the union of the domain \( U_4 \) between \( C \subset D \) and \( L_2 \subset D \) and \( C \), \( F \) is represented as a product of a Morse function on an interval with exactly one singular point as just before and the identity map on \( C \), which is a line.

5. Over the complement of the union \( U_3 \cup U_4 \) of the two domains before in \( D \), \( F \) is represented as a trivial smooth bundle whose fiber is a disjoint union of two points.

6. Canonically, we can extend \( F \) to a smooth map \( \tilde{F} \) on a surface which is not closed or open. More precisely, this satisfies the following properties.
   a. The image of \( \tilde{F} \) is the closure of \( D \).
   b. The preimages of \((p_1, -g(p_1)), (p_3, (p_3 - p_2)^2) \) and \((p_2 - (p_3 - p_2), (p_3 - p_2)^2) \) are single points.
   c. The preimages of points in the complement of the union of the image of \( F \) and \( \{(p_1, -g(p_1)), (p_3, (p_3 - p_2)^2), (p_2 - (p_3 - p_2), (p_3 - p_2)^2)\} \) in the image of \( \tilde{F} \) consist of two points.

We can define the composition of \( \tilde{F} \) with the projection \( p(x, y) := y \). The singular value set is \( \{0\} \). See also FIGURE 5. After scaling, we can obtain desired new functions instead of \( d - a \) trivial bundles. Thus we can obtain a desired local function satisfying the first, second, third and fourth conditions in the statement.
Figure 5. The image of a smooth map $\tilde{F}$ into the plane and the composition of the map and with the projection $p$: $I$ in the explanation of preimages of regular values denotes a closed interval and the dot on the line in the right is the singular value.

Figure 6. A local deformation of level sets when the value of the function increases.

By the construction, at each singular point, except finitely many ones, the function is a Morse or a Morse-Bott function. More precisely, the preimage of $(p_2, 0)$ by $\tilde{F}$ is a single point and a singular point at which the function is Morse. The preimages of points in $A$ by $\tilde{F}$ are single points and singular points at which the functions are Morse-Bott functions. FIGURE 6 represents a local deformation of level sets when the value of the local function $p \circ \tilde{F}$ increases.

In the case $a > d$, we consider the minus of the function obtained above.

CASE 1-C $a \neq d$, $a = 0$, $b > 0$, and $c = 0$ hold. First, we construct a local Morse function as in Theorem 2 where "$a$" and "$b$" in the proof of Theorem 2 are $a$ and $b$ respectively and "$c$" in the proof is 1. As we did in CASE 1-B, we consider $d - a = d$ trivial bundles and change them into new
functions. One of these functions is changed into a new function. We construct this new function.

Let \( g \) be a \( C^\infty \) function on \( \mathbb{R} \) such that \( g(x) = 0 \) for \( x \leq 0 \) and \( g(x_2) - g(x_1) > 0 \) for any \( 0 \leq x_1 < x_2 \) (set \( g(x) = e^{-x} \) as in CASE 1-B). Let \( p_1 \) and \( p_2 \) be positive numbers and \( p_3 < p_4 \) be positive numbers satisfying \( p_3 > p_2 \) as in CASE 1-B. We introduce several points and subsets in the plane. We set \( A := \{(t,0) \mid t < 0\} \), \( B := \{(t,-\epsilon(t)) \mid 0 < t < p_1\} \) and \( O := (0,0) \) as before.

We can construct a smooth map \( F' \) from a surface into the plane satisfying the following properties.

1. \( F' \) is a fold map from an open surface into the plane such that the interior of the image is one of the domains bounded by the union of the following sets and that the image of the composition of \( F' \) with the projection \( p(x,y) := y \) is \( (-g(p_1), (p_3 - p_2)^2) \subset \mathbb{R} \).
   (a) \( A \).
   (b) \( \{O\} \).
   (c) \( B \).
   (d) \( \{(t,-g(p_1)) \mid p_1 \leq t \leq p_4\} \).
   (e) \( \{(p_4,t) \mid -g(p_1) \leq t \leq (p_3 - p_2)^2\} \).
   (f) \( \{(t, (p_3 - p_2)^2) \mid t \leq p_4\} \).
2. Let us denote the domain before by \( D \). The image of \( F' \) is the disjoint union of \( D, A, \{O\} \) and \( B \). Moreover, the union of \( A \cup \{O\} \cup B \) is the singular value set of the fold map \( F' \) and the restriction of \( F' \) to the singular set is an embedding.
3. Let \( \epsilon' > 0 \) be a small number. \( L_1' := D \cap \{(t,-\epsilon(t) + \epsilon') \mid t \in \mathbb{R}\} \). Over the union of the domain \( U_5 \) between the union of \( A \cup \{O\} \cup B \subset D \) and \( L_1' \subset D \) and the union \( A \cup \{O\} \cup B \), \( F' \) is represented as a product of a Morse function on an interval with exactly one singular point and the identity map on the union of \( A \subset \{O\} \subset B \), which is a line: note that the graph of the Morse function on an interval is a parabola as in FIGURE 2.
4. Over the complement of the domain \( U_5 \) in the previous property in \( D \), \( F' \) is represented as a trivial smooth bundle whose fiber is a disjoint union of two points.
5. Canonically, we can extend \( F' \) to a smooth map \( \tilde{F}' \) on a surface which is not closed or open. More precisely, this satisfies the following properties.
   (a) The image of \( \tilde{F}' \) is the closure of \( D \).
   (b) The preimage of \( (p_1, -g(p_1)) \) is a single point.
   (c) The preimages of points in the complement of the union of the image of \( F' \) and \( \{(p_1, -g(p_1))\} \) in the image of \( \tilde{F}' \) consist of two points.

We can define the composition of \( \tilde{F}' \) with the projection \( p(x,y) := y \). The singular value set is \( \{0\} \). See also FIGURE 7.

After scaling, we can obtain the new function. We remove the original \( d - a \) trivial bundles as in CASE 1-B. We use this new function and \( d - a - 1 \) copies of a function used in CASE 1-B instead of the trivial bundles. We can obtain a desired local function on an orientable surface satisfying the first, second, third and fourth properties in the statement. By the construction, at each singular point, except finitely many ones, the function is a Morse-Bott function. The preimages of points in \( A \) by \( \tilde{F}' \) are single points and singular points at which the functions are
Figure 7. The image of a smooth map $\tilde{F}'$ into the plane and the composition of the map with the projection $p$: the dot on the line in the right is the singular value.

Figure 8. A local deformation of level sets when the value of the function increases.

Morse-Bott functions. FIGURE 8 represents a local deformation of level sets when the value of the local function $p \circ \tilde{F}'$ increases.

CASE 1-D $a \neq d$, $d = 0$, $c > 0$, and $b = 0$ hold. We consider the minus of the function obtained in CASE 1-C.

We have considered all cases and this completes STEP 1.

STEP 2 Construction around a vertex at which the good function $h$ has a local extremum.

If the vertex is of degree larger than 1, then we can argue as we do in the proof of Theorem 2 using the local function.

If the vertex is of degree 1, then the label 1 must be assigned to the edge.

Let $g$ be a $C^\infty$ function on $\mathbb{R}$ such that $g(x) = 0$ for $x \leq 0$ and $g(x_2) - g(x_1) > 0$ for any $0 \leq x_1 < x_2$ as in STEP 1. We introduce several points and subsets in the plane as in STEP 1. Set $A_1 := \{(t, 0) \mid t < 0\}$ and $B_1 := \{(t, g(t)) \mid 0 < t < p\}$ for a positive number $p > 0$. Set $O := (0, 0)$ also in this case.
We can construct a smooth map \( F_1 \) from a surface into the plane satisfying the following properties.

1. \( F_1 \) is a fold map from an open surface into the plane such that the interior of the image is the domain bounded by the union of the following sets and that the image of the composition of this with the projection \( p(x, y) := y \) is \([0, g(p))] \subset \mathbb{R}.
   (a) \( A_1 \).
   (b) \( \{O\} \).
   (c) \( B_1 \).
   (d) \( \{(t, g(p)) \mid t \leq p\} \).

2. Let us denote the domain before by \( D_1 \). The image of \( F_1 \) is the union of \( D_1, A_1, \{O\} \) and \( B_1 \). Moreover, the union \( A_1 \cup \{O\} \cup B_1 \) is the singular value set of the fold map \( F_1 \) and the restriction of \( F_1 \) to the singular set is an embedding. Moreover, as in the case for the maps \( F_0, F, F' \) and \( F' \), over a suitable small collar neighborhood of the singular value set and the preimage, \( F_1 \) is represented as a product map of a Morse function on an interval with exactly one singular point and the identity map on the union \( A_1 \cup \{O\} \cup B_1 \).

3. Canonically, we can extend \( F_1 \) to a smooth map \( \tilde{F}_1 \) on a surface which is not closed or open. More precisely, this satisfies the following properties.
   (a) The image of \( \tilde{F}_1 \) is the closure of \( D_1 \).
   (b) The preimage of \((p, g(p))\) is a single point.
   (c) The preimages of points in the complement of the union of the image of \( F_1 \) and \( \{(p, g(p))\} \) in the image of \( \tilde{F}_1 \) consist of two points.

We can define the composition of \( \tilde{F}_1 \) with the projection \( p(x, y) := y \). The singular value set is \( \{0\} \). See also FIGURE 9. After scaling, we can obtain a desired local function.

As a result, for each vertex at which the good function has a local extremum, we obtain a local function on an orientable surface satisfying the first, second, third and fifth properties in the statement. This completes STEP 2.
STEP 3 Completing the construction.

Last, we construct functions around remaining parts. However, we can do this in a way similar to the proof of Theorem 2. This completes the proof. □

**Theorem 5.** Let \( n \) be a positive integer. As Theorem 3, the \((n + 1)\)-dimensional version of Theorem 4 holds: we take \( S^n \) and \( \mathbb{R}^n \) instead of a circle and a line respectively as connected components of preimages of regular values.

We can prove this similarly to Theorem 4. We only mention remarks and rigorous proofs are left to readers.

**Remarks on the proof.** In the discussions of considering \( F_0, F, F', F_1 \) and their extensions in the proof of Theorem 4, we take a standard \((n - 1)\)-dimensional sphere instead of the two point set as the preimage of each regular value. For a local Morse function, we take a natural height function on an \( n \)-dimensional unit disc instead of a Morse function whose graph is a parabola. □

### 4. A further result

**Theorem 6.** Let \( n > 1 \) be an integer. Let \( G \) be a finite and connected graph having a good function \( h \) such that a non-negative integer \( p \) is assigned to each edge satisfying the following condition: if an edge contains a vertex of degree 1, then 0, 1 or 2 is assigned to the edge.

Then there exists an \((n + 1)\)-dimensional connected and orientable manifold \( M \) and a smooth function \( f : M \to \mathbb{R} \) satisfying the following five properties.

1. The Reeb graph \( W_f \) is isomorphic to \( G \): we denote an isomorphism by \( \phi : W_f \to G \).
2. If we consider the natural quotient map onto the graph and for each point that is not a vertex and that is in an edge an integer \( p \) is assigned to, then the preimage is diffeomorphic to a manifold obtained by removing \( p \) copies of a standard closed disc \( D^n \) disjointly smoothly embedded into \( S^n \) \((p = 0)\) means that the resulting manifold is diffeomorphic to \( S^n \) and \( p = 1 \) means that the resulting manifold is diffeomorphic to \( \mathbb{R} \).
3. For a point \( p \in M \) mapped by the quotient map \( q_f \) to a vertex \( v \), \( f(p) = h(\phi(v)) \).
4. At each singular point at which the function \( f \) does not have a local extremum, except finitely many ones, the function is a Morse function or a Morse-Bott function.
5. At each singular point at which the function \( f \) has a local extremum, except finitely many ones, the function is a Morse function, a Morse-Bott function, or represented as a composition of two Morse functions or a composition of a Morse-Bott function with a Morse function.

**Proof.** STEP 1 Construction around a vertex at which \( h \) does not have a local extremum.

First set the family of edges whose ending points are the vertex by \( \{ e_\lambda \} \) and assume that a positive integer \( a_\lambda \) is assigned to \( e_\lambda \). We also assume that the number of edges whose starting points are the vertex is \( k > 0 \).
We can construct a local Morse function as in Theorem 2 so that for each edge whose ending point is the vertex, the second property of the five properties holds. For the vertex, we may assume that the third property of the five properties holds. We can also obtain the function so that locally the Reeb graph is isomorphic to $G$ as is explained in the proof of Theorem 2, there exists a homeomorphism from the Reeb space onto a small regular neighborhood of the vertex in the given graph mapping a vertex (the point representing the level set containing some singular points) to a vertex of the given graph.

We explain precise construction. We consider handle attachments as the following. We can attach these handles simultaneously. This produces a desired local function.

1. We attach 1-handles to the product of the disjoint union $F$ of manifolds obtained by removing $\lambda$ copies of a standard closed disc $D^n$ disjointly smoothly embedded into $S^n$ and $\{0\} \subset [0, 1]$.

2. We attach $k - 1$ $n$-handles to obtain an $(n + 1)$-dimensional connected and orientable manifold such that the boundary consists of two $n$-dimensional manifolds: one is diffeomorphic to $F \times \{\{0\}\} \subset F \times [0, 1]$ and the other is an $n$-dimensional manifold consisting of $k$ connected components diffeomorphic to manifolds obtained by removing finite copies of a standard closed disc $D^n$ disjointly smoothly embedded into $S^n$. For $k = 1$, we may need to attach extra $n$-handles and 1-handles to obtain a desired $(n + 1)$-dimensional manifold and a function having at least one singular point as a desired function.

This argument is completed by locally using functions (on $(n + 1)$-dimensional manifolds) in CASE 1-C in the proof of Theorem 4 (5) instead of trivial $D^n$-bundles over the closed interval suitably. This function changes manifolds diffeomorphic to $D^n (S^{n-1} \times [0, 1])$ in preimages into ones diffeomorphic to $S^{n-1} \times [0, 1]$ when the value of the function increases (decreases). This change increases (decreases) the numbers of copies of an $n$-dimensional standard closed disc disjointly smoothly embedded into $S^n$ to remove to obtain manifolds of the connected components of preimages of regular values by one.

Thus we obtain a desired local function. At each singular point of the obtained function, except finitely many ones, this is a Morse or a Morse-Bott function.

STEP 2 Construction around a vertex at which $h$ has a local extremum.

If the vertex is of degree larger than 1, then we can apply an argument similar to that of the proof of Theorem 2 using the local function.

Consider a case where the vertex is of degree 1. The case where 2 is assigned to the edge containing the vertex is the only new case to consider. We consider a natural height function on the $n$-dimensional unit disc and the product of this and the identity map on a line so that the image is $\mathbb{R} \times [0, 1]$ and that the singular value set is $\mathbb{R} \times \{0\} (\mathbb{R} \times \{1\})$. Then we compose the projection $p(x, y) := y$ and scale the resulting function. We obtain a desired local function.

This completes the proof.
