(Dated: August 20, 2019)

We compare accuracy of two prime time evolution algorithms involving Matrix Product States - tDMRG (time-dependent density matrix renormalization group) and TDVP (time-dependent variational principle). The latter is supposed to be superior within a limited and fixed auxiliary space dimension. Surprisingly, we find that the performance of algorithms depends on the model considered. In particular, many-body localized systems as well as the crossover regions between localized and delocalized phases are better described by tDMRG, contrary to the delocalized regime where TDVP indeed outperforms tDMRG in terms of accuracy and reliability. As an example, we study many-body localization transition in a large size Heisenberg chain. We discuss drawbacks of previous estimates [Phys. Rev. B\textbf{98}, 174202 (2018)] of the critical disorder strength for large systems.

\section{I. INTRODUCTION}

In recent years, matrix product states (MPS) \cite{1, 2} have become a major tool in representing quantum states and their dynamics in many-body one-dimensional systems. For static calculations, the MPS-based density matrix renormalization group (DMRG) \cite{3–5} has become the \textit{de facto} standard for obtaining the ground and a few low-lying excited states of many-body Hamiltonians because of the accuracy and reliability of the method. In case of time-evolution, the breakthrough came with the development of time-evolving-block-decimation (TEBD) algorithm \cite{6, 7} and its variant, time-dependent density matrix renormalization group (tDMRG) \cite{3, 8–10}, as a variant of time evolving-block-decimation (TEBD) technique \cite{1, 6, 7, 17}, with similarities and differences between the two approaches being discussed soon \cite{10}. The simple and transparent algebraic properties of MPS used in the algorithms shortly led to different developments, such as treatment of translationally invariant infinite systems \cite{11, 12}, matrix product operators (MPO) technique \cite{13}, time-dependent variational principle (TDVP) scheme with its one-site and two-site versions \cite{14–16} to name a few. Rapid development in the field has been summarized in seminal reviews \cite{1, 17} with leading methods presented and compared in accuracy and speed on representative examples (see also \cite{18–20}). The cases studied correspond to very demanding examples with a rapid entanglement growth (for initial weakly entangled states), which show that the TDVP (with two-site version in the initial phases and one-site version afterwards) is less error-prone and more accurate than other available methods, and should be selected as a method of choice. This seems understandable as the variational approach should, in most cases, lead to optimal solutions.

On the other hand, time-dynamics of large systems have been often addressed with TEBD-based approaches \cite{21–30}, and the MPS-based techniques seem also a natural tool to consider time-dynamics in many-body localization (MBL) problems, especially as experiments \cite{31} deal with systems not amenable to exact diagonalization techniques \cite{32–38}. Recent study using TDVP in XXZ spin chain addresses the MBL transition in detail \cite{39} claiming that the critical disorder corresponding to MBL transition strongly depends on the system size. We also analyse this issue in this work, but first we compare the performance of tDMRG and TDVP in systems close to localized regime. Surprisingly, we have found indications that when non-ergodic features in the dynamics become pronounced (as at the onset of MBL regime) the standard, old-fashioned tDMRG may perform very well. Moreover, results obtained with too small auxiliary space lead to spurious effects for TDVP that may affect the conclusions concerning intermediate and long-time dynamics. We believe this interesting observation calls for a detailed studies presented below. Having an excellent overview of different methods at hand \cite{17}, we only briefly mention our implementations of algorithms in Section II. The core of our results is presented in Section III where we compare the performance of TDVP based and TEBD-based schemes with a numerically exact propagation obtained via Chebyshev expansion of the evolution operator \cite{40}. Larger system sizes, where no exact results are available, are discussed in Section IV, while in Section V we discuss the difficulties with an estimation of the critical disorder value for disordered Heisenberg spin chain from such time-dynamics. We conclude in Section VI.

\section{II. NUMERICAL TOOLS}

In this section, we briefly discuss our implementations of two MPS-based time-evolution strategies used in this work – A: time-dependent density matrix renormalization group (tDMRG) \cite{3, 8–10}, as a variant of time evolving block decimation (TEBD) technique \cite{1, 6, 7, 17} and B: recently developed time-dependent variational principle (TDVP) \cite{14–16}.  

\* piotr.sierant@uj.edu.pl
A. tDMRG

Instead of using more commonly used Suzuki-Trotter decomposition for implementing tDMRG/TEBD methods, we use the second-order Sornberger-Stewart [41] decomposition of the time-evolution operator as first described in [9]. For a nearest-neighbor many-body Hamiltonian $H = \sum_{i=1}^{L-1} H_i$ consisting of $L$ sites, where $H_i$ denotes the term on $i^{th}$ bond, the decomposition of the small-time-evolution operator is given by

$$e^{-iH\delta t} \approx e^{-iH_1 \frac{\delta t}{2}} \cdots e^{-iH_{L-1} \frac{\delta t}{2}} e^{-iH_L \frac{\delta t}{2}} \cdots e^{-iH_1 \frac{\delta t}{2}},$$

which incurs error of the order $O(\delta t^3)$ as similar to the second-order Suzuki-Trotter one. The term in Eq. (1) is then applied to a physical state, represented by MPS ansatz, in left-to-right and right-to-left sweeps exactly as in a two-site DMRG algorithm [9, 10]. After each such a sweep, the dimension of the auxiliary space (MPS bond dimension) grows with time, and if the bond dimension becomes larger than a desired value, say $\chi$, it is truncated by keeping only $\chi$ largest singular values after a renormalization. In our simulations, we set the time-step for tDMRG as $\delta t = 0.02$ in units of the Hamiltonian.

B. TDVP

In TDVP, the time-evolution of a MPS is attained by computing the action of the Hamiltonian only along the tangent direction to the present variational MPS manifold, described by the MPS bond dimension $\chi$. Mathematically, instead of solving the time-dependent Schrödinger equation, we solve

$$\frac{d|\psi(t)\rangle}{dt} = -i \mathcal{P}_{MPS} H |\psi(t)\rangle,$$

where the projector $\mathcal{P}_{MPS}$ projects the action of the Hamiltonian $H$ to the tangent plane of the variational MPS manifold of bond dimension $\chi$. In our work, we follow the prescription described in Refs. [16, 17] (see Ref. [15] for an alternative one) to implement both two-site and one-site versions of TDVP. Since the two-site version allows to grow the MPS bond dimension dynamically during the TDVP sweeps, we employ this version in the initial stage of the dynamics. As soon as the bond dimensions in the bulk of the MPS is saturated to a desired value, say $\chi$, we switch to the one-site version, where dimensions of auxiliary spaces do not change. Such a hybrid method of time-evolution using TDVP has been argued to incur lesser errors [17, 19]. We use the step-size $\delta t = 0.1$ (in units of the Hamiltonian) for TDVP calculations, however, since we use properly converged Lanczos exponentialization [42] in TDVP simulations, smaller step-sizes do not affect the results indicating the convergence with respect to the time step.

III. MPS TIME EVOLUTION VERSUS “EXACT” RESULTS

As a model to study, we take the Heisenberg spin chain with random field, often studied in the context of MBL [43, 44]. Explicitly we consider the Hamiltonian

$$H = J \sum_{i=1}^{L-1} \vec{S}_i \cdot \vec{S}_{i+1} + \sum_{i=1}^{L} h_i S_i^z,$$

where $S_i^z$ are spin-1/2 degrees of freedom at site $i$, $J$ is the spin coupling strength, from now on we set $J = 1$ fixing the energy scale and $h_i$ is the random magnetic field drawn in our examples form a random uniform distribution in $[-W; W]$ with $W$ denoting the disorder strength. The Hamiltonian (3) maps directly to an interacting spinless fermions model making it, in principle, accessible in cold atoms experiment. Level statistics analysis of small systems ($L \leq 22$) indicates a transition between extended and MBL regimes at $W_c = 3.72(6)$ (the value extrapolated to the thermodynamic limit via a finite size analysis of level spacing ratios) [44]. Similar value is obtained from the entanglement entropy scaling [44]. On the other hand, the recent study [39] of larger systems (size $L = 100$) gives the estimate of the transition at a much larger value $W_c \approx 5.5$ on the basis of time dynamics obtained using TDVP. This obviously contradicts the above mentioned result based on finite size scaling of data for systems with $L \leq 22$ and suggests that either the time-dynamics of observables gives different answer than analysis of level statistics and properties of eigenvectors or results obtained by TDVP [39] have to be reconsidered.

We analyse a time-evolution obtained for the Hamiltonian (3) starting from the Néel state with every second spin pointing up and every second spin down $|\psi\rangle = |\uparrow\downarrow\cdots\uparrow\downarrow\rangle$. In the fermionic language such a state corresponds to a perfect density wave with every second site occupied. It is known that the properties of the system (3) may depend on energy, leading to the so called mobility edge for the precise location of the MBL transition [44], such that to probe the system properties initial states should be adjusted to a particular realization of disorder to assure probing of the same energy region. We nevertheless choose a single state mentioned above to facilitate comparison with [39]. It is worth remembering that a similar state was also prepared in the experiments [31] to study MBL dynamics. In all numerical examples shown, we disregard two sites on each edge of the chain to minimize the effect of open boundary conditions. This allows us for a better comparison of systems of different sizes as discussed in Section V.

Let us commence our numerical studies with moderate size system $L = 26$ with open boundary conditions within total $S_z = 0$ sector (corresponding to fermionic half filling). Its exact evolution using standard Hamiltonian diagonalization approach would be a formidable task. On the contrary, Chebyshev polynomial expansion
dimensions, data from below as the bond dimension. Interestingly, TDVP leads to a much faster decay of the “exact” result obtained by the Chebyshev approach. In-studies, we consider 200 disorder realizations and monitor the performance of tDMRG and TDVP. For these times in the context of MBL [45–47] allows us to obtain the time-evolution operator [40] used already a few order value is higher than the constant $C$ assures that $I(0) = 1$ for the initial Néel state.

As in experiment [31], a decay of the imbalance with time indicates a delocalized regime while its saturation at some finite value points towards MBL.

Let us now consider how the exact time-dynamics of imbalance is approximated with TDVP and tDMRG algorithms. Fig. 1 shows the exemplary time evolution of imbalance $I(t)$ for $W = 3.0$ and $L = 26$ for different dimensions $\chi$ of the auxiliary space as compared with the “exact” result obtained by the Chebyshev approach. Interestingly, TDVP leads to a much faster decay of the imbalance than the exact result, approaching the “exact” data from below as the bond dimension $\chi$ is increased. tDMRG does just the opposite - too small $\chi$ values lead to a false saturation of the imbalance. Errors $\Delta I(t)$ with respect to the exact result are comparable being a bit smaller for TDVP.

The superiority of TDVP approach is, however, clearly visible when the entanglement entropy $S(t)$ in the middle of the chain is considered. We trace out half of the chain (13 sites in this case) and plot the entanglement entropy growth as a function of time in Fig. 2. While both TDVP and tDMRG underestimate the entanglement entropy growth, TDVP follows the exact growth for a slightly longer time, while tDMRG yields a spurious decrease of the entanglement entropy at large times.

Let us now come closer to MBL crossover region by increasing the disorder amplitude to $W = 4.0$. This disorder value is higher than $W_c = 3.7$, the critical disorder value for the MBL transition extracted from the finite size analysis in [44]. The direct inspection of the numerical data as well as of the errors with respect to exact results indicates that, surprisingly, tDMRG becomes superior to TDVP showing consistently smaller errors with respect to Chebyshev propagation exact results (see Fig. 3).

The similar conclusion can be reached by analyzing the entanglement entropy (Fig. 4), where tDMRG shows a consistent behavior, namely, as long as $\chi$ is sufficient to represent the dynamics, it gives a correct prediction for the entanglement entropy, and for longer times it always underestimates the exact value. The behavior of TDVP calculation at long times, on the contrary, is markedly different. For longer times, when the bond dimension $\chi$ is insufficient to represent the dynamics, TDVP overshoots the entropy growth. In effect, at a given value of
\( \Delta S(t) \) for two different \( \chi \) values, a comparison of values obtained with TDVP becomes, surprisingly, more accurate with increasing disorder.

Figure 4. The entanglement entropy growth for \( L = 26 \) and \( W = 4 \) as compared to exact results due to Chebyshev propagation (top) and the residuals (bottom). Observe that TDVP overshoots the growth for large times when \( \chi \) is not sufficient for convergence. The behavior of tDMRG is more predictable converging smoothly with increasing \( \chi \).

Figure 5. Time evolution of the imbalance for disorder strength \( W = 3 \) (on the delocalized side) for different dimensions of the auxiliary Hilbert space \( \chi \) as indicated in the figure. For this disorder value even \( \chi = 512 \) is not sufficient for the convergence up to times \( t = 350 \). Top five curves correspond to tDMRG showing an apparent saturation of the imbalance, diminishing with increasing \( \chi \). Five bottom curves correspond to TDVP with an opposite behavior, the bigger \( \chi \) the slower the decay. The same 200 disorder realizations are used for each curve.

\( \chi \) the entropy coming from TDVP may overestimate the exact value, a comparison of values obtained with TDVP for two different \( \chi \) values might be of little help. For instance, increasing the bond dimension from \( \chi = 64 \) to \( \chi = 128 \) one could conclude that entanglement entropy growth is quicker than logarithmic at times \( t > 300 \). Only once the bond dimension is sufficiently large, \( S(t) \) obtained from TDVP converges monotonically to the exact result.

By comparison, the entropy \( S(t) \) in tDMRG underestimates the exact result in a predictable, monotonic way. Therefore, our results indicate that the value of \( S(t) \) obtained from tDMRG can be regarded a lower bound for the entanglement entropy for any time.

We have presented the data for \( L = 26 \), the data for \( L = 20 \) show a similar behavior with tDMRG becoming a method of choice for even lower values of the disorder \( \chi \) as the “critical” region occupies larger interval of disorder amplitudes for a smaller system).

IV. TDMRG VERSUS TDVP FOR LARGE SYSTEMS

As a standard “large” system we consider the same model (as given in Eq. (3)) with \( L = 50 \) sites with open boundary conditions. This is a typical system size met in cold atoms experiments [31]. The previous TDVP based analysis [39] has concentrated on \( L = 100 \) showing that \( L = 100 \) and \( L = 50 \) do not differ substantially. Still \( L = 50 \) is computationally less expensive and, on the other hand, it seems sufficiently large to ensure that boundary effects are small. We consider 200 disorder realizations for each curve.

Let us consider again the \( W = 3 \) case first. For this disorder value and due to the large size, we expect the
system to be on the delocalized side of the transition with TDVP working significantly better than tDMRG. The results of the simulations for the dynamics of imbalance $I(t)$ using both TDVP and tDMRG are shown in Fig. 5 again for the antiferromagnetic Néel initial state. Firstly, we observe a similar behavior as for smaller system sizes. Too small $\chi$ leads to a false saturation of the imbalance for tDMRG, with increasing $\chi$ the imbalance decays for longer times. TDVP shows an opposite effect, too fast decay for small $\chi$. The “exact” result is expected somewhere between the tDMRG and TDVP curves. Observe that TDVP seems to be almost converged when comparing $\chi = 384$ and $\chi = 512$ curves while the corresponding tDMRG curves show a bigger discrepancy. Both methods should converge to the same result, but looking at the curves it seems apparent that a much larger bond dimension than used in the simulations is needed to sufficiently explore the Hilbert space and get a truly converged result even for TDVP.

The corresponding growth of entanglement entropy $S(t)$ in the middle of the chain (computed after tracing out half of the chain) in time is depicted in Fig. 6. Observe a clear saturation of entropy for tDMRG when the chosen $\chi$ values are insufficient to represent the dynamics, and the almost converged entropy growth for TDVP, where $\chi = 512$ data is reasonably fitted with a power law growth $S(t) \propto t^{0.29}$ in accordance with the expectation that the entanglement entropy growth is faster than logarithmic on the delocalized side of the crossover.

Let us consider slightly bigger disorder $W = 4$. The corresponding evolution of the imbalance is shown in Fig. 7 for different $\chi$ values both for TDVP and tDMRG using 200 realizations of disorder. While differences between various $\chi$ values indicate smaller deviations in imbalance for tDMRG, TDVP with $\chi = 384$ matches almost exactly TDVP result for $\chi = 512$ up to $t = 350$. The corresponding entropy growth, this time relative to $\chi = 512$, data is represented in Fig. 8. Although the entanglement entropy error is much smaller for TDVP showing an apparent better convergence, the curves are not monotonically decreasing with time which strongly suggests that the entropy obtained from TDVP will ultimately overestimate (for $t > 350$) the actual value if $\chi$ is not sufficient, similar to the $L = 26$ situation mentioned in the previous section.

V. ANALYSIS OF THE CROSSOVER AND ITS PROPERTIES

The convergence examples studied in the previous section show significant fluctuations due to a relatively small number $N = 200$ of realizations of disorder. Still they are sufficient to draw some preliminary conclusions. Firstly, in the interesting interval of disorder values, $\chi = 64$ or
The imbalance for 200 realizations of disorder with $W = 3.5$ for $L = 26$ as obtained from time-evolution by Chebyshev expansion. The main panel shows the decay for long times, up to $t = 1000$. Both the power law and logarithmic decay match the data with a comparable precision. Exponential decay is by comparison ruled out. The inset shows the data for smaller times where prominent oscillations may affect the fit.

Even $\chi = 128$, as used e.g. in [39], lead to unconverged results affecting the shape and the decay of imbalance curves. Only for $W > 4.5$ such small values of $\chi$ seem to produce results one could rely on. We decided to compromise on $\chi = 384$ data as a proper choice for estimating the imbalance decay, for which we have reasonably reliable data up to $t = 500$. Still, we may not be, as exemplified in detail above, be convinced about the convergence for $W < 4$ even for shorter times. For better statistics from now on we use 400 realizations of disorder for $L = 50$.

As discussed earlier [48, 49], it is suggested that the imbalance decays as a power law on a delocalized side of ergodic-MBL crossover. However, there exists, as far as we know, no real theoretical foundation for this conjecture. Small system sizes at short times (up to $t = 100$) were fitted in [48] by a nine parameters formula matching also rapid oscillations at very short times with a power-law component. The experimental data [19] were fitted by the power law decay, $t^{-\beta}$, as well as (see supplementary material of [49]) the exponential decay. In the previous study [39] power law fits in $t \in [50, 100]$ interval were analyzed.

The difficulty encountered by fitting the data is exemplified in Fig. 9. To leave out the convergence problems for a moment, we present the exact data for $L = 26$ with 200 disorder realizations. The inset shows the fits of different time-dependencies of the decay in $t \in [50, 100]$ interval. Bearing in mind the existence of significant oscillations in the data for short times, all three functional dependencies assumed (logarithmic, exponential and power law) fit reasonably well the average decay. The main panel shows the decay on a large time scale (available for Chebyshev propagation) where clearly the exponential decay is ruled out but both power law and logarithmic fits are practically indistinguishable. This clearly shows the ambiguity in extracting reasonable critical disorder value by curve-fitting in such small time-windows (even when $t$ is considered up to 1000).

Such large times are practically unreachable with TDVP and tTDMRG due to convergence problems as shown in the previous Section. Therefore we have to make a reasonable compromise and we settle for $t \in [100, 200]$ interval. This increases twice the time interval as compared to [39] study, makes the role of oscillations weaker (they obviously affect the fit as the maxima and minima shift with the disorder strength), and produces almost satisfactory convergence in TDMRG and TDVP simulations. From now on we use the power law fit for a better comparison with earlier works.

In fact, the discrepancies observed from not fully converged TDMRG and TDVP data may be quite informative. MBL is known to be characterized by area-law-entangled eigenvectors [50] and slow logarithmic growth of the entanglement entropy from the initial separable state [24, 51]. One could envision that this property could be used in our simulations, but a casual glance at examples given in the previous section, shows that entanglement entropy converges slowly with $\chi$, moreover making a distinction between logarithmic and power law growth is difficult on short time intervals (as for imbalance). Still in MBL regime we expect a better, faster convergence with increasing $\chi$ as well as smaller differences between TDVP and tTDMRG results.

We now turn to analysis of imbalance decay. Comparison of power law fits for TDVP and tTDMRG are shown in Fig. 10. Shaded regions are discrepancies appearing in the delocalized regime. The data for $L = 26$ are of course more converged than those for $L = 50$ with the same assumed bond dimension $\chi = 384$. However, for $W > 4$, the discrepancies between fits to TDVP and TDMRG data are independent of the system size. These data suggest that a qualitative change in the behavior of

Figure 9. The imbalance for 200 realizations of disorder with $W = 3.5$ for $L = 26$ as obtained from time-evolution by Chebyshev expansion. The main panel shows the decay for long times, up to $t = 1000$. Both the power law and logarithmic decay match the data with a comparable precision. Exponential decay is by comparison ruled out. The inset shows the data for smaller times where prominent oscillations may affect the fit.

Figure 10. The power law $(t^{-\beta})$ coefficients obtained from fits of imbalance obtained from both TDVP and TDMRG in $t \in [100, 200]$ interval for $L = 26$ left and $L = 50$ right for $\chi = 384$. The error-bars correspond to $4\sigma$-error of the fit. The exact data from Chebyshev time evolution lie within a shaded area for $L = 26$. Results of both methods practically coincide for $W > 4.0$ for both $L = 26$ and $L = 50$. 

$\chi$
the system occurs around $W \approx 4$.

This is further supported by Fig. 11 showing results of the fits only where TDVP data are taken into account. Considering only 400 realizations of disorder (dictated by the relatively large $\chi$ value in simulations) we deal with quite a noisy data as shown in the previous section. Thus, we take $\beta = 0.02$ corresponding to 4σ-error of our data as a threshold value consistent with no decay of imbalance for $W_c$ estimate, which is in parity with experimental considerations [49]. A small shift of the fitted curves with the system size is observed, but nevertheless, the curves for $L = 50$ and $L = 200$ practically coincide at larger disorder strengths yielding the estimate of the critical disorder value around $W \approx 4.2$. For comparison, we also fit $L = 26$ data obtained from Chebyshev method in a bigger time window $t \in [100, 500]$, as convergence problem for longer time can be ruled out in this situation. Like $L = 50$ and 200, the $L = 26$ curve also shows a qualitative change around $W \approx 4$. Both the weak dependence on the system size and the value of the critical disorder estimate differ significantly from the conclusions of [39]. The main difference in the value of critical disorder strength, however, originates from the different “$\beta$ cutoff” assumed to be at $\beta = 0.01$ in [39], which does actually shift the apparent value of $W_c$ beyond (or close to) 5 even for smaller system-sizes like $L = 26$. We also note that the critical disorder value $W \approx 4.2$ obtained in our analysis is in good correspondence with results of [52] that suggest critical disorder strength to be about $W = 4.5(1)$ in the middle of the spectrum. Necessarily the critical value for the Neél state should be lower.

In [39] the critical disorder value was compared with $W_c \approx 3.7$ found in [44] on the basis of finite size scaling of the average level spacing ratio $\bar{\tau}$ obtained for system sizes $L = 14, ..., 22$. The analysis of [44] was conducted for a system with periodic boundary conditions while time evolution studies are carried out with open boundary conditions (OBC). Surprisingly, the choice of boundary conditions strongly affects critical disorder strength value obtained from finite size scaling of data from level statistics. To demonstrate this, we find 500 eigenvalues $E_i$ from the middle of the spectrum of system with sizes $L = 14, 16, 18, 20$ with shift-and-invert technique [53], calculate the level spacing ratios $r_i = \frac{\min(E_{i+1}, E_{i+2}, E_{i, i+1})}{\max(E_{i+1}, E_{i+2}, E_{i, i+1})}$ and average it within given disorder sample and, subsequently, over 2000 (500) disorder realization for $L = 14, 16, 18 (L = 20)$ to obtain the average level spacing ratio $\bar{\tau}$. The results are shown in Fig. 12. A clear crossover between $\bar{\tau} = 0.5307(1)$ in the ergodic regime and $\bar{\tau} = 0.3863(1)$ in the MBL regime is visible. Rescaling the disorder strength according to $W \rightarrow (W - W_c)L^{1/\nu}$ leads to a collapse of the data yielding value of critical disorder strength $W_c = 3.29(9)$ (and $\nu = 0.92(5)$). Discrepancy of the critical value of disorder strength for system with OBC and the result of [44] for periodic boundary conditions demonstrates the significance of the edges of the system which should be negligible if $W_c$ obtained in this way was truly a thermodynamic limit quantity.

Moreover, there is an obvious disagreement between $W_c = 3.29(9)$ obtained from finite-size scaling of $\bar{\tau}(W)$ and from time evolution of imbalance $W \approx 4.2$. We believe that there is no reason to expect the critical disorder estimates obtained by these two approaches to coincide. The level spacing ratio $r_n$ contains information about properties of the system at energy scale of single level spacing. The corresponding time scale (Heisenberg time) is exponentially large is system size $L$. Features of level statistics at scales of few and many level spacings [54] correspond to shorter time scales and can be observed in time dynamics [55]. Nevertheless, the in-

*Figure 11.* The power law ($t^{-\beta}$) $\beta$ coefficient obtained from fits of TDVP data in $t \in [100, 200]$ interval for $\chi = 384$ and different system sizes. The exact data from Chebyshev time evolution are given for $L = 26$ in $t \in [100, 500]$. The errorbars corresponds to 4σ-error of the fit. The dashed line at $\beta = 0.02$ is our assumed confidence level.

![Figure 12](image2.png)

*Figure 12.* The average level spacing ratio $\bar{\tau}$ as a function of disorder strength $W$ for various system sizes $L$ with open boundary conditions. The inset shows collapse of the data upon rescaling of disorder strength according to $W \rightarrow (W - W_c)L^{1/\nu}$. The obtained value of critical disorder strength $W_c = 3.29(9)$ is markedly smaller than value found in [44] for the system with periodic boundary conditions.
volved time scales are still exponentially large in system size $L$. However, the analysis of time-dependence of imbalance necessarily addresses finite time intervals comparable to experiments in cold atoms and long time scales are not reachable by present state-of-the-art tools used by us. From that perspective, the time evolution study of ergodic-MBL transition, even of very large systems, may only suggest ergodic or localized behavior at some intermediate disorder strengths whereas the precise location of the transition point between the two phases can be pinpointed only in limit of infinite times.

VI. CONCLUSIONS OUTLOOKS

We have discussed two distinct but related issues. On the technical side, we compare the performance of two popular schemes for simulation of time-evolution in large one-dimensional systems – tDMRG (as a variant of TEBD) and TDVP. While TDVP outperforms tDMRG for delocalized systems, in the crossover region between delocalized and MBL side tDMRG may be slightly better, in particular errors in the entanglement entropy accumulate in tDMRG in controllable and predictable way. It is in this crossover region that we found a rather slow convergence of both algorithms with increasing auxiliary Hilbert space size, $\chi$. Interestingly, studies of imbalance indicate that tDMRG/TDVP over/underestimates the imbalance, so joining the information from both algorithms allows to estimate the proper imbalance behavior as a function of time.

Our study, extended to longer times, larger system and, importantly much larger $\chi$ show, that at the assumed level of accuracy, the dependence of disordered Heisenberg spin chain on the system size is rather weak, contrary to earlier findings [39]. While we provide arguments towards the estimate of the critical disorder value at $W_c \approx 4.2$, we must stress that this estimate is limited to the time interval (up to $t = 200$) - extending this time to much larger values is beyond the current computational power - except for systems very deep in the MBL regime.

ACKNOWLEDGMENTS

We thank Marek M. Rams, E. Miles Stoudenmire, and Matthew Fishman for helpful suggestions regarding the implementations of the TDVP algorithm. The MPS-based techniques have been implemented using ITensor library v2 (https://itensor.org). Support of the Polish National Science Centre via grants Quantera 2017/25/Z/ST2/03029 (T.C.) and Opus 2015/19/B/ST2/01028 (P.S. and J.Z.) is acknowledged. P.S. thanks Polish National Science Centre for an additional support via Etiuda programme 2018/28/T/ST2/00401.
