Abstract

This work is concerned with the convergence of Gaussian process regression. A particular focus is on hierarchical Gaussian process regression, where hyper-parameters appearing in the mean and covariance structure of the Gaussian process emulator are a-priori unknown, and are learnt from the data, along with the posterior mean and covariance. We work in the framework of empirical Bayes, where a point estimate of the hyper-parameters is computed, using the data, and then used within the standard Gaussian process prior to posterior update. We provide a convergence analysis that (i) holds for any continuous function $f$ to be emulated; and (ii) shows that convergence of Gaussian process regression is unaffected by the additional learning of hyper-parameters from data, and is guaranteed in a wide range of scenarios. As the primary motivation for the work is the use of Gaussian process regression to approximate the data likelihood in Bayesian inverse problems, we provide a bound on the error introduced in the Bayesian posterior distribution in this context.

Keywords: inverse problem, Bayesian inference, surrogate model, Gaussian process regression, posterior consistency, hierarchical, empirical Bayes

1 Introduction

Mathematical modelling and simulation are indispensable tools frequently used to inform decisions and assess risk. In practice, the parameters appearing in the models are often unknown, and have to be inferred from indirect observations. This leads to an inverse problem, where one infers the parameters of the model given incomplete, noisy observations of the model outputs. Adopting a Bayesian approach [16, 38], we incorporate our prior knowledge of the parameters into a probability distribution, referred to as the prior distribution, and obtain a more accurate representation of the parameters in the posterior distribution, which results from conditioning the prior distribution on the observations.

The goal of simulations is typically to (i) sample from the posterior distribution, using methods such as Markov chain Monte Carlo (MCMC), and/or (ii) compute a point estimate of the parameters, such as the most likely value under the posterior distribution (known as the maximum a-posteriori (MAP) estimate). Both of these tasks quickly become computationally infeasible when the mathematical model involved is complex. In many applications, for example when the forward
model is given by a partial differential equation, computing one instance of the forward model is computationally very expensive, and the sheer number of model evaluations required for the sampling and/or optimisation is prohibitively large.

This drawback of fully Bayesian inference for complex models was recognised several decades ago in the statistics literature, and resulted in key papers which had a profound influence on methodology [32, 17, 26]. These papers advocated the use of a Gaussian process surrogate model (also called emulator) to approximate the solution of the governing equations, and in particular the data likelihood, at a much lower computational cost.

The focus of this work is on the convergence analysis of Gaussian process surrogate models, in the case where the hyper-parameters in the distribution of the Gaussian process are a-priori unknown and inferred as part of the construction of the surrogate. This situation is of significant importance and interest, for, amongst others, the following reasons. Firstly, by correctly tuning the hyper-parameters, we will obtain a Gaussian process surrogate model that mimics closely the behaviour of the function we are approximating, resulting in a smaller error in the approximation. Secondly, the variance of the Gaussian process surrogate model is often used to represent the error in the approximation. However, for this interpretation to make sense, the hyper-parameters have to be chosen correctly. For example, the variance of the Gaussian process surrogate model can artificially be driven to zero by letting the marginal variance of the covariance kernel go to zero, but the error does not vanish in reality.

We adopt an empirical Bayes approach, also known as a plug-in approach, where we compute an estimate of the hyper-parameters, and plug this into the predictive equations for a Gaussian process surrogate model with known hyper-parameters. We present a convergence analysis of these hierarchical Gaussian process surrogate models, which shows that convergence of the mean and variance of the Gaussian process emulator is guaranteed under very mild assumptions on the estimated hyper-parameters. In particular, the convergence rates of the hierarchical Gaussian process emulator are the same as the convergence rates obtained for Gaussian process emulators with fixed, known values of the hyper-parameters, if the estimated hyper-parameters converge to the known values.

As particular examples of covariance kernels used to construct the emulators, we consider the family of Matérn kernels and the family of separable (or multiplicative/tensor-product) Matérn kernels. As we will see in section 4, the type of covariance kernel one should employ depends on the structure and smoothness of the function being emulated. The use of Matérn kernels corresponds to assuming a certain Sobolev smoothness, whereas the use of separable Matérn kernels assumes a tensor-product Sobolev structure. For more details, see section 3.

The question of how the estimation of hyper-parameters influences the error in Gaussian process emulators is not new, and has been dealt with in the spatial statistics literature [35, 36, 28, 11, 33, 10, 6]. A summary of relevant results is given in section 2. As evident from this summary, these results are of a different nature to our new results presented in section 3 and to the type of error bounds needed to justify the use of Gaussian process emulators in Bayesian inverse problems [37]. In particular, our results (i) are non-asymptotic results, (ii) give bounds for a fixed, deterministic function being emulated, rather than averaging over a certain distribution of functions, and (iii) do not require any notion of equivalence or contiguity of the Gaussian process distributions with the true and the estimated hyper-parameters.

A further distinction to previous studies, is that we do not require a notion of ”true” values of the hyper-parameters. The customary (and often necessary) definition in spatial statistics (cf
is to choose the true parameter values such that the function being emulated is a sample of the corresponding Gaussian process. In our analysis, we do not require any such assumption on the function being emulated. True parameter values in our context would simply represent a good choice of hyper-parameters, and can be defined in any way that the user finds suitable (including the customary definition above). Likewise, the estimated hyper-parameters can be defined in many suitable ways, e.g through maximum likelihood or maximum a-posteriori estimation (cf [14]) or cross-validation (cf [31]). Our results are independent of how the hyper-parameters are estimated, and also do not rely on the sequence of estimated hyper-parameters being convergent.

1.1 Our Contributions

In this paper, we make the following contributions to the analysis of Gaussian process regression:

1. We provide a convergence analysis of Gaussian process regression with estimated hyper-parameters, which shows convergence of the emulators to the true function as the number of design points tends to infinity.

2. We justify the use of hierarchical Gaussian process emulators to approximate the forward model in Bayesian inverse problems, by bounding the error introduced in the posterior distribution. Previous results, well known in the spatial statistics literature and summarised in section 2, are not sufficient for this purpose.

1.2 Paper Structure

The paper is organised as follows. Section 2 introduces hierarchical Gaussian process regression, and summarises relevant results from the spatial statistics literature. Section 3 analyses the error in hierarchical Gaussian process regression in a wide range of scenarios. We set up the Bayesian inverse problem of interest in section 4 whereas Section 5 then considers the use of hierarchical Gaussian process emulators to approximate the posterior distribution in the Bayesian inverse problem. Section 6 provides a summary and discussion of the main results.

2 Hierarchical Gaussian Process Regression

We want to use Gaussian process regression (also known as Gaussian process emulation or kriging) to derive a computationally cheaper approximation to a given function \( f : U \to \mathbb{R} \), where \( U \subseteq \mathbb{R}^d_u \). Our focus here is on the case where the hyper-parameters defining the Gaussian process emulator are unknown a-priori, and are inferred as part of the construction of the emulator. We will denote these hyper-parameters by \( \theta \), and treat them using an empirical Bayes approach.

2.1 Set-up

Let now \( f : U \to \mathbb{R} \) be an arbitrary function. To derive the Gaussian process emulator of \( f \), we again use a Bayesian procedure and assign a Gaussian process prior distribution to \( f \):

\[
 f_0|\theta \sim \text{GP}(m(\theta; \cdot), k(\theta; \cdot, \cdot)). \quad (2.1)
\]
To avoid confusion between the true function $f$ and its prior distribution, we have added the subscript zero in the above prior. Here, $\theta \in R^d \subseteq R^{d_\theta}$ are now hyper-parameters defining the mean function $m(\theta; \cdot) : U \to \mathbb{R}$ and the two-point covariance function $k(\theta; \cdot, \cdot) : U \times U \to \mathbb{R}$, assumed to be positive-definite for all $\theta \in S$, for any compact subset $S \subseteq R^d$. Particular examples of covariance kernels $k(\theta)$ are the Matérn and separable Matérn families discussed in sections 2.2 and 2.3. For the mean function $m(\theta)$, we can for example use polynomials, in which case the hyper-parameters are typically the unknown polynomial coefficients. We will write $\theta = \{ \theta_{\text{mean}}, \theta_{\text{cov}} \}$ when we want to explicitly distinguish between the hyper-parameters appearing in the mean and covariance function, respectively.

We further put a prior distribution $\mathbb{P}(\theta)$ on $\theta$, with Lebesgue density $p(\theta)$. The joint prior distribution on $(f, \theta)$ is then given by

$$\mathbb{P}(f_0, \theta) = \mathbb{P}(f_0|\theta) \mathbb{P}(\theta).$$

Then, given data in the form of a set of distinct design points $D_N := \{u^n\}_{n=1}^N \subseteq U$, together with corresponding function values $f(D_N) := \{f(u^1), \ldots, f(u^N)\} \in \mathbb{R}^N$, we condition the prior distribution $\mathbb{P}(f_0, \theta)$ on the observed data $f(D_N)$ to obtain the posterior distribution

$$\mathbb{P}(f_0, \theta|f(D_N)) = \mathbb{P}(f_0, \theta, f(D_N)) \mathbb{P}(\theta|f(D_N)).$$

The distribution $\mathbb{P}(f_0|\theta, f(D_N))$ is again a Gaussian process, with explicitly known mean function $m^f_N(\theta; \cdot)$ and covariance kernel $k^f_N(\theta; \cdot, \cdot)$:

$$m^f_N(\theta; u) = m(\theta; u) + K(\theta; D_N)^{-1} (f(D_N) - m(\theta; D_N)), \tag{2.2}$$
$$k^f_N(\theta; u, u') = k(\theta; u, u') - K(\theta; D_N)^{-1} k(\theta; u', D_N), \tag{2.3}$$

where $k(\theta; u, D_N) = [k(\theta; u, u^1), \ldots, k(\theta; u, u^N)] \in \mathbb{R}^N$, $K(\theta; D_N) \in \mathbb{R}^{N \times N}$ is the matrix with $ij^{th}$ entry equal to $k(\theta; u^i, u^j)$ and $m(\theta; D_N) := [m(\theta; u^1), \ldots, m(\theta; u^N)] \in \mathbb{R}^N$. These are the well-known formulae for Gaussian process emulation [29], here adopting notation that will enable us to make use of the analysis of such emulators in [37]. When we wish to make explicit the dependence on the prior mean $m$, we will denote the predictive mean in (2.2) by $m^{f, m}_N(\theta)$.

The marginal distribution

$$\mathbb{P}(f_0|f(D_N)) = \int_{\theta} \mathbb{P}(f_0, \theta|f(D_N)) \, d\theta = \int_{\theta} \mathbb{P}(f_0|\theta, f(D_N)) \mathbb{P}(\theta|f(D_N)) \, d\theta$$

is typically not available in closed form, since the integrals involved are intractable. In practice one therefore often uses a plug-in approach, also known as empirical Bayes. This consists of calculating an estimate $\hat{\theta}_N$ of $\theta$ using the data $f(D_N)$, and then approximating

$$\mathbb{P}(f_0|f(D_N)) \approx \mathbb{P}(f_0|\hat{\theta}_N, f(D_N)) = \text{GP}(m^f_N(\hat{\theta}_N; \cdot), k^f_N(\hat{\theta}_N; \cdot, \cdot)).$$

This corresponds to approximating the distribution $\mathbb{P}(\theta|f(D_N))$ by a Dirac measure at $\theta = \hat{\theta}_N$. For the remainder of this work, we will use

$$f_N(\hat{\theta}_N) \sim \text{GP}(m^f_N(\hat{\theta}_N; \cdot), k^f_N(\hat{\theta}_N; \cdot, \cdot)) \tag{2.4}$$
as a Gaussian process emulator of $f$. The process in (2.4) is also referred to as the predictive process, and we shall refer to $m_N^*(\hat{\theta}_N; \cdot)$ and $k_N^*(\hat{\theta}_N; \cdot, \cdot)$ as the predictive mean and the predictive variance, respectively.

The remainder of this section is devoted to a literature review on issues related to computing a good estimate $\hat{\theta}_N$ of the hyper-parameters $\theta$ from the data $f(D_N)$, and analysing the effect that approximating $\hat{\theta}_N$ has on the outcome of the regression. For this purpose, the notion of identifiability plays an important role.

**Definition 2.1.** [13] Two probability measures $\mathbb{P}_1$ and $\mathbb{P}_2$, defined on the same probability space $(\Omega, \mathcal{A})$, are called equivalent if they are mutually absolutely continuous, i.e. if for any event $A \in \mathcal{A}$ we have $\mathbb{P}_1(A) = 0$ if and only if $\mathbb{P}_2(A) = 0$. The measures $\mathbb{P}_1$ and $\mathbb{P}_2$ are called orthogonal if there exists an event $A \in \mathcal{A}$ such that $\mathbb{P}_1(A) = 1$ and $\mathbb{P}_2(A) = 0$.

It can be shown that two Gaussian measures are either equivalent or orthogonal [13, 15].

**Definition 2.2.** [44] A random field model $g \sim \text{GP}(m(\theta; \cdot), k(\theta; \cdot, \cdot))$ on $U$ is called identifiable if different values of $\theta$ give rise to orthogonal Gaussian measures.

Following [44], the random field model $g \sim \text{GP}(m(\theta; \cdot), k(\theta; \cdot, \cdot))$ is identifiable if it is theoretically possible to learn the true value of $\theta$ after obtaining an infinite number of observations of $g$ on $U$. A relevant result in this context is the Cameron-Martin Theorem.

**Proposition 2.3.** (Cameron-Martin Theorem, [5]) Let $\mathbb{P}_i$, for $i = 1, 2$, be two probability measures such that under $\mathbb{P}_i$, $g$ is a Gaussian process on $U$ with mean $m_i(\cdot)$ and covariance function $k(\cdot, \cdot)$. Then $\mathbb{P}_1$ and $\mathbb{P}_2$ are equivalent if and only if $m_1 - m_2$ is an element of the reproducing kernel Hilbert space associated to $k$.

In particular, Proposition 2.3 implies that models with polynomial mean functions $m(\theta)$, where the parameters $\theta$ represent the coefficients or the degree of the polynomial, are in most cases not identifiable, since polynomials are typically contained in the reproducing kernel Hilbert space associated to $k$. In particular, this is the case for the Matérn and separable Matérn kernels presented below.

### 2.2 Matérn Covariance Kernels

Covariance functions $k(\theta; \cdot, \cdot)$ frequently used in applications are the Matérn covariance functions

$$k_{\text{Mat}}(\theta; u, u') = \frac{\sigma^2}{\Gamma(\nu)2^{\nu-1}} \left( \frac{\|u - u'\|}{\lambda} \right)^\nu B_\nu \left( \frac{\|u - u'\|}{\lambda} \right), \quad (2.5)$$

with hyper-parameters $\theta_{\text{cov}} = \{\sigma^2, \lambda, \nu\} \in (0, \infty)^3$. Here, $\Gamma$ denotes the Gamma function, and $B_\nu$ denotes the modified Bessel function of the second kind [22]. The parameter $\sigma^2$ is usually referred to as the (marginal) variance, $\lambda$ as the correlation length and $\nu$ as the smoothness parameter. The expression for the Matérn covariance kernel simplifies for particular choices of $\nu$. Notable examples include the exponential covariance kernel $\sigma^2 \exp(-\|u - u'\|_2/\lambda)$ with $\nu = 1/2$, and the Gaussian covariance kernel $\sigma^2 \exp(-\|u - u'\|_2^2/\lambda^2)$ in the limit $\nu \to \infty$.

We have the following results on the identifiability of the Matérn model [45, 44, 2].
Proposition 2.4. Let $\mathbb{P}_i$, for $i = 1, 2$, be two probability measures such that under $\mathbb{P}_i$, $g$ is a Gaussian process on $U$ with mean 0 and Matérn covariance function with variance $\sigma_i^2$, correlation length $\lambda_i$ and smoothness parameter $\nu_i$.

(i) If $\nu_1 \neq \nu_2$, then $\mathbb{P}_1$ and $\mathbb{P}_2$ are orthogonal.

(ii) If $\nu_1 = \nu_2$ and $d_u \leq 3$, then $\mathbb{P}_1$ is equivalent to $\mathbb{P}_2$ if and only if $\sigma_1^2 \lambda_1^{-2\nu_1} = \sigma_2^2 \lambda_2^{-2\nu_2}$.

(iii) If $\nu_1 = \nu_2$ and $d_u > 4$, then $\mathbb{P}_1$ and $\mathbb{P}_2$ are orthogonal if $\lambda_1 \neq \lambda_2$ or $\sigma_1^2 \neq \sigma_2^2$.

Proof. Part (ii) was proven in [44], and part (iii) in [2]. Part (i) follows from the fact $\mathbb{P}_i(C_\alpha(U)) = 1$, for all $0 \leq \alpha < \nu_i$ and $\mathbb{P}_i(C_\alpha(U)) = 0$, for all $\alpha \geq \nu_i$.

It follows from Proposition 2.4 that the hyper-parameters $\theta_{\text{cov}}$ are not identifiable in the setting of (ii), and in general, ML and MAP estimators of the hyper-parameters do not contract around the true parameter values as $N \to \infty$ [44]. Only the quantity $\sigma^2 \lambda^{-2\nu}$ is identifiable in this setting. To alleviate this problem, the recent paper [14] discusses good choices for the prior distribution $\mathbb{P}(\theta)$ on the hyper-parameters $\{\sigma^2, \lambda\}$, such that the MAP estimate $\hat{\theta}_N^{\text{MAP}}$ gives a good estimate of the true value of $\theta$.

We would also like to point out here that the identifiability issues in Proposition 2.4 (ii) are related to the fact that our parameter space $U$ is bounded, which means that we are dealing with what is usually referred to as in-fill asymptotics. If $U$ were unbounded, we would be dealing with increasing domain asymptotics, where all parameters are identifiable also in the setting of (ii) [45].

2.3 Separable Matérn Covariance Kernels

As an alternative to the classical Matérn covariance functions in the previous section, one can consider using their separable versions (also called multiplicative or tensor-product versions). These are obtained by taking the product of one-dimensional Matérn covariance functions:

$$k_{\text{sepMat}}(\theta; u, u') = \prod_{j=1}^{d_u} k_{\text{Mat}}(\theta_j; u_j, u'_j).$$

(2.6)

Since the marginal variances $\sigma_j^2$ only enter as multiplicative pre-factors, the hyper-parameters in this case are $\{\nu_j, \lambda_j\}_{j=1}^{d_u}$ and $\sigma^2 := \prod_{j=1}^{d_u} \sigma_j^2$, leading to $\theta_{\text{cov}} \in (0, \infty)^{2d_u+1}$. A particular example is the separable exponential covariance kernel, which corresponds to $\nu_j \equiv 1/2$ and hence takes the form

$$k_{\text{sepExp}}(\theta; u, u') = \sigma^2 \exp\left(-\sum_{j=1}^{d_u} \frac{|u_j - u'_j|}{\lambda_j}\right).$$

(2.7)

The separable versions of Matérn kernels can have better properties than the classical Matérn kernels in terms of identifiability, as illustrated by the following result.

Proposition 2.5. [44, Theorem 1] Provided $d_u > 1$, the Gaussian process model $g \sim \text{GP}(0, k_{\text{sepExp}}(\theta; \cdot, \cdot))$ on $U$ is identifiable.
The case of general separable Matérn covariance kernels appears to be open, but related results in this direction can be found in [20, 21, 9]. Note that for \( d_u = 1 \), the classical and separable Matérn kernels coincide and Proposition 2.3 applies. In particular, for the stationary Ornstein-Uhlenbeck process given by \( d_u = 1 \) and \( \nu = 1/2 \), only the quantity \( \sigma^2 \lambda^{-1} \) is identifiable on the bounded domain \( U \).

### 2.4 Optimal Prediction Error

In this section, we review some results on how the estimate \( \hat{\theta}_N \) influences the prediction error of \( m_N^f(\hat{\theta}_N; u) \). To this end, we assume that there exists a true parameter value \( \theta_0 \) such that \( f \sim \text{GP}(0, k(\theta_0; \cdot, \cdot)) \), and we view the predictive mean \( m_N^f(\theta; u) \) as an estimator of \( f(u) \). The prediction error of \( m_N^f(\theta; u) \) is defined as its mean square error

\[
e^2(\theta; u) := \mathbb{E}_{\theta_0} \left( \left( m_N^f(\theta; u) - f(u) \right)^2 \right),
\]

where the expectation is taken with respect to the distribution \( f \sim \text{GP}(0, k(\theta_0; \cdot, \cdot)) \).

Classically, the question of how the misspecification of \( \theta_0 \) influences the prediction error has been addressed in the setting where \( \theta_0 \) is approximated by \( \hat{\theta} \), with \( \hat{\theta} \) fixed and independent of \( f(D_N) \) (see e.g. [35, 36]).

**Proposition 2.6.** [28, Theorem 1] Suppose \( e^2(\theta_0; u) \to 0 \) as \( N \to \infty \). Let \( u \) be a point in \( U \), and suppose the design points \( \{u^n\}^\infty_{n=1} \) form a sequence in \( U \) not containing \( u \) but having \( u \) as a limit point (possibly along a sub-sequence). Denote by \( \mathbb{P}_1 \) the measure corresponding to \( f \sim \text{GP}(0, k(\theta_0; \cdot, \cdot)) \), and by \( \mathbb{P}_2 \) the measure corresponding to \( f \sim \text{GP}(0, k(\hat{\theta}; \cdot, \cdot)) \). If the measures \( \mathbb{P}_1 \) and \( \mathbb{P}_2 \) are equivalent, then

\[
\lim_{N \to \infty} \frac{e^2(\hat{\theta}; u)}{e^2(\theta_0; u)} = 1.
\]

The dependency of the estimate \( \hat{\theta}_N \) on the evaluations \( f(D_N) \) complicates the analysis. For example, the predictive mean \( m_N^f(\hat{\theta}_N) \) is no longer a linear function of \( f(D_N) \). The following result was proven in [28] [1].

**Definition 2.7.** Sequences of probability measures \( \{\mathbb{Q}_{1,N}\}_{N \in \mathbb{N}} \) and \( \{\mathbb{Q}_{2,N}\}_{N \in \mathbb{N}} \), defined on the same sequence of measurable spaces \( \{\Omega_N, \mathcal{A}_N\} \), are mutually contiguous if for any sequence \( A_N \in \mathcal{A}_N \), we have \( \mathbb{Q}_{1,N}(A_N) \to 0 \) as \( N \to \infty \) if and only if \( \mathbb{Q}_{2,N}(A_N) \to 0 \) as \( N \to \infty \).

**Proposition 2.8.** [28, Theorem 2.1] Suppose \( e^2(\theta_0; u) \to 0 \) as \( N \to \infty \). Let \( u \) be a point in \( U \), and suppose the design points \( \{u^n\}^\infty_{n=1} \) form a sequence in \( U \) not containing \( u \) but having \( u \) as a limit point (possibly along a sub-sequence). For \( N \in \mathbb{N} \), denote by \( \mathbb{P}_{1,N} \) the distribution of \( [f(u), f(u^1), \ldots, f(u^N)] \in \mathbb{R}^{N+1} \) under \( f \sim \text{GP}(0, k(\theta_0; \cdot, \cdot)) \), and by \( \mathbb{P}_{2,N} \) the distribution of \( [f(u), f(u^1), \ldots, f(u^N)] \) (see e.g. [35, 36]).

---

1. We are here considering a zero mean in the Gaussian process prior [24]. The result proved in [28] is proved for universal kriging, where one assumes an unknown constant mean \( m(\theta; \cdot) \equiv \theta_{\text{mean}} \) in [24]. The predictive equations (2.2) - (2.3) are different in the two settings. However, since the proof of [28, Theorem 2.1] only relies on the best unbiased predictor of the Gaussian process emulator, as well as properties of Gaussian random variables, the same proof technique can be applied in the zero mean (or simple kriging) set-up considered here.
In this section, we are concerned with the convergence of the hierarchical Gaussian process emulator \( f_N \) to the function \( f \). Although the main idea behind the error estimates in this section is related to section 2.4, we are here interested in error bounds which (i) are non-asymptotic, (ii) bound the error for a fixed function \( f \), rather than averaging over a distribution on \( f \), and (iii) are flexible with respect to the definition of the estimated and the true hyper-parameters, so do not require any notion of equivalence or contiguity of the corresponding distributions. Furthermore, the error analysis here will be performed in norms amenable to the use of the hierarchical Gaussian process emulators as surrogate models in Bayesian inverse problems, see section 5 for details.

Since the error analysis depends on various properties of the covariance kernel, such as the corresponding reproducing kernel Hilbert space (also known as the native space or Cameron-Martin space), we will consider two particular examples, namely the classical and the separable Matérn covariance kernels already considered in sections 2.2 and 2.3.

The definition of the estimated parameter values \( \hat{\theta}_N \) is open, and our analysis does not require any assumptions on how these estimates are computed. We do not require that the sequence \( \{ \hat{\theta}_N \}_{N \in \mathbb{N}} \) converges, neither do we require the parameters \( \theta \) to be identifiable. We could for example use maximum likelihood or maximum a-posteriori estimators, choose \( \hat{\theta}_N \) to minimise the error \( \| f - m_N^f(\hat{\theta}_N) \|_{L^2(U)} \), or use a combination of different approaches for different hyper-parameters. Note, however, that we do not want to minimise the predictive variance \( \| k_N^{1/2}(\hat{\theta}_N) \|_{L^2(U)} \), since this can be made arbitrarily small by letting \( \hat{\sigma}_N^2 \to 0 \). We want to choose \( \hat{\sigma}_N^2 \) such that \( k_N^{1/2}(\hat{\theta}_N) \) is a good representation of our remaining uncertainty about the function \( f \), after observing the \( f(D_N) \).

We would like to quantify the performance of the estimated mean and covariance functions \( m_N^f(\hat{\theta}_N; \cdot) \) and \( k_N(\hat{\theta}_N; \cdot, \cdot) \). In particular, in light of the error bounds required for the Bayesian posterior distribution in section 5 we are interested in the quantities \( \| f - m_N^f(\hat{\theta}_N) \|_{L^2(U)} \) and \( \| k_N(\hat{\theta}_N) \|_{L^2(U)} \). We recall the following fundamental results, which hold for any kernel \( k(\theta) \).

**Proposition 3.1.** [42] The function \( m_N^{f,0}(\theta) \), given by (2.2) with \( m(\theta) \equiv 0 \), is the minimal norm interpolant of \( f \) in the native space corresponding to \( k(\theta) \), with interpolation points \( D_N \):

\[
m_N^{f,0}(\theta) = \arg \min_{g \in H_{k(\theta)(U)} : g(D_N) = f(D_N)} \| g \|_{H_{k(\theta)(U)}}.
\]

In particular, \( \| m_N^{f,0}(\theta) \|_{H_{k(\theta)(U)}} \leq \| f \|_{H_{k(\theta)(U)}} \).
Proposition 3.2. \[33, 37\] Suppose \( k_N(\theta) \) is given by (2.3). Then
\[
k_N(\theta; u, u) = \sup_{\|g\|_{H_k(\theta)} = 1} |g(u) - m^q_d(\theta; u)|,
\]
where \( m^q_d(\theta) \) is given by (2.2) with \( m(\theta) = 0 \).

Given the set of design points \( D_N = \{ u^n \}_{n=1}^N \subseteq U \), we define the fill distance \( h_{D_N,U} \), separation radius \( q_{D_N,U} \) and mesh ratio \( \rho_{D_N,U} \) by
\[
h_{D_N,U} := \sup_{u \in U} \inf_{a^n \in U} \| u - a^n \|, \quad q_{D_N,U} := \frac{1}{2} \min_{i \neq j} \| u^i - u^j \|, \quad \rho_{D_N,U} := \frac{h_{D_N,U}}{q_{D_N,U}} \geq 1. \tag{3.1}
\]
The fill distance (also known as the maximin distance) is the maximum distance any point in \( U \) can be from \( D_N \), and the separation radius is half the smallest distance between any two distinct points in \( D_N \). The three quantities above provide measures of how uniformly the design points \( D_N \) are distributed in \( U \).

The fill distance \( h_{D_N,U} \) and the separation radius \( q_{D_N,U} \) are decreasing functions of \( N \), and these quantities will tend to zero as \( N \) tends to infinity for space-filling designs. The best possible rate of convergence for any choice of \( D_N \) and \( U \) is \( h_{D_N,U} \leq C N^{-1/d_u} \) (see e.g. [30]). The mesh ratio \( \rho_{D_N,U} \), on the other hand, is an non-decreasing function of \( N \). Point sets \( D_N \) for which \( \rho_{D_N,U} \) can be bounded uniformly in \( N \), i.e. sets for which the fill distance and the separation radius decrease at the same rate with \( N \), are called quasi-uniform. In general, however, the mesh ratio can be strictly increasing in \( N \).

3.1 Matérn Covariance Kernels

Suppose we use a Matérn covariance kernel \( k_{\text{Mat}}(\tilde{\theta}_N) \), defined in (2.5), to construct the hierarchical Gaussian process emulator \( f_N \), defined in (2.4).

3.1.1 Predictive Mean

We first consider the predictive mean \( m^f_N(\tilde{\theta}_N) \). The main result is given in Theorem 3.3. To prove explicit error bounds, recall the following characterisation of the native space (also known as reproducing kernel Hilbert space) of the Matérn kernel.

Proposition 3.3. \[42\] Let \( k(\theta) = k_{\text{Mat}}(\theta) \), with \( \theta_{\text{cov}} = \{ \nu, \lambda, \sigma^2 \} \subseteq S \), for some compact set \( S \subseteq (0, \infty)^3 \). Then the native space \( H_{k_{\text{Mat}}}(U) \) is equal to the Sobolev space \( H^{\nu + d_u/2}(U) \) as a vector space, and the native space norm and the Sobolev norm are equivalent.

There hence exist constants \( C_{\text{low}}(\theta; U) \) and \( C_{\text{up}}(\theta; U) \) such that for all \( g \in H^{\nu + d_u/2}(U) \), there holds
\[
C_{\text{low}}(\theta; U) \| g \|_{H_{k_{\text{Mat}}}(\theta)(U)} \leq \| g \|_{H^{\nu + d_u/2}(U)} \leq C_{\text{up}}(\theta; U) \| g \|_{H_{k_{\text{Mat}}}(\theta)(U)}.
\]

We then have the following result on the convergence of \( m^f_N(\tilde{\theta}_N) \) to \( f \) as \( N \to \infty \). In particular, it shows that we obtain convergence in a wide range of scenarios, under very mild assumptions on the estimated hyper-parameters. If the estimated hyper-parameters converge, we obtain the same convergence rate as in the case where all the hyper-parameters are fixed at the limiting value, cf [37] Proposition 3.4. Note that Theorem 3.4 trivially also applies to the special case \( \tilde{\theta}_N = \tilde{\theta} \), where a fixed value of the hyper-parameter is used.
Theorem 3.4. (Convergence in N of $m^f_N(\hat{\theta}_N)$) Suppose we have a sequence of estimates $\{\hat{\theta}_N\}_{N=1}^\infty \subseteq S$, for some compact set $S \subseteq R_d$. Assume

(a) $U \subseteq \mathbb{R}^{d_u}$ is a bounded Lipschitz domain that satisfies an interior cone condition,

(b) the native space $H_{k(\theta)}(U)$ is isomorphic to the Sobolev space $H^{r(\theta)}(U)$,

(c) $f \in H_{\hat{r}}(U)$, for some $\hat{r} = n + r$, with $n \in \mathbb{N}$, $n > d_u/2$ and $0 \leq r < 1,$

(d) $m(\theta) \in H_{\hat{r}}(U)$ for all $\theta \in S$,

(e) for some $N^* \in \mathbb{N}$, the quantities $\tau^- := \inf_{N \geq N^*} \tau(\hat{\theta}_N)$ and $\tau^+ := \sup_{N \geq N^*} \tau(\hat{\theta}_N)$ satisfy

$$\tau^- = n' + r', \text{ with } n' \in \mathbb{N}, n' > d_u/2 \text{ and } 0 \leq r' < 1.$$ 

Then there exists a constant $C$, which is independent of $f$ and $N$, such that

$$\|f - m^f_N(\hat{\theta}_N)\|_{H^{\beta}(U)} \leq C h_{D_{N,U}}^{\min(\hat{r}, \tau^-)} \beta m_{D_{N,U}}^{\max(\tau^+, \hat{r}) - \beta} \left(\|f\|_{H^{\tau^+}(U)} + \sup_{N \geq N^*} \|m(\hat{\theta}_N)\|_{H^{\tau^+}(U)}\right),$$

for any $\beta \leq \hat{r}$ and $N \geq N^*$.

**Proof.** First, we note that it follows from (2.2) that $m^f_N(\hat{\theta}_N) = m^f_N(\hat{\theta}_N) + m(\hat{\theta}_N) - m^m_N(\hat{\theta}_N)$. By [23, Theorems 4.1 and 4.2], we have, for fixed $N \in \mathbb{N},$

$$\|f - m^f_N(\hat{\theta}_N)\|_{H^{\beta}(U)} = \|f - m^0_N(\hat{\theta}_N) + m(\hat{\theta}_N) - m^m_N(\hat{\theta}_N)\|_{H^{\beta}(U)}$$

$$\leq C_{3.4}(\hat{\theta}_N) h_{D_{N,U}}^{\min(\hat{r}, \tau(\hat{\theta}_N)) - \beta} m_{D_{N,U}}^{\max(\tau(\hat{\theta}_N) - \beta, 0)} \left(\|f\|_{H^{\tau^+}(U)} + \|m(\hat{\theta}_N)\|_{H^{\tau^+}(U)}\right),$$

for some constant $C_{3.4}(\hat{\theta}_N)$ independent of $f$, $h_{D_{N,U}}$, and $\rho_{D_{N,U}}$. An inspection of the proof shows that the constant $C_{3.4}(\hat{\theta}_N)$ is such that $\|m^f_N(\hat{\theta}_N)\|_{H^{\tau(\hat{\theta}_N)}(U)} \leq C_{3.4}(\hat{\theta}_N)\|f\|_{H^{\tau(\hat{\theta}_N)}(U)}$. Using Proposition 3.1, an appropriate choice for $C_{3.4}(\hat{\theta}_N)$ is hence $C_{up}(\hat{\theta}_N; U)C_{low}(\hat{\theta}_N; U)^{-1}$, which is a locally bounded function of $\hat{\theta}_N$. The claim then follows by the compactness of $S$. 

Assumption (a) in Theorem 3.4 is an assumption on the domain $U$ being sufficiently regular, containing no sharp corners or cusps, and is satisfied, for example, for the unit cube $U = [0,1]^{d_u}$. Assumption (b) reiterates that the native space of Matérn kernels is a Sobolev space. Theorem 3.4 applies in fact not just to Matérn kernels, but to any kernel which has a Sobolev space as native space, including the compactly supported Wendland functions [42].

Assumption (c) is an assumption on the regularity of the function $f$ being emulated. We point out here that this assumption is rather mild, and modulo some technicalities (cf Remark 3.6), this assumption simply means that $f$ should be at least continuous. We also point out here that Theorem 3.4 does not require the function $f$ to be in the native space of any of the kernels $k(\hat{\theta}_N)$. The smoothness of $f$, denoted by $\hat{r}$, can be both greater or smaller than the estimated smoothness $\tau(\hat{\theta}_N)$. The best possible convergence rates are obtained when the estimated smoothness matches the true smoothness of $f$ (cf Remark 3.5). Recall that $h_{D_{N,U}}$ is decreasing in $N$, whereas $\rho_{D_{N,U}}$ is either constant or increasing in $N$. If we are underestimating the smoothness of $f$, then $\tau^- < \hat{r}$, and we do not achieve the best possible exponent in $h_{D_{N,U}}$. If we are overestimating the smoothness of $f$, then $\tau^+ < \hat{r}$ and we obtain a positive power of $\rho_{D_{N,U}}$. 

Assumption (d) ensures that the chosen mean $m$ has at least the same regularity as $f$. This can be relaxed, but less regularity in $m$ would lead to lower convergence rates in the error, so in practice, one should ensure that $m$ is sufficiently smooth.

The quantities $\tau^-$ and $\tau^+$ in assumption (e) can be thought of as $\liminf_{N \to \infty} \tau(\hat{\theta}_N)$ and $\limsup_{N \to \infty} \tau(\hat{\theta}_N)$, respectively. If $\lim_{N \to \infty} \tau(\hat{\theta}_N)$ exists, then this can be substituted for both quantities. Assumption (e) is the only assumption we make on the estimated hyper-parameters, other than that $\{\hat{\theta}_N\}_{N=1}^\infty \subseteq S$, for some compact set $S \subseteq \mathbb{R}^d$. In particular, this means that the only assumptions required on $\lambda_N$ and $\hat{\sigma}^2_N$ are that they are bounded away from zero and infinity. For the estimated smoothness $\tilde{\nu}_N$, we again essentially require $0 < \tilde{\nu}_N < \infty$, however, due some technical issues in the proof (cf Remark 3.6), we require a slightly larger lower bound on $\tilde{\nu}_N$.

**Remark 3.5.** (Choice of $\nu$) Under the assumptions of Theorem 3.4, we have

$$\|f - m_N^f(\theta_0)\|_{H^\nu(U)} \leq C \|m_N^{\tilde{\nu}}(\theta_0)\|_{H^\nu(U)},$$

for any $\theta_0 \in S$. The best possible convergence rate in $N$ of this bound is obtained when $\tilde{\nu} = \tau(\theta_0)$, i.e. when $f$ is in the reproducing kernel Hilbert space corresponding to $k(\theta_0): f \in H^{\tau(\theta_0)}(U) = H_{k(\theta_0)}(U)$. This is different from defining $\theta_0$ such that $f$ is a sample of the Gaussian process $GP(m(\theta_0; \cdot), k(\theta_0; \cdot, \cdot))$, since samples of a Gaussian process are almost surely not in the corresponding reproducing kernel Hilbert space. This point has also already been noted in [33].

**Remark 3.6.** (Valid choice of $\tau$) The Sobolev space $H^\tau(U)$ is a reproducing kernel Hilbert space for any $\tau > d_u/2$. The restriction on $\tau$ in assumption (c) of Theorem 3.4 is hence slightly stronger than expected, requiring that the integer part of $\tau$ is greater than $d_u/2$. This is due to a technical detail in the proofs of [23], Theorems 4.1 and 4.2, and could be fisible. The same comment applies to assumption (e) in Theorem 3.4 and assumptions (d) and (f) in Theorem 3.9.

### 3.1.2 Predictive Variance

Next, we investigate the predictive variance $k_N(\hat{\theta}_N)$. An application of Proposition 3.2 gives the following result on the convergence of $k_N(\hat{\theta}_N)$ to 0, which in particular shows that we obtain the same rate of convergence as when the hyper-parameters are fixed, cf [37].

**Theorem 3.7.** (Convergence in $N$ of $k_N(\hat{\theta}_N)$) Let the assumptions of Theorem 3.4 hold. Then there exists a constant $C$, independent of $N$, such that

$$\|k_N^{1/2}(\hat{\theta}_N)\|_{L^2(U)} \leq C N^{\min\{\tilde{\tau}, \tau^\nu\} - d_u/2 - \epsilon \max\{\tau^+, \tilde{\tau}, 0\}} \rho_{D_N, U},$$

for any $N \geq N^*$ and $\epsilon > 0$.

**Proof.** An application of Proposition 3.2 gives

$$\|k_N^{1/2}(\hat{\theta}_N)\|_{L^2(U)} = \left( \int_U k_N(\hat{\theta}_N; u, u) du \right)^{1/2} \leq C \sup_{u \in U} k_N(\hat{\theta}_N; u, u)^{1/2}$$

$$= C \sup_{u \in U} \frac{\|g(u) - m_N^\theta(\hat{\theta}_N; u)\|_{H^{\tilde{\nu}}(U)}}{\|g\|_{H^{\tilde{\nu}}(U)}},$$

$$= C \sup_{\|g\|_{H^{\tilde{\nu}}(U)} = 1} \sup_{u \in U} |g(u) - m_N^\theta(\hat{\theta}_N; u)|.$$
The Sobolev embedding theorem (see e.g. [1]), together with Theorem 3.4 then gives
\[ \|k_N^{1/2}(\hat{\theta})\|_{L^2(U)} \leq C \sup_{\|g\|_{H_k(\hat{\theta})}(U) = 1} \|g(u) - m_N^g(\hat{\theta}N; u)\|_{H^{d_u/2+\varepsilon}(U)} \leq \sup_{\|g\|_{H_{k(\hat{\theta})}}(U) = 1} \|g\|_{H^{d_u/2+\varepsilon}(U)}. \]

Finally, using Proposition 3.3 and the compactness of \( S \) proves the claim. \( \square \)

3.2 Separable Matérn Covariance Kernels

Rather than the Matérn kernels employed in the previous section, suppose now that we use a separable Matérn covariance kernel \( k_{\text{sepMat}}(\hat{\theta}), \) as defined in [24], to define the Gaussian process emulator (2.4). Due to the tensor product structure of the kernel \( k_{\text{sepMat}}(\hat{\theta}), \) we will assume that our parameter domain \( U \) also has a tensor product structure \( U = \prod_{j=1}^{d_u} U_j, \) with \( U_j \subset \mathbb{R} \) bounded.

3.2.1 Predictive Mean

We again start with the predictive mean \( m_N^g(\hat{\theta}N). \) The main result in this section is Theorem 3.9.

We have the following equivalent of Proposition 3.3 characterising the native space of separable Matérn covariance kernels on the tensor-product domain \( U. \)

**Proposition 3.8.** [24, 31] Suppose \( U = \prod_{j=1}^{d_u} U_j, \) with \( U_j \subset \mathbb{R} \) bounded. Let \( k(\theta) = k_{\text{sepMat}}(\theta) \) be a separable Matérn covariance kernel with \( \theta \in S, \) for some compact set \( S \subseteq (0, \infty)^{2d_u+1}. \) Then the native space \( H_{k(\theta)}(U) \) is equal to the tensor product Sobolev space \( H_{\otimes_{j=1}^{d_u}}^{\nu_j+1/2}(U_j) := \otimes_{j=1}^{d_u} H_{\nu_j+1/2}(U_j) \) as a vector space, and the native space norm and the Sobolev norm are equivalent.

There hence exist constants \( C_{\text{low}}'(\theta; U) \) and \( C_{\text{up}}'(\theta; U) \) such that for all \( g \in H_{\otimes_{j=1}^{d_u}}^{\nu_j+1/2}(U), \) there holds
\[ C_{\text{low}}'(\theta; U)\|g\|_{H_{k(\text{sepMat})}(U)} \leq \|g\|_{H_{\otimes_{j=1}^{d_u}}^{\nu_j+1/2}(U)} \leq C_{\text{up}}'(\theta; U)\|g\|_{H_{k(\text{sepMat})}(U)}. \]

We will write \( \{\beta_j\} \leq \{\alpha_j\} \) if \( \beta_j \leq \alpha_j \) for all \( 1 \leq j \leq d_u. \)

For our further analysis, we now want to make use of the convergence results from [24], related results are also found in [31] and the references in [24]. For the design points \( D_N, \) we will use Smolyak sparse grids [4]. For \( 1 \leq j \leq d_u, \) we choose a sequence \( X_j^{(i)} := \{x_j^{(i)}, \ldots, x_{j,m_j}^{(i)}\}, \) \( i \in \mathbb{N}, \) of nested sets of points in \( U_j. \) We then define the sparse grid \( H(q,d_u) \subseteq U, \) as the set of points
\[ H(q,d_u) := \bigcup_{|i| = q} X_1^{(i_1)} \times \cdots \times X_{d_u}^{(i_{d_u})}, \tag{3.2} \]
where \( |i| = i_1 + \cdots + i_{d_u} \) for a multi-index \( i \in \mathbb{N}^{d_u}, \) and \( q \geq d_u. \) We denote by \( N = N(q,d_u) \) the number of points in the sparse grid \( H(q,d_u). \)

We then have the following equivalent of Theorem 3.4 which is again concerned with the convergence as \( N \to \infty. \)

**Theorem 3.9.** (Convergence in \( N \) of \( m_N^g(\hat{\theta}N) \)) Suppose we have a sequence of estimates \( \{\hat{\theta}N\}_{N=1}^\infty \subseteq S, \) for some compact set \( S \subseteq \mathbb{R}^d. \) Assume
(a) \( U = \prod_{j=1}^{d_u} U_j \), with \( U_j \subset \mathbb{R} \) bounded,

(b) \( D_N \) is chosen as the Smolyak sparse grid \( H(q,d_u) \), for some \( q \geq d_u \), with

\[
    h_{X_j^{(i)}(U)} \leq C_1 m_i^{-r_h}, \quad \text{and} \quad \rho_{X_j^{(i)}(U)} \leq C_2 m_i^{r_\rho},
\]

for positive constants \( C_1, C_2, r_h \) and \( r_\rho \) independent of \( m_i \) and \( j \),

(c) the native space \( H_{k(\theta)}(U) \) is isomorphic to a tensor product Sobolev space \( H_{\otimes d_u}^{(r_j(\theta))}(U) \),

(d) \( f \in H_{\otimes d_u}^{(r_j)}(U) \), for some \( \{\tilde{r}_j\} \) such that \( \min_{1 \leq j \leq d_u} \tilde{r}_j \geq 1 \),

(e) \( m(\theta) \in H_{\otimes d_u}^{(r_j)}(U) \) for all \( \theta \in S \),

(f) for some \( N^* \in \mathbb{N} \), the quantities \( r_{j,-} := \inf_{N \geq N^*} r_j(\tilde{\theta}_N) \) and \( r_{j,+} := \sup_{N \geq N^*} r_j(\tilde{\theta}_N) \) satisfy \( \min_{1 \leq j \leq d_u} r_{j,-} \geq 1 \).

Then there exists a constant \( C \), which is independent of \( f \) and \( N \), such that

\[
    \|f - m_N^f(\tilde{\theta}_N)\|_{H_{\otimes d_u}^{(r_j)}(U)} \leq C N^{-\alpha} \log N^{(1+\alpha')(1+d_u)} \left( \|f\|_{H_{\otimes d_u}^{(r_j)}(U)} + \sup_{N \geq N^*} \|m(\tilde{\theta}_N)\|_{H_{\otimes d_u}^{(r_j)}(U)} \right),
\]

for any \( \{\beta_j\} \subseteq \{\tilde{r}_j\} \) and \( N \geq N^* \), where

\[
    \alpha = \min_{1 \leq j \leq d_u} r_h(\min\{\tilde{r}_j, r_{j,-}\} - \beta_j) - r_\rho \max\{r_{j,+} - \tilde{r}_j, 0\},
\]

and

\[
    \alpha' = \min_{1 \leq j \leq d_u} r_h(\min\{\tilde{r}_j, r_{j,+}\} - \beta_j) - r_\rho \max\{r_{j,-} - \tilde{r}_j, 0\},
\]

Proof. Theorem 3.3 is based on a generalisation of [24, Theorem 3], to the case where the function \( f \) is not necessary in the native space of the kernel used to construct \( m_N^f(\tilde{\theta}_N) \). The structure of the proof remains identical, and we only need to replace [24, Proposition 4] with a corresponding result. All other assumptions required for [24, Theorem 3] remain valid.

So let \( U' \subseteq \mathbb{R} \) be bounded, and let \( X_n := \{x_1, \ldots, x_n\} \subseteq U' \) be a set of \( n \) points in \( U' \). For any \( r \geq 1 \) and \( \beta \leq r \), let us denote by \( \text{Id} : H^r(U') \to H^\beta(U') \) the identity operator, and by \( S_{X_n}^\theta : H^r(U') \to H^\beta(U') \) the interpolation operator defined by \( S_{X_n}^\theta(g) = m_{n,0}(\theta) \) (defined as in (3.1) with \( m = 0 \)). Using [24, Theorems 4.1 and 4.2], we immediately have

\[
    \|\text{Id} - S_{X_n}^\theta\|_{H^r(U') \to H^\beta(U')} := \sup_{\|g\|_{H^r(U')} = 1} \|g - m_{n,0}(\theta)\|_{H^\beta(U')}
\]

\[
    \leq C(\theta; U') h_{X_n,U'}^{\min(r,r(\theta)) - \beta \max(r(\theta) - r, 0)},
\]

for any \( \beta \leq r \), where \( H^r(U') \) is the reproducing kernel Hilbert space corresponding to \( k(\theta) \) used to construct \( m_{n,0}^f(\theta) \). The fill distance \( h_{X_n,U'} \) and mesh ratio \( \rho_{X_n,U'} \) are as defined in (3.1), and the constant \( C(\theta; X) \) depends on \( \theta \) only through the constant \( C_{up}(\theta; U') C_{low}(\theta; U')^{-1} \) appearing in the inequality \( \|m_{n,0}^f(\theta)\|_{H^r(U')} \leq C_{up}(\theta; U') C_{low}(\theta; U')^{-1} \|g\|_{H^r(U')} \).

Following the proof of [24, Theorem 3] and replacing [24, Proposition 4] with (3.3), gives

\[
    \|g' - m_{N,0}^f(\theta)\|_{H_{\otimes d_u}^{(r_j)}(U)} \leq C(\theta) N^{-\alpha(\theta)} \log N^{(1+\alpha(\theta))(d_u+1)} \|g'\|_{H_{\otimes d_u}^{(r_j)}(U)},
\]

(3.4)
for any \( \{ \beta_j \} \leq \{ \tilde{r}_j \} \) and \( g' \in H^{(\tilde{r}_j)}_{\otimes d_u} (U) \), where
\[
\alpha (\theta) = \min_{1 \leq j \leq d_u} r_h (\min \{ \tilde{r}_j , r_j (\theta) \} - \beta_j) - r_\rho \max \{ r_j (\theta) - \tilde{r}_j , 0 \}.
\]

By [24, Remark 4], the constant \( C(\theta) \) depends on \( \theta \) only through \( \prod_{j=1}^{d_u} C(\theta; U_j)^{\alpha (\theta)} \), where \( C(\theta; U_j) \) is the constant appearing in (3.3). To finish the proof, we use the triangle inequality and the equality \( m_N^f (\tilde{\theta}_N) = m_N^{f,0} (\tilde{\theta}_N) + m (\tilde{\theta}_N) - m_N^{m,0} (\tilde{\theta}_N) \), and apply (3.4):
\[
\| f - m_N^f (\tilde{\theta}_N) \|_{H^{(\beta_j)}_{\otimes d_u} (U)} \leq \| f - m_N^{f,0} (\tilde{\theta}_N) \|_{H^{(\beta_j)}_{\otimes d_u} (U)} + \| m (\tilde{\theta}_N) - m_N^{m,0} (\tilde{\theta}_N) \|_{H^{(\beta_j)}_{\otimes d_u} (U)} \\
\leq C (\tilde{\theta}_N) N^{-\alpha (\tilde{\theta}_N)} | \log N |^{(1+\alpha (\tilde{\theta}_N))(d_u+1)} \left( \| f \|_{H^{(r_j)}_{\otimes d_u} (U)} + \| m (\tilde{\theta}_N) \|_{H^{(r_j)}_{\otimes d_u} (U)} \right).
\]

The claim then follows by the compactness of \( S \).

Many of the same comments apply as to Theorem 3.4. Assumption (a) means that the domain \( U \) is of tensor-product structure, which is natural when using tensor-product kernels, and is satisfied, for example, for the unit cube \( U = [0, 1]^{d_u} \).

Assumption (b) is a specific choice of design points \( D_N \), and in contrast to Theorem 3.4, the choice of design points \( D_N \) as a sparse grid is explicitly used in the proof and is crucial for obtaining the error bound. The values of \( r_h \) and \( r_\rho \) will depend on the particular choice of one-dimensional point sets. A particular choice of one-dimensional nested point sets are the Clenshaw-Curtis point sets \( X_{CC}^{(i)} \), defined on \([-1, 1]\) by \( m_i = 2^{(i-1)} + 1 \), \( X_{CC}^{(1)} = \{ 0 \} \) and
\[
x_{j,n}^{(i)} = - \cos \left( \frac{\pi (n-1)}{m_i - 1} \right), \quad 1 \leq n \leq m_i.
\]

General intervals \([a, b]\) can be dealt with through a linear transformation. For this particular point set, we can use the Lipschitz continuity of the cosine function, together with Kober’s inequality \( \cos (x) \leq 1 - \frac{x^2}{2} \) for \( x \in [0, \frac{\pi}{2}] \), to show that \( h_{X_{CC}^{(i)}, U_j} \leq C_1 m_i^{-1} \) and \( \rho_{X_{CC}^{(i)}, U_j} \leq C_2 m_i \). This shows that assumption (b) is satisfied for Clenshaw-Curtis point sets, with \( r_h = r_\rho = 1 \).

Assumption (c) reiterates that the native space of the separable Matérn kernel is a tensor-product Sobolev space, and Theorem 3.9 applies to any kernel with such a native space.

Assumption (d) is a regularity assumption on \( f \), and again roughly corresponds to the function \( f \) being at least continuous. We would ideally have the restriction \( \min_{1 \leq j \leq d_u} \tilde{r}_j > 1/2 \); however, we need a slightly stronger restriction due to some technicalities in the proof (cf Remark 3.6). The so-called mixed regularity of \( f \) assumed here is crucial to obtaining the error bound in Theorem 3.9.

Note in particular that the convergence rate in \( N \) is (up to logarithmic factors) independent of the dimension \( d_u \), and can in high dimensions be much larger than the convergence rate obtained in Theorem 3.4. Theorem 3.9 does not require the function \( f \) to be in the native space of any of the kernels \( k(\theta_N) \). Optimal convergence rates are again obtained when the estimated smoothness matches the true smoothness of \( f \).

Assumption (e) ensures that the mean \( m \) is at least as smooth as the function \( f \), but this can again be relaxed. The assumptions on the estimated hyper-parameters \( \{ \nu_j , \lambda_j \}_{j=1}^{d_u} \) and \( \sigma^2 \) are again very mild. \( \{ \lambda_j \}_{j=1}^{d_u} \) and \( \sigma^2 \) are simply required to be bounded away from zero and infinity, and we require only a slightly larger lower bound on \( \nu_j \) (cf assumption (f)).
3.2.2 Predictive Variance

Next, we investigate the predictive variance $k_N(\hat{\theta}_N)$, proving the convergence of $k_N(\hat{\theta}_N)$ to 0 as $N \to \infty$.

**Theorem 3.10.** (Convergence in $N$ of $k_N(\hat{\theta}_N)$) Let the assumptions of Theorem 3.8 hold. Then there exists a constant $C$, independent of $N$, such that

$$\|k_N^{1/2}(\hat{\theta}_N)\|_{L^2(U)} \leq CN^{-\alpha}|\log N|^{(1+\alpha')/(d_u+1)}$$

for any $N \geq N^*$ and $\varepsilon > 0$, where

$$\alpha = \min_{1 \leq j \leq d_u} r_h(\min\{\tilde{r}_j, r_{j,+}\} - 1/2 - \varepsilon) - r_\rho \max\{r_{j,-} - \tilde{r}_j, 0\},$$

and $\alpha' = \min_{1 \leq j \leq d_u} r_h(\min\{\tilde{r}_j, r_{j,+}\} - 1/2 - \varepsilon) - r_\rho \max\{r_{j,-} - \tilde{r}_j, 0\}$.

**Proof.** The proof is identical to Theorem 3.7 using Theorem 3.9 instead of Theorem 3.4.

3.3 Point-wise prediction error

We now briefly discuss the point-wise prediction error, i.e. the error in using $m_N^f(\hat{\theta}_N)$ or $f_N(\hat{\theta}_N)$ to predict $f(u)$, for an unobserved location $u \in U \setminus D_N$.

For prediction using the mean $m_N^f(\hat{\theta}_N)$, we immediately obtain an error bound using Theorem 3.4 or 3.9 together with the Sobolev embedding theorem:

$$|f(u) - m_N^f(\hat{\theta}_N; u)| \leq \sup_{u \in U} |f(u) - m_N^f(\hat{\theta}_N; u)| \leq \begin{cases} C\|f - m_N^f(\hat{\theta}_N)\|_{H^{d_u/2+\varepsilon}(U)}, & \text{in the set-up of Theorem 3.4} \\ C\|f - m_N^f(\hat{\theta}_N)\|_{H_0^{1/2+\varepsilon}(U)^1}, & \text{in the set-up of Theorem 3.9} \end{cases}$$

Convergence of this prediction error to zero as $N \to \infty$ then follows, under very mild assumptions on the estimated hyper-parameters (as in Theorem 3.4 or 3.9).

For prediction using the predictive process $f_N(\hat{\theta}_N)$, we obtain a bound on the error

$$\mathbb{E}((f(u) - f_N(\hat{\theta}_N; u)^2))^{1/2} = k_N(\hat{\theta}_N; u, u)^{1/2},$$

where the expectation is over the distribution of $f_N(\hat{\theta}_N)$. As in the proof of Theorem 3.7, we use Theorem 3.4 or 3.9 together with Proposition 3.2 and the Sobolev embedding theorem:

$$k_N(\hat{\theta}_N; u, u)^{1/2} \leq \sup_{u \in U} k_N(\hat{\theta}_N; u, u)^{1/2} \leq \begin{cases} C \sup_{\|g\|_{H_{k_0}(\theta)}} \|g - m_N^g(\hat{\theta}_N)\|_{H^{d_u/2+\varepsilon}(U)}, & \text{in the set-up of Theorem 3.4} \\ C \sup_{\|g\|_{H_{k_0}(\theta)}} \|g - m_N^g(\hat{\theta}_N)\|_{H_0^{1/2+\varepsilon}(U)^1}, & \text{in the set-up of Theorem 3.9} \end{cases}$$

Convergence of this prediction error to zero as $N \to \infty$ then follows, under very mild assumptions on the estimated hyper-parameters (as in Theorem 3.4 or 3.9).

We can also obtain convergence rates for the prediction error

$$\mathbb{E}((f(u) - m_N^f(\hat{\theta}_N; u)^2))^{1/2},$$
where the expected value is now over some probability distribution over $f$. In particular, consider the setting $f \sim \text{GP}(0, k(\theta_0; \cdot, \cdot))$, for some true value $\theta_0$ of the hyper-parameters, as was used in section 2.3. Assume for simplicity that we are using Matèrn kernels; similar arguments apply in the case of separable Matèrn kernels.

Every sample of the Gaussian process $\text{GP}(0, k(\theta_0; \cdot, \cdot))$ belongs to the Sobolev space $H^{\nu_0}(U)$. Hence, we can apply Theorem 3.4 sample-wise, with $\tilde{\tau} = \nu_0$. If the estimated hyper-parameter $\hat{\theta}_N = \hat{\theta}$ is independent of $f$, then the error bounds on $|f(u) - m^f_N(\hat{\theta}; u)|$ coming from Theorem 3.4 depend on $f$ only through $\|f\|_{H^{\nu_0}(U)}$, from which it follows that

$$
\mathbb{E}_{\theta_0}(\langle f(u) - m^f_N(\hat{\theta}; u) \rangle)^{1/2} \leq C \left( h_{D_N,U}^{\min(\nu_0, \tau_-)} - d_\nu/2 - \varepsilon \max(\nu^0, \nu_0, 0) \right) \mathbb{E}_{\theta_0}(\|f\|_{H^{\nu_0}(U)})^{1/2}.
$$

Since $\mathbb{E}_{\theta_0}(\|f\|_{H^{\nu_0}(U)})^{1/2} < \infty$ (see e.g. [39]), the above gives convergence to zero of the prediction error as $N$ tends to $\infty$, under the assumptions of Theorem 3.4. Note that this does not require any particular relation between the true hyper-parameters $\theta_0$ and the estimated hyper-parameters $\hat{\theta}$.

If the observed values of $f$ at the design points $D_N$ is used to form the estimate $\hat{\theta}_N$, then

$$
\mathbb{E}_{\theta_0}(\langle f(u) - m^f_N(\hat{\theta}_N; u) \rangle)^{1/2} \leq C \sup_{f \in H^{\nu_0}(U)} \left( h_{D_N,U}^{\min(\nu_0, \tau_-)} - d_\nu/2 - \varepsilon \max(\nu^0, \nu_0, 0) \right) \mathbb{E}_{\theta_0}(\|f\|_{H^{\nu_0}(U)})^{1/2},
$$

and convergence to zero as $N \to \infty$ is again guaranteed. The restrictions on $\hat{\tau}_N$ and $\hat{\lambda}_N$ are unchanged from Theorem 3.4. The restrictions on $\hat{\nu}_N$ become slightly stronger, and require the quantities $\tau_-$ and $\tau_+$ to be uniformly bounded in $f$. This can easily be achieved by imposing a fixed upper and lower bound on $\hat{\nu}_N$, which is independent of the observed function values $f(u^1), \ldots, f(u^N)$.

## 4 Bayesian Inverse Problems

The inverse problem of interest is to determine the unknown parameters $u \in U$ from noisy data $y \in \mathbb{R}^d_y$ given by

$$
y = \mathcal{G}(u) + \eta. \tag{4.1}
$$

We assume that the noise $\eta$ is a realisation of the $\mathbb{R}^d_y$-valued Gaussian random variable $\mathcal{N}(0, \Gamma)$, for some known, positive-definite covariance matrix $\Gamma$, and that the parameter space $U$ is a compact subset of $\mathbb{R}^d_u$. The map $\mathcal{G}$ will be referred to as the parameter-to-observation map or forward model. For $x \in \mathbb{R}^m, m \in \mathbb{N}$, we denote by $\|x\|_A = x^TA^{-1}x$ the norm weighted by (the inverse of) a positive-definite matrix $A \in \mathbb{R}^{m \times m}$.

We adopt a Bayesian perspective in which, in the absence of data, $u$ is distributed according to a prior measure $\mu_0$. We are interested in the posterior distribution $\mu^y$ on the conditioned random variable $u|y$, which can be characterised as follows.

**Proposition 4.1.** ([16, 38]) Suppose $\mathcal{G} : U \to \mathbb{R}^d_y$ is continuous and $\mu_0(U) = 1$. Then the posterior distribution $\mu^y$ on the conditioned random variable $u|y$ is absolutely continuous with respect to $\mu_0$ and given by Bayes’ Theorem:

$$
\frac{d\mu^y}{d\mu_0}(u) = \frac{1}{Z} \exp \left( - \Phi(u) \right),
$$

where

$$
\Phi(u) = \frac{1}{2} \|y - \mathcal{G}(u)\|_\Gamma^2 \quad \text{and} \quad Z = \mathbb{E}_{\mu_0} \left( \exp \left( - \Phi(u) \right) \right).
$$
Common to many of practical applications is that the evaluation of the parameter-to-observation map $G$ is analytically impossible and computationally very expensive, and, in simulations, it is therefore often necessary to approximate $G$ (or directly $\Phi$) by a surrogate model. In this work, we are interested in Gaussian process emulators as surrogate models, as already discussed in [37].

Remark 4.2. (Distribution of the noise $\eta$) The assumption that the distribution of the observational noise $\eta$ is Gaussian with zero mean is not essential, and is for ease of presentation only. Inclusion of a non-zero mean, representing for example model discrepancy [17], is straightforward, and leads only to a shift in the misfit functional $\Phi$. Other distributions, leading to other forms of the log-likelihood $\Phi$, are also possible, and it is only the smoothness of $\Phi$ as a function of $u$ that is important for the analysis presented in this paper. See for example [19] for a more general formulation.

5 Approximation of the Bayesian Posterior Distribution

We now use the hierarchical Gaussian process emulator to define computationally cheaper approximations to the Bayesian posterior distribution $\mu^y$. We will consider emulation of either the parameter-to-observation map $G: U \rightarrow \mathbb{R}^d_y$ or the negative log-likelihood $\Phi : U \rightarrow \mathbb{R}$. An emulator of $G$ in the case $d_y > 1$ is constructed by emulating each entry independently.

The analysis presented in this section is for the most part independent of the specific covariance kernel used to construct the Gaussian process emulator. When the analysis does depend on the covariance kernel, we again consider the classical and separable Matern families.

5.1 Approximation Based on the Predictive Mean

Using simply the predictive mean of a Gaussian process emulator of the parameter-to-observation map $G$ or the negative log-likelihood $\Phi$, we can define the approximations $\mu_{\text{mean}}^{y,N,G,\theta}$ and $\mu_{\text{mean}}^{y,N,\Phi,\theta}$, given by

$$\frac{d\mu_{\text{mean}}^{y,N,G,\theta}}{d\mu_0}(u) = \frac{1}{Z_{\text{mean}}^{N,G,\theta}} \exp\left(-\frac{1}{2} \|y - m_{y,N}^G(\theta; u)\|^2\right),$$

$$Z_{\text{mean}}^{N,G,\theta} = \mathbb{E}_{\mu_0}\left(\exp\left(-\frac{1}{2} \|y - m_{y,N}^G(\theta)\|^2\right)\right),$$

$$\frac{d\mu_{\text{mean}}^{y,N,\Phi,\theta}}{d\mu_0}(u) = \frac{1}{Z_{\text{mean}}^{N,\Phi,\theta}} \exp\left(-m_{y,N}^\Phi(\theta; u)\right),$$

$$Z_{\text{mean}}^{N,\Phi,\theta} = \mathbb{E}_{\mu_0}\left(\exp\left(-m_{y,N}^\Phi(\theta)\right)\right),$$

where $m_{y,N}^G(\theta; u) = [m_{y,1,N}^G(\theta; u), \ldots, m_{y,d_y,N}^G(\theta; u)] \in \mathbb{R}^{d_y}$.

We have the following result on the convergence of the approximate posterior distributions. A combination of Theorem 5.1 with Theorem 3.4 or Theorem 3.9 allows us to obtain convergence rates in $N$ for the error in approximate posterior distributions.

Theorem 5.1. Suppose we have a sequence of estimates $\{\hat{\theta}_N\}_{N=1}^{\infty} \subseteq S$, for some compact set $S \subseteq \mathbb{R}_\theta$. Assume

(a) $U \subseteq \mathbb{R}^{d_u}$ is bounded,
(b) \( \sup_{u \in U} \| G(u) - m_N^G(\hat{\theta}_N; u) \| \) and \( \sup_{u \in U} | \Phi(u) - m_N^\Phi(\hat{\theta}_N; u) | \) can be bounded uniformly in \( N \).

(c) \( \sup_{u \in U} \| G(u) \| \leq C_G < \infty \).

Then there exist constants \( C_1 \) and \( C_2 \), independent of \( N \), such that
\[
d_{\text{Hil}}(\mu^y, \mu_{\text{mean}}^{y,N,G,\hat{\theta}_N}) \leq C_1 \left\| G - m_N^G(\hat{\theta}_N) \right\|_{L^2_{\text{eq}}(U; \mathbb{R}^d_y)},
\]
and
\[
d_{\text{Hil}}(\mu^y, \mu_{\text{mean}}^{y,N,\Phi,\hat{\theta}_N}) \leq C_2 \left\| \Phi - m_N^\Phi(\hat{\theta}_N) \right\|_{L^2_{\text{eq}}(U)}.
\]

Proof. This is essentially [37, Theorem 4.2]. The change from the distribution \( \eta \sim \mathcal{N}(0, \sigma_0^2 I) \), considered in [37], to the more general distribution \( \eta \sim \mathcal{N}(0, \Gamma) \) considered here in (4.1), only influences the values of the constants \( C_1 \) and \( C_2 \), since all norms on \( \mathbb{R}^d_y \) are equivalent. The constants \( C_1 \) and \( C_2 \) involve taking the supremum over \( \hat{\theta}_N \) over the corresponding constants in [37, Theorem 4.2], and we use the compactness of \( S \) to make sure this can be bounded independently of \( N \). Furthermore, it is sufficient for the quantities in (b) to be bounded uniformly in \( N \) rather than converging to 0 as \( N \) tends to infinity (cf [37, Proof of Lemma 4.1]).

Since Theorems 3.4 and 3.9 hold only on bounded domains \( U \), we have for simplicity assumed that \( U \) is bounded in assumption (a). This assumption can be relaxed in general. Assumption (b) is required to ensure the constants \( C_1 \) and \( C_2 \) are independent of \( N \). Assumption (c) is satisfied for example when \( G \) is continuous on \( \overline{U} \).

### 5.2 Approximation Based on the Predictive Process

We now consider approximations to the posterior distribution \( \mu^y \) obtained using the full predictive processes \( G_N \) and \( \Phi_N \). In contrast to the mean, the full Gaussian process also carries information about the uncertainty in the emulator due to only using a finite number of function evaluations to construct it. Randomising the approximations to \( G \) and \( \Phi \), with the randomness tuned to represent the surrogate modelling error, can be crucial to obtaining statistically efficient sampling algorithms for the approximate posterior distributions [37].

For the remainder of this section, we denote by \( \nu_{\nu,N}^G,\theta \) the distribution of \( G_N(\theta) \) and by \( \nu_{\nu,N}^\Phi,\theta \) the distribution of \( \Phi_N(\theta) \), for \( N \in \mathbb{N} \). The process \( G_N \) consists of \( d_y \) independent Gaussian processes \( G_{N,j} \), so the measure \( \nu_{\nu,N}^G,\theta \) is a product measure, \( \nu_{\nu,N}^G,\theta \equiv \prod_{j=1}^{d_y} \nu_{\nu,N}^{G_{N,j},\theta} \). \( \Phi_N \) is a Gaussian process with mean \( m_N^\Phi \) and covariance kernel \( k_N \), and \( G_{N,j} \), for \( j = 1, \ldots, d_y \), is a Gaussian process with mean \( m_{N,j}^{G_j} \) and covariance kernel \( k_N \). Replacing \( G \) by \( G_N \) in (4.1), we obtain the approximation \( \mu_{\text{sample}}^{y,N,G,\theta} \) given by
\[
\frac{d \mu_{\text{sample}}^{y,N,G,\theta}}{d \mu_0}(u) = \frac{1}{Z_{\text{sample}}^{N,G,\theta}} \exp \left( -\frac{1}{2} \left\| y - G_N(\theta; u) \right\|_I^2 \right),
\]
where
\[
Z_{\text{sample}}^{N,G,\theta} = \mathbb{E}_{\mu_0} \left( \exp \left( -\frac{1}{2} \left\| y - G_N(\theta) \right\|_I^2 \right) \right).
\]

Similarly, we define for the predictive process \( \Phi_N \) the approximation \( \mu_{\text{sample}}^{y,N,\Phi,\theta} \) by
\[
\frac{d \mu_{\text{sample}}^{y,N,\Phi,\theta}}{d \mu_0}(u) = \frac{1}{Z_{\text{sample}}^{N,\Phi,\theta}} \exp \left( -\Phi_N(\theta; u) \right), \quad Z_{\text{sample}}^{N,\Phi,\theta} = \mathbb{E}_{\mu_0} \left( \exp \left( -\Phi_N(\theta) \right) \right).
\]
The measures $\mu_{\text{sample}}^{y,\mathcal{G},\theta}$ and $\mu_{\text{sample}}^{y,\Phi,\theta}$ are random approximations of the deterministic measure $\mu^y$. The uncertainty in the posterior distribution introduced in this way can be thought of representing the uncertainty in the emulator, which in applications can be large (or comparable) to the uncertainty present in the observations. A user may want to take this into account to “inflate” the variance of the emulator, which in applications can be large (or comparable) to the uncertainty in the posterior distribution introduced in this way can be thought of representing the uncertainty in the posterior distribution and avoid over-confident inference.

Deterministic approximations of the posterior distribution $\mu^y$ can now be obtained by fixing a sample of $\mathcal{G}_N$ or $\Phi_N$, or by taking the expected value with respect to the distribution of the Gaussian processes. The latter results in the marginal approximations involves computing an expectation, and methods from the pseudo-marginal MCMC literature can be used within an MCMC method in this context.

We have the following result on the convergence of the approximate posterior distributions, which can then be combined with Theorems 3.14 and 3.7 or Theorems 3.9 and 3.10 to obtain convergence rates in $N$ for the error in approximate posterior distributions (cf [37, Corollary 4.10 and 4.12]). This requires the parameter-to-observation map $\mathcal{G}$ to be sufficiently smooth.

**Theorem 5.2.** Suppose we have a sequence of estimates $\{\hat{\theta}_N\}_{N=1}^\infty \subseteq$, for some compact set $S \subseteq \mathbb{R}_\theta$.

Assume

(a) $U \subseteq \mathbb{R}^{d_u}$ is bounded,

(b) $\sup_{u \in U} \left\| \mathcal{G}(u) - m^\mathcal{G}_N(\hat{\theta}_N; u) \right\|$ and $\sup_{u \in U} \left| \Phi(u) - m^\Phi_N(\hat{\theta}_N; u) \right|$ can be bounded uniformly in $N$, and $\sup_{u \in U} k_N(\hat{\theta}_N; u, u)$ converges to 0 as $N$ tends to infinity,

(c) $\sup_{u \in U} \left\| \mathcal{G}(u) \right\| \leq C_{\mathcal{G}} < \infty$,

(d) $\mathbb{E} \left( \sup_{u \in U} \left( \Phi_N(u) - m^\Phi_N(\hat{\theta}_N; u) \right) \right)$ and $\mathbb{E} \left( \sup_{u \in U} \left( \mathcal{G}_N(u) - m^\mathcal{G}_N(\hat{\theta}_N; u) \right) \right)$, for $1 \leq j \leq d_y$, can be bounded uniformly in $N$.

Then there exist constants $C_1, C_2, C_3$ and $C_4$, independent of $N$, such that for any $\delta > 0$,

$$d_{\text{Hell}}(\mu^y, \mu_{\text{marginal}}^{y,\mathcal{G}}) \leq C_1 \left\| \mathbb{E}_{\nu_N}^{\mathcal{G}} \left( \left\| \mathcal{G} - \mathcal{G}_N(\hat{\theta}_N) \right\|^{1+\delta} \right) \right\|_{L^2_{\mu}(U)},$$

$$d_{\text{Hell}}(\mu^y, \mu_{\text{marginal}}^{y,\Phi}) \leq C_2 \left\| \mathbb{E}_{\nu_N}^{\Phi} \left( \left\| \Phi - \Phi_N(\hat{\theta}_N) \right\|^{1+\delta} \right) \right\|_{L^2_{\mu}(U)},$$

$$d_{\text{Hell}}(\mu^y, \mu_{\text{marginal}}^{y,\mathcal{G}}, \mu_{\text{marginal}}^{y,\Phi}) \leq \max\{C_1, C_2\} \left\| \mathbb{E}_{\nu_N} \left( \left\| \mathcal{G} - \mathcal{G}_N(\hat{\theta}_N) \right\|^{1+\delta} \right) \right\|_{L^2_{\mu}(U)} + \max\{C_1, C_2\} \left\| \mathbb{E}_{\nu_N} \left( \left\| \Phi - \Phi_N(\hat{\theta}_N) \right\|^{1+\delta} \right) \right\|_{L^2_{\mu}(U)}.$$
and
\[
\left( \mathbb{E}_{\mathcal{G}_N} \left( d_{\text{Hell}}(\mu^y, \mu_{\text{sample}}^y) \right)^2 \right)^{1/2} \leq C_5 \left\| \mathbb{E}_{\mathcal{G}_N} \left( \| \mathcal{G} - \mathcal{G}_N(\hat{\theta}_N) \|^2 + \delta \right) \right\|_{L^2_{\mu_0}(U)},
\]
\[
\left( \mathbb{E}_{\mathcal{G}_N} \left( d_{\text{Hell}}(\mu^y, \mu_{\text{sample}}^y) \right)^2 \right)^{1/2} \leq C_4 \left\| \mathbb{E}_{\mathcal{G}_N} \left( \| \mathcal{Phi} - \Phi_N(\hat{\theta}_N) \|^2 + \delta \right) \right\|_{L^2_{\mu_0}(U)}.
\]

Proof. This is essentially [37, Theorems 4.9 and 4.11]. As in Theorem [5.1], it is sufficient for the first two quantities in (b) to be bounded uniformly in \( N \) rather than converging to 0 as \( N \) tends to infinity (cf. [37, Proof of Lemma 4.7]), and the change in the distribution of \( \eta \) in [4.1] only influences the constants. In [37], assumption (d) is replaced by an assumption involving the Sudakov-Fernique inequality (see Proposition [5.3] below), which is a sufficient condition for (d) to hold. However, that assumption is not satisfied in the case of the hierarchical Gaussian process emulators considered here, so we have introduced the more general assumption (d).

We have for simplicity again assumed that \( U \) is bounded in assumption (a). This assumption can be relaxed in general; see [19] for a more general statement of 5.2. Assumptions (b) and (d) are required to ensure the constants \( C_1, C_2, C_3 \) and \( C_4 \) are independent of \( N \). Assumption (c) is satisfied for example when \( \mathcal{G} \) is continuous on \( U \).

To verify assumption (d) in Theorem 5.1, we make use of the following two results.

**Proposition 5.3.** (Sudakov-Fernique Inequality, [27]) Let \( g \) and \( h \) be scalar, almost surely bounded Gaussian fields on the compact domain \( U \subseteq \mathbb{R}^d \). Suppose \( \mathbb{E}(g(u) - g(u'))^2 \leq \mathbb{E}(h(u) - h(u'))^2 \) and \( \mathbb{E}(g(u)) = \mathbb{E}(h(u)) \), for all \( u, u' \in U \). Then
\[
\mathbb{E}(\sup_{u \in U} g(u)) \leq \mathbb{E}(\sup_{u \in U} h(u)).
\]

**Proposition 5.4.** (Dudley’s Inequality, [11, 18]) Let \( g \) be a scalar Gaussian field on the compact domain \( U \subseteq \mathbb{R}^d \), with zero mean \( \mathbb{E}(g(u)) = 0 \), and define on \( U \) the pseudo-metric \( d_g(u, u') = \mathbb{E}(g(u) - g(u'))^2 \). For \( \epsilon > 0 \), denote by \( M(U, d_g, \epsilon) \) the minimal number of open \( d_g \)-balls of radius \( \epsilon \) required to cover \( U \). Then
\[
\mathbb{E}(\sup_{u \in U} g(u)) \leq C_D \int_0^\infty \sqrt{\log M(U, d_g, \epsilon)} \, d\epsilon,
\]
for a constant \( C_D \) independent of \( g \).

The Sudakov-Fernique inequality is a comparison inequality between Gaussian processes, whereas Dudley’s inequality relates extreme values of a Gaussian process to its metric entropy. These results can be used to verify assumption (d) in Theorem 5.1 for general covariance functions \( k(\theta) \), but we will in the following lemma concentrate on the particular case of covariance kernels chosen from the Matérn family or the separable Matérn family.

**Lemma 5.5.** Suppose \( U \subseteq \mathbb{R}^d \) is compact, and \( k(\theta) \) is chosen as either the Matérn kernel in (2.5) with \( \theta = \{\nu, \lambda, \sigma^2\} \) and \( \nu \geq \frac{1}{2} \), or the separable Matérn kernel in (2.6), with \( \theta = \{\nu_j \}_{j=1}^{d_u}, \{\lambda_j \}_{j=1}^{d_u}, \sigma^2 \) and \( \nu_j \geq 1/2 \), for \( 1 \leq j \leq d_u \). Assume \( \hat{\theta}_k \}_{k \in \mathbb{N}} \subseteq \mathbb{S} \), for some bounded set \( S \subseteq (0, \infty)^{d_u} \). Then there exists a constant \( C \), independent of \( N \), such that
\[
\mathbb{E}(\sup_{u \in U} \Phi_N(u) - m_N^\Phi(\hat{\theta}_N; u)) \leq C, \quad \text{and} \quad \mathbb{E}(\sup_{u \in U} G_N(u) - m_N^G(\hat{\theta}_N; u)) \leq C, \quad j = 1, \ldots, d_y.
\]
Proof. We will give the proof for $\Phi$, the proof for $G^j$ is similar. By [37, Lemma 4.8], it follows that the assumptions of Proposition 5.3 are satisfied with $g = \Phi_N - m_\Phi(\hat{\theta}_N)$ and $h = \Phi_N$, where $\Phi_N$ is the Gaussian process with mean zero and covariance kernel $k(\hat{\theta}_N)$. We hence have
\[
\mathbb{E}\left(\sup_{u \in U} (\Phi_N(u) - m_\Phi(\hat{\theta}_N; u))\right) \leq \mathbb{E}(\sup_{u \in U} \Phi_N(u)).
\]
We now use Proposition 5.4, and consider separately the two types of covariance functions.

The covariance kernel $k_{\text{Mat}}(\hat{\theta}_N)$ is Lipschitz continuous for any $\nu \geq 1/2$ (see e.g. [25, Lemma C.1]), and so
\[
|k(\hat{\theta}_N; u_1, u_2) - k(\hat{\theta}_N; u_1', u_2')| \leq L(\hat{\theta}_N)||u_1 - u_2||_2 - ||u_1' - u_2'||_2.
\]
Thus, for any $u, u' \in U$,
\[
d_{\Phi_N}(u, u')^2 = \mathbb{E}\left((\Phi_N(u) - \Phi_N(u'))^2\right)
= k_{\text{Mat}}(\hat{\theta}_N; u, u) - k_{\text{Mat}}(\hat{\theta}_N; u, u') - k_{\text{Mat}}(\hat{\theta}_N; u', u) + k_{\text{Mat}}(\hat{\theta}_N; u', u')
\leq 2L(\hat{\theta}_N)||u - u'||_2
\leq \bar{C}||u - u'||_2,
\]
where $\bar{C} = 2\sup_{\hat{\theta}_N \in S} L(\hat{\theta}_N)$ is finite and independent of $N$. It follows that $M(U, d_{\Phi_N}, \epsilon) \sim \epsilon^{-2d_u}$ can be chosen independently of $N$, which together with Proposition 5.4 gives
\[
\mathbb{E}(\sup_{u \in U} \Phi_N(u)) \leq C_D \int_0^\infty \sqrt{\log M(U, d_{\Phi_N}, \epsilon)}d\epsilon \leq C' < \infty,
\]
where $C'$ is independent of $N$.

The proof for $k_{\text{sepMat}}(\hat{\theta}_N)$ is similar. Iterating the inequality $|ab - cd| \leq |a||b - d| + |d||a - c|$, for real, positive numbers $a, b, c, d$, and using the Lipschitz continuity of the Matérn kernel for $\nu \geq 1/2$, as well as the bound $k_{\text{Mat}}(\hat{\theta}_N; u_j, u_j') \leq \sigma_N^2$, we have for any $u, u' \in U$,
\[
d_{\phi_N}(u, u')^2 = \mathbb{E}\left((\Phi_N(u) - \Phi_N(u'))^2\right)
= k_{\text{sepMat}}(\hat{\theta}_N; u, u) - k_{\text{sepMat}}(\hat{\theta}_N; u, u') - k_{\text{sepMat}}(\hat{\theta}_N; u', u) + k_{\text{sepMat}}(\hat{\theta}_N; u', u')
= \prod_{j=1}^{d_u} k_{\text{Mat}}(\hat{\theta}_N; u_j, u_j) - \prod_{j=1}^{d_u} k_{\text{Mat}}(\hat{\theta}_N; u_j, u_j') - \prod_{j=1}^{d_u} k_{\text{Mat}}(\hat{\theta}_N; u_j', u_j) + \prod_{j=1}^{d_u} k_{\text{Mat}}(\hat{\theta}_N; u_j', u_j')
\leq 2d_u(\sigma_N^2)^{d_u - 1} L(\hat{\theta}_N) \sum_{j=1}^{d_u} |u_j - u_j'|
\leq \bar{C}||u - u'||_1,
\]
where $\bar{C} = 2d_u \max_{\hat{\theta}_N \in S}(\sigma_N^2)^{d_u - 1} L(\hat{\theta}_N)$. It follows that $M(U, d_{\phi_N}, \epsilon) \sim \epsilon^{-2d_u}$, as in the case of Matérn kernels. This finishes the proof. \qed
6 Conclusions and Discussion

Gaussian process regression is frequently used to approximate complex models. In this work, we looked at how the accuracy of the approximation depends on the number of model evaluations used to construct the Gaussian process emulator, in the setting where the hyper-parameters in the Gaussian process emulator are a-priori unknown and inferred as part of the emulation. The main results here are Theorems 3.4, 3.7, 3.9 and 3.10. These results show how fast we can expect the error to decay as a function of the number of model evaluations, and relate the decay rate of the error to the smoothness of both the function we are approximating and the employed kernel.

Generally speaking, we obtain error estimates of the form

\[ \| f - m^f_N \|_{L^2(U)} \leq C_1 N^{-r_1} (\| f \| + \| m \|), \quad \text{and} \quad \| k^f_N \|_{L^2(U)} \leq C_2 N^{-r_2}, \]

for the predictive mean \( m^f_N \) (as in (2.2)) and predictive variance \( k^f_N \) (as in (2.3)). The constants \( C_1 \) and \( C_2 \) depend on all hyper-parameters, whereas the rates \( r_1 \) and \( r_2 \) depend only on the estimated smoothness parameter \( \hat{\nu}_N \) in the Matérn model and the true smoothness parameter (i.e. the smoothness of the given \( f \)). To obtain the best possible rates, the estimated smoothness has to match the true smoothness:

- if we underestimate the smoothness of \( f \), we don’t obtain the fastest rate possible for this class of functions \( f \),
- if we overestimate the smoothness of \( f \), we may have to pay a penalty for assuming that \( f \) is smoother than it actually is.

For a given function \( f \), convergence of the Gaussian process emulator \( f_N \) is guaranteed under very mild assumptions on the values of the hyper-parameters (cf Theorems 3.4 and 3.9 and the discussions thereafter).

We also briefly examine the point-wise prediction error in section 3.3 where we bound the error of using the predictive mean \( m^f_N \) or the predictive process \( f_N \) (as in (2.4)) to predict \( f(u) \) at some unobserved location \( u \in U \setminus D_N \). Again, we obtain convergence to zero as \( N \) tends to infinity under very mild assumptions on the estimated hyper-parameters.

We note here that the estimation of hyper-parameters in an empirical Bayes’ framework can in general have severe effects on issues such as consistency of MAP estimators; see the recent work [12] for a discussion. Gaussian process regression, viewed as an inverse problem to recover the function \( f \) from the function values \( f(u^1), \ldots, f(u^n) \), does however not fit into the framework considered in [12], and the results in this paper show that we do get consistency of the MAP estimate (i.e. the convergence of \( m^f_N \) to \( f \)) also with estimated hyper-parameters.

Furthermore, we looked at the effect of approximating the parameter-to-observation map, or directly the log-likelihood, in a Bayesian inference problem by a Gaussian process emulator in section 5. This results in a computationally cheaper approximation to the Bayesian posterior distribution, which is crucial in large scale applications. The main results in this context are Theorems 5.1 and 5.2 which bound the error between the true posterior and the approximate posterior in terms of the accuracy of the Gaussian process emulator. These results give a justification for using Gaussian process emulators to approximate the Bayesian posterior, as they show that the approximate Bayesian posterior is close to the true posterior as long as the Gaussian process emulator approximates the data likelihood sufficiently well.
