(Dated: August 20, 2019)

We discuss the origin of an enigmatic low-temperature behavior of one-dimensional decorated spin systems which was coined the pseudo-transition. Tracing out the decorated parts results in the standard Ising-chain model with temperature-dependent parameters and the unexpected low-temperature behavior of thermodynamic quantities and correlations of the decorated spin chains can be tracked down to the critical point of the standard Ising-chain model at $H = 0$ and $T = 0$. We illustrate this perspective using as examples the spin-1/2 Ising-XYZ diamond chain, the coupled spin-electron double-tetrahedral chain, and the spin-1/2 Ising-Heisenberg double-tetrahedral chain.

Keywords: decorated spin chains, Ising chain, thermodynamics, correlations

I. INTRODUCTION

For a number of decorated one-dimensional spin models with short-range interactions, the low-temperature thermodynamic quantities exhibit an intriguing behavior which resembles the discontinuous or continuous temperature-driven phase transitions [1, 2]; it was coined the pseudo-transition [3, 4]. Of course, these pseudo-transitions are not the true temperature-driven phase transitions [1–4]; it was coined the pseudo-transition [5, 6]. Of course, these pseudo-transitions are not the true temperature-driven phase transitions showing only abrupt changes or sharp maxima in thermodynamic quantities at $T = T_p > 0$ as have been demonstrated in detail in several papers [5, 7–12]. However, a sudden increase of the entropy and the internal energy at $T = T_p$ and an impressively fine peak of the second derivative of the free energy (the magnetic susceptibility and the specific heat, see, e.g., the inset in Fig. 2 below [13]) at $T = T_p$ are rather striking features which call for explanations [3]. Further on, it was found that the correlation functions at $T = T_p$ have very large correlation length, i.e., decrease very slowly with the distance increase [3], and that the zero-temperature phase boundary residual entropy may serve as an indicator of the pseudo-transition [3]. Moreover, in the vicinity of (but not too close to) $T_p$, both ascending as well as descending part of the peaks fits precisely a power-law behavior. Calculations for four specific models (Ising-XYZ diamond chain, coupled spin-electron double-tetrahedral chain, Ising-XXZ two-leg ladder, and Ising-XXZ three-leg tube) yield a universal set of pseudo-critical exponents with the values $\alpha = \alpha' = 3$ for the specific heat, $\gamma = \gamma' = 3$ for the susceptibility, and $\nu = \nu' = 1$ for the correlation length [10]. It is worth noting here that decorated Ising-chain models may be realized in certain real magnetic compounds containing lanthanide ions [13].

What remains outside of those studies, in our opinion, is the reasons for the emergence of pseudo-transitions. With the present study we wish to fill in this gap illustrating what is behind the enigmatic low-temperature dependences of the one-dimensional systems exhibiting pseudo-transition. An important step in our consideration is a mapping of the decorated spin chains onto an Ising-chain model (Section II and three Appendices A, B, and C). Although this mapping was mentioned in all previous studies, however, to our mind, it was not enough appreciated. The distinctive feature of the resulting effective Ising-chain model is the temperature-dependent parameters. Pseudo-transitions are observed when the effective exchange is ferromagnetic and the effective field changes its sign at certain temperature, Eq. 2.2 (Section I). If this temperature is low enough, we face remnants of the critical point of the standard Ising-chain model. Moreover, the temperature-dependent parameters lead to interesting relations between the internal energy, the entropy, and the specific heat on one side and the magnetization and the susceptibility on the other side, Eqs. (3.5), (3.6), (3.7) (Section III). These relations provide the background for understanding universality found in Ref. 10 (Section IV). The elaborated perspective unveils the “mystery” of pseudo-transitions and yields a useful tool for revealing new decorated-spin-model candidates with peculiar low-temperature behavior to be explored theoretically and, hopefully, experimentally (Section V).

II. EFFECTIVE ISING-CHAIN MODEL

Decorated spin models in the regime when they exhibit temperature-driven pseudo-transitions (for example, the spin-1/2 Ising-XYZ diamond chain, see Appendix A, the coupled spin-electron double-tetrahedral chain, see Appendix B, or the spin-1/2 Ising-Heisenberg double-tetrahedral chain, see Appendix C) can be rigorously reduced to the effective Ising-chain model with the...
Hamiltonian
\[ H_{\text{eff}} = C - J_{\text{eff}} \sum_{n} \sigma_{n} \sigma_{n+1} - H_{\text{eff}} \sum_{n} \sigma_{n}, \quad (2.1) \]

where \( n = 1, \ldots, N \), \( C = C(T) \), \( J_{\text{eff}} = J_{\text{eff}}(T) > 0 \) is ferromagnetic, whereas \( H_{\text{eff}} = H_{\text{eff}}(T) \) does change its sign while the temperature \( T \) grows. Then the pseudo-critical temperature \( T_{p} \) is defined by \[ H_{\text{eff}}(T_{p}) = 0. \quad (2.2) \]

Equation (2.2) provides the necessary condition for occurrence of the pseudo-transition. Moreover, \( J_{\text{eff}}(T) \) varies slowly and does not change its sign. Temperature dependences of the constant term, the ferromagnetic exchange, and the magnetic field reflect a certain internal structure of the initial model (i.e., the decorated spin chain), which is hidden now in the specific functions \( C(T) \), \( J_{\text{eff}}(T) \), and \( H_{\text{eff}}(T) \).

Using the vocabulary
\[ \frac{J_{\text{eff}}(T)}{T} = \frac{J}{T}, \quad \frac{H_{\text{eff}}(T)}{J} = \frac{H}{J}, \quad (2.3) \]
we may introduce the standard ferromagnetic Ising-chain model,
\[ H(N, J, H) = -J \sum_{n} \sigma_{n} \sigma_{n+1} - H \sum_{n} \sigma_{n}, \quad J > 0, \quad (2.4) \]
\( n = 1, \ldots, N \), periodic boundary conditions are implied, \( \sigma_{n} = \pm 1 \), which is explained in most textbooks on statistical mechanics [13]. The model is exactly solvable by the transfer-matrix method. Knowing the eigenvalues of the transfer matrix
\[ \lambda_{\pm} = \exp \left\{ \frac{J}{T} \left[ \cosh \frac{H}{T} \pm \sqrt{\sinh^{2} \frac{H}{T} + \exp \left( -\frac{4J}{T} \right) } \right] \right\}, \quad (2.5) \]
one immediately gets all required quantities, e.g., the Helmholtz free energy \( F(T, H, N)/N \rightarrow -T \ln \lambda_{+} \) or the pair spin correlations at the distance \( m \) which behaves as \( \propto (\lambda_{-}/\lambda_{+})^{m} \). Around the critical point, \( H = T = 0 \), the behavior of thermodynamic quantities is characterized by the set of critical exponents: \( \alpha = 1, \beta = 0, \gamma = 1, \nu = 1 \), and \( \eta = 1 \) [15].

Usually, only the region \( H \geq 0 \) is discussed, since the results for \( H \leq 0 \) follow directly by symmetry arguments. However, for the case at hand it would be convenient to consider further both signs of \( H \) explicitly.

Using the relations given in Eq. (2.3), we can construct the trajectories in the \( H/J - T/J \) plane, along which the initial system [or, equivalently, the effective system (2.1) with \( T \)-dependent parameters] moves as \( T \) grows from low to high values passing \( T_{p} \). Some of such trajectories for the spin-1/2 Ising-XYZ diamond chain (see Appendix A), for the coupled spin-electron double-tetrahedral chain (see Appendix B), and for the spin-1/2 Ising-Heisenberg double-tetrahedral chain (see Appendix C) are shown in Fig. [1] in Fig. [2] and in Fig. [3] respectively. In what follows, we use the \( H/J - T/J \) plane to demonstrate certain \( T \)-dependences for the effective model (and thus for the initial model) moving along such trajectories (see, e.g., Figs. [4] [5] below which regard to the case of the spin-1/2 Ising-XYZ diamond chain).

It is worth making few remarks here. First of all, the reported trajectories in the \( H/J - T/J \) plane permit one to compare different decorated models. For instance, comparing Figs. [1] and [2] one notes several important differences. Equation (2.2) for the double-tetrahedral chain case has two solutions (green filled diamonds and empty squares in Fig. [2]), although the higher-temperature one (green empty squares) does not manifest itself in the observed properties of the decorated spin chain, see Eq. (3.10) below. The temperature scale for two models is obviously different which results in “stronger” peculiarities for the spin-1/2 Ising-XYZ diamond chain since they occur at lower temperatures \( T/J \). Moreover, while for the first model \( T/J \) which corresponds to \( T_{p} \) can be made infinitesimally small (Fig. [1]), for the second model \( T/J \) cannot be lower than \( T/J = 0.211 \ldots \) (Fig. [2]). As it will be seen later, a slope of the trajectory at the point where it crosses the straight vertical line \( H = 0 \) may be also important. While for the spin-1/2 Ising-XYZ diamond case the slope obviously decreases as \( h \) tends to \( h = 12.75 \), for the double-tetrahedral chain case the slope is less sensitive to the value of \( H < 1.884 \).
They straightforwardly yield the Helmholtz free energy by the eigenvalues of the transfer matrix (and thus of the initial decorated model) are determined.

\[ H < T/J \]

Pseudo-critical temperatures respond to the following values of \( H \): 1, 1.2, 1.3, 1.4, 1.5, 1.6, 1.7, 1.8, 1.9 (bottom). Sky blue circles correspond to \( T/J = 0.01, 0.03, 0.06, \ldots, 0.285 \) (for \( H = 1 \) in the top panel and for \( H = 1.5 \) in the bottom panel). Green diamonds and squares correspond to pseudo-critical temperatures \( T_p \), see Eq. (2.2), for different \( H < 1.884 \).

**III. EFFECTIVE ISING-CHAIN MODEL AROUND \( T_p \)**

The properties of the effective Ising-chain model (2.1) (and thus of the initial decorated model) are determined by the eigenvalues of the transfer matrix \( \lambda \). (2.2), (2.3). They straightforwardly yield the Helmholtz free energy per site

\[ f = \frac{C}{N} - T \ln \lambda_+ \quad (3.1) \]

Taking the derivatives with respect to the field, we immediately obtain the Ising-spin magnetization and susceptibility

\[ m = - \frac{\partial f}{\partial H_{\text{eff}}} = - \frac{\sinh \frac{H_{\text{eff}}}{T}}{\sqrt{\sinh^2 \frac{H_{\text{eff}}}{T} + \exp \left( - \frac{4 J_{\text{eff}}}{T} \right)}} \quad (3.3) \]

\[ \chi = \frac{\partial m}{\partial H_{\text{eff}}} = \frac{1}{T} \frac{\cosh \frac{H_{\text{eff}}}{T} \exp \left( - \frac{4 J_{\text{eff}}}{T} \right)}{\left[ \sinh^2 \frac{H_{\text{eff}}}{T} + \exp \left( - \frac{4 J_{\text{eff}}}{T} \right) \right]^{\frac{3}{2}}} \quad (3.4) \]

see Ref. [15].

The only important peculiarity of the effective Ising-chain model (2.1) is related to the temperature dependences of the effective parameters. Therefore one has to take the derivatives with respect to the temperature with caution. Thus, the internal energy, the entropy, and the specific heat are given by the following formulas:

\[ e = -T^2 \frac{\partial f}{\partial T} - T \frac{\partial f}{\partial J_{\text{eff}}} \frac{\partial J_{\text{eff}}}{\partial T} - T \frac{\partial f}{\partial H_{\text{eff}}} \frac{\partial H_{\text{eff}}}{\partial T} \]

\[ = -T^2 \frac{\partial f}{\partial T} - T \frac{\partial f}{\partial J_{\text{eff}}} J'_{\text{eff}} + T m H'_{\text{eff}} \]

\[ = \sum_{j=1}^{3} e^{(j)}(T) \quad (3.5) \]
for this assumption, Eq. (3.9) gives the following estimate

\[ s = -\frac{\partial f}{\partial T} = \frac{\partial f}{\partial J_{\text{eff}}} J'_{\text{eff}} + m H'_{\text{eff}} = \sum_{j=1}^{3} s^{(j)}(T), \quad (3.6) \]

Interestingly, according to Eqs. (3.5), (3.6), and (3.7), the internal energy and the entropy are related to the magnetization [the terms \( e^{(3)}(T) \) and \( s^{(3)}(T) \)], whereas the specific heat is related to the susceptibility [the term \( c^{(8)}(T) \)]; obviously, this happens owing to the temperature-dependent Hamiltonian parameters.

Now we can discuss the temperature dependences of various quantities for the decorated spin chains which can be presented as the effective model \( \xi \). Consider first the correlation length \( \xi \),

\[ \frac{1}{\xi} = \ln \frac{\cosh \frac{H_{\text{eff}}}{T} + \sqrt{\sinh^{2} \frac{H_{\text{eff}}}{T} + \exp \left( -\frac{4J_{\text{eff}}}{T} \right)}}{\cosh \frac{H_{\text{eff}}}{T} - \sqrt{\sinh^{2} \frac{H_{\text{eff}}}{T} + \exp \left( -\frac{4J_{\text{eff}}}{T} \right)}} \quad (3.8) \]

At the pseudo-critical temperature \( T_{p} \), Eq. (3.8) becomes

\[ \frac{1}{\xi(T_{p})} = \ln \frac{1 + \exp \left( -\frac{2J_{\text{eff}}(T_{p})}{T_{p}} \right)}{1 - \exp \left( -\frac{2J_{\text{eff}}(T_{p})}{T_{p}} \right)} \quad (3.9) \]

Evidently, \( \xi(T_{p}) \) tends to infinity only for \( 2J_{\text{eff}}(T_{p})/T_{p} \to \infty \). We may suggest as a sufficient condition for the pseudo-transition the following one:

\[ \frac{2J_{\text{eff}}(T_{p})}{T_{p}} \gg 1, \quad (3.10) \]

where \( T_{p} \) is defined in Eq. (2.2). Obviously, Eq. (3.10) says that \( T/J \ll 2 \) at \( T = T_{p} \), i.e., that the temperature \( T \) which corresponds to \( T_{p} \) is sufficiently low. Under this assumption, Eq. (3.9) gives the following estimate for \( \xi(T_{p}) \)

\[ \xi(T_{p}) \approx \frac{1}{2} \exp \left( \frac{2J_{\text{eff}}(T_{p})}{T_{p}} \right) < \infty. \quad (3.11) \]

However, in the vicinity of \( T_{p} \), when

\[ \sinh^{2} \frac{H_{\text{eff}}}{T} \gg \exp \left( -\frac{4J_{\text{eff}}}{T} \right), \quad (3.12) \]

we may suggest as a sufficient condition for the pseudo-transition the following one:

\[ \frac{2J_{\text{eff}}(T_{p})}{T_{p}} \gg 1, \quad (3.10) \]

where \( T_{p} \) is defined in Eq. (2.2). Obviously, Eq. (3.10) says that \( T/J \ll 2 \) at \( T = T_{p} \), i.e., that the temperature \( T \) which corresponds to \( T_{p} \) is sufficiently low. Under this assumption, Eq. (3.9) gives the following estimate for \( \xi(T_{p}) \)

\[ \xi(T_{p}) \approx \frac{1}{2} \exp \left( \frac{2J_{\text{eff}}(T_{p})}{T_{p}} \right) < \infty. \quad (3.11) \]

However, in the vicinity of \( T_{p} \), when

\[ \sinh^{2} \frac{H_{\text{eff}}}{T} \gg \exp \left( -\frac{4J_{\text{eff}}}{T} \right), \quad (3.12) \]

we may suggest as a sufficient condition for the pseudo-transition the following one:

\[ \frac{2J_{\text{eff}}(T_{p})}{T_{p}} \gg 1, \quad (3.10) \]

where \( T_{p} \) is defined in Eq. (2.2). Obviously, Eq. (3.10) says that \( T/J \ll 2 \) at \( T = T_{p} \), i.e., that the temperature \( T \) which corresponds to \( T_{p} \) is sufficiently low. Under this assumption, Eq. (3.9) gives the following estimate for \( \xi(T_{p}) \)

\[ \xi(T_{p}) \approx \frac{1}{2} \exp \left( \frac{2J_{\text{eff}}(T_{p})}{T_{p}} \right) < \infty. \quad (3.11) \]

However, in the vicinity of \( T_{p} \), when

\[ \sinh^{2} \frac{H_{\text{eff}}}{T} \gg \exp \left( -\frac{4J_{\text{eff}}}{T} \right), \quad (3.12) \]
consequences for the temperature dependence of the in-
low temperatures. On the other hand, it has important
ply because of the change of the sign of the field at rather
in the temperature dependence of magnetization is sim-
see the lower panel in Fig. 5). The well-pronounced jump
h small; e.g., the initial model with
T jump at
h
T
H
dence of the magnetization from almost −1 to almost 1
since the values of T which correspond
T
are rather
which corresponds to
T
at
T
ξ
(2.4) at few values of
T
= 12.745, 12.745, 12.749. With temperature grow,
H
changes its sign at
T
resulting in a well-pronounced jump of the magnetization from almost −1 to almost 1
(see Fig. 13) by blue curves (ξ, ordinate) upon violet
curves (T, abscissa) in the H/J − T/J plane. ξ increases
as T approaches
T
p and reaches its maximal value
3.14
at
T
= T
p. Moreover, in the lower panel we also show the dependence
ξ(H) for the standard Ising-chain model
2.4
at few values of T/J = 0.107.9, 0.108.9, . . . , 0.127.9
(brown curves) to reveal the relation between the models
2.4
(thick blue curve) and
2.4
(brown curves). For example, for
h = 12.7, T
p ≈ 0.372.6 which correspond to
H = 0 and T/J ≈ 0.117.9. As it is clear from Fig. 4 the
Ising-chain model singularity at
H = 0 and
T = 0 indicated by the green curves
ξ(T/J) at
H = 0 is related to an abrupt increase of
ξ(T) for the effective model
2.1
at
T
p. However, one should not expect for the effective
model
2.1
the critical behavior inherent in the standard
Ising-chain model, see Sec. IV.

The magnetization of the initial model is given by
magnetization of the effective model
2.1
[the Ising-spin magnetization of the model
A.1
is twice times smaller than the magnetization of the effective model
2.4]. In Fig. 5 we show the temperature dependence of the magnetization of the initial model
m(T) at
h = 12.7, 12.74, 12.745, 12.749. With temperature grow,
H
changes its sign at
T
resulting in a well-pronounced jump of the magnetization from almost −1 to almost 1
since the values of T which correspond
T
are rather
; e.g., the initial model with
h = 12.7 exhibits the jump at
T
p ≈ 0.372.6 which corresponds to T/J ≈ 0.117.9, see the lower panel in Fig. 5. The well-pronounced jump in the temperature dependence of magnetization is simply because of the change of the sign of the field at rather low temperatures. On the other hand, it has important consequences for the temperature dependence of the internal energy and the entropy, see the third terms
3(T)
and
s
3(T)
in Eqs. (3.5) and (3.6).

We pass to the susceptibility (3.4) [the Ising-spin susceptibility of the model
A.1
is four times smaller than the susceptibility of the effective model
2.1]. At
T = T
p, we have

\[ \chi(T_p) = \frac{1}{T_p} \exp \left( \frac{2J_{\text{eff}}(T_p)}{T_p} \right) \approx \frac{2\xi(T_p)}{T_p} \] (3.15)

In the vicinity of
T
p when Eq. (3.12) holds, we have

\[ \chi|_{T \approx T_p} \approx \frac{1}{T} \begin{vmatrix} H_{\text{eff}} \end{vmatrix}^3 \exp \left( -\frac{4J_{\text{eff}}}{T} \right) \right| \approx \frac{1}{T} \begin{vmatrix} H_{\text{eff}} \end{vmatrix}^3 \exp \left( -\frac{4J_{\text{eff}}}{T} \right) \propto \frac{1}{T^{H_{\text{eff}}}}. \] (3.16)

Again, this quantity is large as
T approaches
T
p, however, at
T
we have the finite value given in Eq. (3.15).

Interestingly, the approximate results in Eqs. (3.13) and (3.14) are valid in a wider range of temperatures
T
(not only in the vicinity of
T
p) if one uses here
H
and
J
left given by Eqs. (A.2) and (A.3).

The temperature dependencies of the susceptibility of the initial model at various
h = 12.7, . . . , 12.76 are shown in Fig. 6. As temperature
T
grows approaching
T
p, \( \chi(T) \) abruptly increases at
T
p achieving the value of \( \chi \) for the standard Ising-chain model at
H = 0 and rather low temperature
T/J = T_p/J_{\text{eff}}(T_p) (green curves in Fig. 6). However, this abrupt increase, although related to the criticality at
H = 0 and
T = 0, is by no means identical to it. This is nicely seen, e.g., in the lower panel of Fig. 6. If one compares the blue curve \( \chi(T) \) with the green curve \( \chi(T) \) at
H = 0. We emphasize in passing that the large values of \( \chi(T_p) \) may manifest themselves in the temperature dependence of the specific heat, see the eighth term
8(T)
in Eq. (3.4).

The temperature dependence of the internal energy and the entropy can be easily understood on the basis of Eqs. (3.5) and (3.6) complemented by Fig. 5. The jump
FIG. 6: Susceptibility \( \chi \) in the \( H/J - T/J \) plane; the spin-1/2 Ising-XYZ diamond chain (with \( \gamma = 0.7 \)) is described in Appendix A, see Fig. 13. Ten violet curves in the upper panel correspond to the following values of \( h \): 12.7, 12.71, 12.72, 12.73, 12.74, 12.745, 12.749, 12.755, 12.76. The violet curve corresponding to \( h = 12.745 \) in the upper panel has also violet circles, which correspond to the monotonical increase of \( T \): 0, 0.01, 0.02, \ldots, 0.29, cf. Fig. 14. Blue curves present dependences \( \chi(T) \) at fixed \( h \) given above. The thick blue curve in the upper panel presents \( \chi(T) \) at \( h = 12.7 \). Green curve in the both panels is the dependence \( \chi(T/J) \) at \( H = 0 \) for the standard Ising-chain model. In the lower panel we show the dependence \( \chi(T) \) at \( h = 12.7 \) in detail using another scale. Moreover, by brown curves we show the dependence \( \chi(H) \) for the standard Ising-chain model at several \( T \): 0.1079, 0.1089, \ldots, 0.1279. Intersections of the blue curve with the set of brown curves are denoted by cyan circles.

in the temperature dependence of \( m \) at \( T = T_p \) immediately generates the jump in the temperature dependence of \( e \) and \( s \). In Figs. 7 and 8 we show all three contributions \( e^{(1)}(T), e^{(2)}(T), e^{(3)}(T) \) and \( s^{(1)}(T), s^{(2)}(T), s^{(3)}(T) \), this way illustrating that the jump of the internal energy and the entropy at \( T = T_p \) is conditioned by the terms with \( m \) (thin red dotted curves).

Finally, we turn to the specific heat. According to Eqs. \( 3.7 \) and \( 3.15 \), the dominant contribution to the specific heat around \( T_p \) is expected to come from the susceptibility, \( c(T) \approx c^{(8)}(T) = T \chi(H_{\text{eff}}')^2 \), and hence the specific heat manifests the behavior of the susceptibility. More precisely, the temperature dependence of \( c \) and \( \chi \) around \( T_p \) may be very similar, since for \( H_{\text{eff}} \propto T - T_p \) the factor \( T(H_{\text{eff}}')^2 \) around \( T_p \) is only some finite constant, see Fig. 9. However, it may happen that \( T(H_{\text{eff}}')^2 \)

is extremely small resulting in no peculiarity of the specific heat at \( T_p \), although such peculiarity does exist for the susceptibility, see Fig. 10. Obviously, to find the precise value of \( c \) around \( T_p \) we have to take into account all terms in Eq. \( 3.7 \).

In Fig. 11 we show \( c(T) \) for \( \gamma = 0.7 \) and \( h = 12.7 \). Of course, the result for the decorated spin chain coincides with the result for the effective Ising-chain model \( 2.1 \) with the specific values of \( C(T), J_{\text{eff}}(T), \) and \( H_{\text{eff}}(T) \).
two terms are about at 10 that achieves the values about T vicinity of region shown in Fig. 9. The first term three terms (of eight) are relevant in the temperature term in Eq. (3.7), c T values about 10 c γ diamond chain (with (1) (3), thin black and red dashed curves correspond to c(T), thin black and red dashed curves correspond to c(1)(T) and c(8)(T), respectively, see Eq. (A.2). Moreover, red dashed curve with up-triangles and red dashed curve with down-triangles correspond to (H′ eff) 2 and Tχ, respectively, see the formula for c(8)(T) in Eq. (6.7).

It is worth noting that the height and width of the specific-heat peak at Tp should not violate the thermodynamic relation ∫0∞ dTc/T = ln 2, i.e., a higher the peak is, a narrower it should be.

As it was mentioned above, the relation between the specific heat and the susceptibility may be covered because of a small value of the factor T(H′ eff) 2 at Tp. To illustrate such a case, we consider the set of parameters which implies a small slope of the trajectory at the point where it crosses the vertical line H = 0 in Fig. 4 The results are reported in Fig. 10. The contribution of c(8)(T) (thin red dashed curve) to c(T) (thick blue curve) does not yield any enhancement at T = Tp. The reason for that becomes clear after inspecting the values of two factors of which c(8)(T) is consisted of, that is, Tχ (red dashed with down-triangles curve) and (H′ eff) 2 (red dashed with up-triangles curve). While the first factor is about 10 8 at T = Tp ≈ 0.312 (that corresponds to T/J ≈ 0.0999), the second one is about 10 −15 at T = Tp resulting in no enhancement of the specific heat at T = Tp.

To summarize this section, we have demonstrated that the low-temperature peculiarities of the effective Ising-chain model (and thus of the decorated spin chains) are related to the critical point of the Ising-chain model H = 0 and T = 0. This is obvious from consideration of the correlation length ξ(T) in the H/J − T/J plane, Fig. 1. Both, the magnetization and the susceptibility straightforwardly reflect the low-temperature behavior of the ferromagnetic Ising-chain model, Figs. 6 and 7. The magnetization m(T) has almost not-smeread jump between

given in Eqs. (A.2) and (A.3). We can estimate different contributions c(j)(T), j = 1, . . . , 8 in Eq. (3.7). Only three terms (of eight) are relevant in the temperature region shown in Fig. 9. The first term c(1)(T) (about 10−1) is conditioned by C(T), since the contribution of the second term in Eq. (3.7) is less than 10−4. The second term in Eq. (3.7), c(2)(T), is less than 10−5. The term c(3)(T) = 2T(∂m/∂T)H′ eff although is everywhere small (about 10−5) has the finite jump between almost ±1 at Tp. The fourth term is a smooth function of T having values about 10−1, whereas the fifth one (about 10−1) contains m and therefore has a finite jump at Tp. Next two terms are about 10−7 and 10−6. The most important at T = Tp is the last (eighth) term in Eq. (3.7) which achieves the values about 105. However, outside a small vicinity of Tp, c(8)(T) is extremely small, see Fig. 9.

![FIG. 9: Specific heat c versus T; the spin-1/2 Ising-XYZ diamond chain (with γ = 0.82, h = 12.7) is described in Appendix A, see Fig. 13. Thick blue curve corresponds to c(T), thin black, brown with triangles, green with squares, magenta with circles, and red dashed curves correspond to c(1)(T), c(3)(T), c(4)(T), c(5)(T), and c(8)(T), respectively, see Eq. (3.7).](image1)

![FIG. 10: Specific heat c versus T; the spin-1/2 Ising-XYZ diamond chain (with γ = 0.82, h = 7.916 228) is described in Appendix A, see Fig. 13. Thick blue curve corresponds to c(T), thin black and red dashed curves correspond to c(1)(T) and c(8)(T), respectively, see Eq. (A.2). Moreover, red dashed curve with up-triangles and red dashed curve with down-triangles correspond to (H′ eff) 2 and Tχ, respectively, see the formula for c(8)(T) in Eq. (6.7).](image2)
the two saturation values of opposite signs at $T = T_p$ and the susceptibility $\chi(T)$ exhibits an abrupt increase at $T = T_p$ which reaches the value (3.14) (which corresponds to the zero-field low-temperature value of $\chi$ for the ferromagnetic Ising-chain model). The internal energy and the entropy for the effective Ising-chain model with temperature-dependent parameters (2.1) depend on the magnetization, see Eqs. (3.5) and (3.6), and therefore the magnetization jump at $T_p$ shows up in the temperature profiles of $e$ and $s$, too. Moreover, in contrast to the standard ferromagnetic Ising-chain model, the specific heat for the effective Ising-chain model (2.1) exhibits a sharp maximum at $T_p$; according to Eq. (3.7), this can be traced to the abrupt increase of the susceptibility at $T = T_p$ if it is not quenched by the factor $T(H_{\text{eff}}')^2$ at $T = T_p$.

It should be also noted that the temperatures at which the effective field $H_{\text{eff}}$ vanishes ($T_p$), the correlation length has a peak ($T_{\text{max,corr.1}}$), the susceptibility has a peak ($T_{\text{max,susc.}}$), or the specific heat has a peak ($T_{\text{max,sp.heat}}$) are, generally speaking, not identical. However, for the case $\gamma = 0.7, h = 12.7$ we have $T_p = 0.37262118880$ and these 11 digits for all characteristic temperatures coincide. (For the case $\gamma = 0.7, h = 12$ we have $T_p = 0.81504815005$ and only first 4 digits for all characteristic temperatures coincide.)

### IV. UNIVERSALITY

As it immediately follows from explanations of the previous section, the pseudo-critical behavior is universal and depends 1) on the fact that the Hamiltonian parameters are temperature dependent, Eqs. (3.5), (3.6), and (3.7); 2) on the critical behavior of the standard Ising-chain model around its critical point $H = 0$ and $T = 0$; and also 3) on the specific temperature dependence of the Hamiltonian parameters [especially of $H_{\text{eff}}(T)$] around $T = T_p$.

Thus, Eqs. (3.14) and (3.16) say that as $T$ approaches $T_p$, $\xi(T) \propto |H_{\text{eff}}(T)|^{-1}$ and $\chi(T) \propto |H_{\text{eff}}(T)|^{-3}$. Moreover, Eq. (3.7), when $c(8)(T)$ is relevant, suggests that as $T$ approaches $T_p$, $c(T) \propto \chi(T) \propto |H_{\text{eff}}(T)|^{-3}$. Therefore, the relations $\alpha = \alpha' = \gamma = \gamma' = 3\nu = 3\nu'$ are obvious. Further on, since for the decorated spin chains at hand

$$H_{\text{eff}}(T) \xrightarrow[T \to T_p]{} A(T - T_p),$$

we immediately obtain $\alpha = \alpha' = 3, \gamma = \gamma' = 3$, and $\nu = \nu' = 1$.

In the vicinity of $T_p$ it would be sufficient to consider $J_{\text{eff}}(T) = J_{\text{eff}} > 0$ and $H_{\text{eff}}(T) = A(T - T_p)$ only. But these parameters cannot reproduce the whole range of temperatures leading to such shortcomings as negative entropy, specific heat etc. outside the vicinity of $T_p$.

We have also to underline the role of the slope related to the factor $A$ in Eq. (4.1). As we have demonstrated in Sec. II (see discussion around Fig. 10), a small value of

$T(H_{\text{eff}}')^2|_{T=T_p} = T_pA^2$ may quench the peculiarity coming from $\chi(T \to T_p)$.

### V. CONCLUSIONS

Let us summarize the present study. We have not reported many new calculations, rather we have suggested a new perspective for the temperature-driven pseudo-transitions in one-dimensional decorated spin systems with short-range interactions. First of all, we have illustrated usefulness of the mapping onto the standard Ising-chain model. We have stressed that the observed low-temperature peculiarities of the decorated spin chains are related 1) to the critical point of the Ising-chain model $H = 0$ and $T = 0$ and 2) to the specific temperature dependences of the effective parameters of the effective Ising-chain model which represents the initial decorated spin chain. We have further discussed the necessary and sufficient conditions for occurrence of the pseudo-transition: While the necessary condition (2.2) requires $H_{\text{eff}} = 0$ (and hence $H = 0$) at $T = T_p$, the sufficient condition (3.10) says that $T/J < 2$ at $T = T_p$ (i.e., the temperature for the standard Ising-chain model without field should be sufficiently low). In Fig. 11 we illustrate these arguments for the spin-1/2 Ising-XYZ diamond chain with $J = 100$, $J_z = 24$, and $J_\theta = -24$ in the $\gamma - h$ plane: All points in a triangle which is singled out by the forest-green curve and the straight line $h = 0$ satisfy the necessary condition (2.2) for the existence of the pseudo-transition. The values of $T_p$ are given by the
blue lines. However, only sufficiently close to the forest-green line one can satisfy the sufficient condition (3.10), i.e., one can observe a developing of the sufficiently large correlation length (3.9) which causes peculiarities in the low-temperature properties of the decorated spin chains. Nonetheless, even in this case, just the specific heat may show no enhancement at $T_p$ as was illustrated in Fig. 10.

Finally, we have explained the power-law behavior of various quantities in the vicinity of the pseudo-critical temperature.

We think, that the elaborated perspective has several further extensions which deserve to be studied. The most straightforward one is related to the decorated spin chains which can be reduced to the effective higher-spin Ising-chain models. Moreover, we believe that the decorated two-dimensional spin model we may suggest a diamond-like-decorated square lattice [16].

Strečka (Pavol Jozef Šafárik University in Košice, Slovakia) during the 17th Czech and Slovak Conference on Magnetism (June 3-7, 2019) and the Workshop on Quantum Magnetism: Theoretical Challenges and Future Perspectives (June 7-8, 2019).

Appendix A: Spin-1/2 Ising-XYZ diamond chain

We consider the spin-1/2 Ising-XYZ diamond chain with the Hamiltonian (we use notations of Ref. [5]):

$$H = \sum_{i=1}^{N} H_i,$$

$$H_i = -J(1+\gamma)S_{a,i}^x S_{b,i}^x - J(1-\gamma)S_{a,i}^y S_{b,i}^y - J_s S_{a,i}^z S_{b,i}^z - J_0(S_{a,i}^z + S_{b,i}^z)(\sigma_i + \sigma_{i+1}) - h_z(S_{a,i}^z + S_{b,i}^z) - \frac{h}{2}(\sigma_i + \sigma_{i+1}) \quad \text{(A.1)}$$

see Fig. 12. Here $S_{a(b)}^{\alpha} (\alpha = x, y, z)$ are the spin-1/2 operators, $\sigma$ corresponds to the Ising spins 1/2, $\gamma$ is the XY-anisotropy parameter, $J$ and $J_s$ are the Heisenberg-like interactions between interstitial sites, the exchange parameter $J_0$ represents the Ising-like interaction between nodal and interstitial sites, and the external magnetic fields $h_z$ and $h$ are assumed to be along the $z$ direction. Later on, it is assumed that $h_z = h \geq 0$. Note also that the Ising spin 1/2 in Eq. (A.1) is two times smaller than the Ising spin in Eq. (2.1).

The ground-state phase diagram in the $\gamma-h$ plane for a particular set of coupling parameters $J = 100$, $J_z = 24$, and $J_0 = -24$ is shown in Fig. 13. It contains three phases: One ferrimagnetic phase ($FI$) and two modulated ferromagnetic Heisenberg phases ($MF_0$ and $MF_2$), see Ref. [5] and references therein.

The spin-1/2 Ising-XYZ diamond chain model (A.1) can be mapped onto the standard Ising-chain model with
the Hamiltonian given in Eq. \ref{eq:hamiltonian} and

\begin{align}
C &= -N T \frac{1}{4} \ln \left( w_1 w_2^2 w_{-1} \right), \\
J_{\text{eff}} &= \frac{T}{4} \ln \left( \frac{w_1 w_{-1}}{w_0^2} \right), \\
H_{\text{eff}} &= \frac{T}{2} \ln \left( \frac{w_1}{w_{-1}} \right), \quad \text{(A.2)}
\end{align}

Here

\begin{align}
\Delta \mu &= \sqrt{(h_z + J_0 \mu)^2 + \frac{\gamma^2 J_2^2}{4}},
\end{align}

Importantly, \( J_{\text{eff}} > 0 \) at all temperatures \( T \) for all values of \( \gamma \) and \( h \) in Fig. 13. In contrast, \( H_{\text{eff}} > 0 \) at all temperatures \( T \) for all values of \( \gamma \) and \( h \) in Fig. 13 except those, which belong to the \( MF_0 \) phase. For the values of \( \gamma \) and \( h \) which belong to the \( MF_0 \) phase, \( H_{\text{eff}} < 0 \) at \( T = 0 \) but becomes positive for high temperatures, see, e.g., Fig. 14.

**Appendix B: Coupled spin-electron double-tetrahedral chain**

We consider the double-tetrahedral chain (Fig. 14) of localized Ising spins 1/2 and mobile electrons (two mobile electrons on each triangular plaquette) with the Hamil-

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{fig14.png}
\caption{A part of the spin-electron system on a double-tetrahedral chain. Full circles denote nodal lattice sites occupied by the localized Ising spins 1/2, while the empty circles forming triangular plaquettes are available to mobile electrons (each three equivalent sites of the triangular plaquette are available to two mobile electrons). For further details see Ref. [1].}
\end{figure}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{fig15.png}
\caption{The ground-state phase diagram in the \( t/J - H/J \) plane for the coupled spin-electron double-tetrahedral chain \cite{1} with the antiferromagnetic coupling \( J > 0 \) upon varying a relative strength of the Coulomb term \( U/J = 0, 5, 20, \infty \). For further details see Ref. [1].}
\end{figure}

\textbf{tonian (we use notations of Ref. [1]):}

\[ \mathcal{H} = \sum_{i=1}^{N} H_i, \]

\[ H_i = -t \sum_{\alpha = \uparrow, \downarrow} \left( c^\dagger_{i,\alpha} c_{i+1,\alpha} + c^\dagger_{i+1,\alpha} c_{i,\alpha} + c^\dagger_{i,\alpha} c_{i+1,\alpha} + H.c. \right) + U \sum_{j=1}^{3} n_{i,j,\uparrow} n_{i,j,\downarrow} + J \left( \sigma_i^z + \sigma_{i+1}^z \right) \sum_{j=1}^{3} (n_{i,j,\uparrow} - n_{i,j,\downarrow}) \]

\[ - \frac{H_1}{2} (\sigma_i^z + \sigma_{i+1}^z) - \frac{H_2}{2} \sum_{j=1}^{3} (n_{i,j,\uparrow} - n_{i,j,\downarrow})(B.1) \]

see Fig. 14. Above, \( c^\dagger_{i,\alpha} \) and \( c_{i,\alpha} \) represent usual fermionic creation and annihilation operators for mobile electrons from the \( i \)-th triangular plaquette with spin \( \alpha = \uparrow \) or \( \downarrow \), \( n_{i,j,\alpha} = c^\dagger_{i,j,\alpha} c_{i,j,\alpha} \) is the respective number operator, \( \sigma_i^z = \pm 1/2 \) labels the Ising spin placed at the \( i \)-th nodal lattice site, and \( N \) denotes the total number of nodal lattice sites. The hopping parameter \( t > 0 \) takes into account the kinetic energy of mobile electrons delocalized over triangular plaquettes, \( U \geq 0 \) represents the on-site Coulomb repulsion between two electrons of opposite spins occupying the same lattice site, and \( J \) stands for the Ising coupling between the mobile electrons and their nearest Ising-spin neighbors. Finally, the fields \( H_1 \) and \( H_2 \) enter the Zeeman’s terms accounting for the magnetostatic energy of the localized Ising spins and mobile electrons in the presence of an external magnetic field. Later on, it is assumed that \( H_1 = H_2 = H \geq 0 \). Note also that the Ising spin 1/2 in Eq. (2.1) is two times smaller than the Ising spin in Eq. (2.1).
The authors of Ref. [1] discovered unexpected low-temperature behavior and considered in some detail as an example the set of parameters $U/J = 5$, $t/J = 0.6$, $H/J = 0, \ldots, 2$, and $T/J = 0, \ldots, 10$. (Figs. 6 and 7 of Ref. [1]). For this set of parameters $J_{\text{eff}} > 0$ at all temperatures, whereas $H_{\text{eff}}$ may change its sign twice, see Fig. 2. Only at the smaller temperature $T_p$ which yields $H_{\text{eff}}(T_p) = 0$ and satisfies (3.10) the peculiarities in thermodynamic quantities are clearly seen.

**Appendix C: Spin-1/2 Ising-Heisenberg double-tetrahedral chain**

Previously, in Refs. [17, 19] the pure Heisenberg double-tetrahedral chain was considered. Later, in Refs. [20, 21] the Ising-Heisenberg version of the model was introduced (see Fig. 1). Although the latter model was discussed in Refs. [20, 21], the pseudo-transition property has been explored only recently in Ref. [3]. The corresponding Hamiltonian of this model is

\[ H = -\sum_{i=1}^{N} \left\{ J(S_{a,i}, S_{b,i})_z + J(S_{b,i}, S_{c,i})_z + J(S_{c,i}, S_{a,i})_z + \frac{h}{2} (\sigma_i + \sigma_{i+1}) + (S_{a,i}^z + S_{b,i}^z + S_{c,i}^z) [h_z + J_0 (\sigma_i + \sigma_{i+1})] \right\}, \]

where $J(S_{a,i}, S_{b,i})_z = JS_{a,i}^x S_{b,i}^x + JS_{a,i}^y S_{b,i}^y + JS_{a,i}^z S_{b,i}^z$ with $S_{a,i}^\alpha$ denoting the Heisenberg spin-1/2 and $\alpha = \{x, y, z\}$, while $\sigma_i$ denotes the Ising spin ($\sigma_i = \pm 1/2$). In a similar way the Heisenberg operators are defined for sites $b$ and $c$ in (C.1).

The zero-temperature phase diagram of this model is reported in Fig. 17. We observe there four different states, for details see Ref. [3]. Here we illustrate the phase boundary between the frustrated phase ($FR_2$) and the ferrimagnetic phase ($FI$) by a solid line, where the pseudo-transition shows up in the low-temperature region.

For the present model, the Boltzmann factor was obtained in Ref. [3], it can be expressed as follows:

\[ w_n = 2 \exp \left( \frac{2h_n - J_z}{4T} \right) \times \left\{ \exp \left( \frac{J_z}{2T} \right) \cosh \frac{h_z + J_0 n}{2T} + \exp \left( \frac{J_z}{2T} \cosh \frac{3(h_z + J_0 n)}{2T} \right) \right\}, \]

where $n = \{-1, 0, 1\}$. The effective parameters in Eq. (2.1) are determined through $w_n$ (C.2) as follows:

\[ C = -N \frac{T}{4} \ln \left( w_1 w_0^2 w_{-1} \right), \]
\[ J_{\text{eff}} = \frac{T}{4} \ln \frac{w_1 w_{-1}}{w_0^2}, \]
\[ H_{\text{eff}} = \frac{T}{2} \ln \frac{w_1}{w_{-1}}. \]
