Quasi-integrable systems are slow to thermalize but may be good scramblers

(Dated: November 19, 2019)

Classical quasi-integrable systems are known to have Lyapunov times orders of magnitude shorter than their ergodic time, the most clear example being the Solar System. This puzzling fact may be understood by considering the simple situation of an integrable system perturbed by a weak, random noise: there is no KAM regime and the Lyapunov instability may be shown to happen almost tangent to the tori. We extend here this analysis to the quantum case, and show that the discrepancy between Lyapunov and ergodicity times still holds. Quantum mechanics limits the Lyapunov regime by spreading wavepackets on a torus up to a pre-scrambling time. Still, the system is a relatively good scrambler in the sense that $\lambda_0/T$ is finite, at low temperature $T$. The essential features of the problem, both classical and quantum, are already present in a rotor that is kicked weakly but randomly.

INTRODUCTION

Lyapunov exponents are a measure of chaos but do not necessarily reflect the ergodic properties of a classical system. A particularly interesting instance where this is manifest concerns systems in which integrability is broken by a small perturbation. The paradigm of these is the Solar System: we now know that, even if the stability time (for Mercury’s orbit) is at least 5 bYrs, the Lyapunov time of the entire system is much shorter, of the order of a few million years [1]. Similarly, for the Fermi-Pasta-Ulam-Tsingou chain (a perturbed Toda lattice) at low energy, the equilibration time is much larger than the Lyapunov time [2].

This somewhat paradoxical result may be understood rather simply: the motion combines a fast chaotic exploration of the tori of the unperturbed system, with slow diffusion from one torus to another. The divergence of nearby trajectories – Lyapunov instability – is tangential to the torus. A simple example one can consider illustrates this. It consists of an integrable system with dynamics perturbed by a white additive noise of zero mean and (small) variance $\epsilon$. The idea is that the artificial noise mimics the interactions if there are many, weak and incoherently interacting systems: the construction reproduces many features beyond the Kolmogorov-Arnold-Moser regime (which is essentially irrelevant for many degrees of freedom) but still not far from integrability. One can show in general that [3]:

- Considering nearby trajectories with the same realization of noise, they diverge within a torus with a Lyapunov exponent $\propto \epsilon^{1/3}$; there is no value of $\epsilon$ below which regular motion subsists.
- Combined with this there is a much slower diffusion for both trajectories, with rate $\propto \epsilon$, from one torus to another, and a different scaling for the Lyapunov instability in that regime.

The purpose of this Letter is to extend this construction to the quantum case by studying the behavior of the out-of-time-order correlator (OTOC) between two observables $\langle [A(t), B_0] \rangle$, and to study what are the limits on the Lyapunov exponent so-defined placed by quantum uncertainty. The Letter contains two parts: in the first one we draw some general arguments concerning the Lyapunov regime. This is done by going back and forth from the the classical to the quantum problem. The full analysis of the latter is given in an accompanying publication [4] (referred to hereafter as the Extended Paper). In the second part we demonstrate the results by solving numerically a representative example—a weakly and randomly kicked rotor.

A SIMPLE MODEL

The physics is already contained in a one-dimensional problem of a particle in a power potential, driven by a random field:

$$H(q,p) = \frac{p^2}{2m} + aq^\nu + \epsilon^{1/2}q \eta(t), \quad (1)$$

where $m$ is the mass of the particle and $\langle \eta(t)\eta(t') \rangle = \delta(t-t')$. For the classical system, the next step is to go to action-angle variables $(I, \Theta)$. Quantum mechanically this is also possible, if done with care (see the reviews [5, 6]), on condition that instead of $\Theta$ we work with $e^{i\Theta} = \cos \Theta + i \sin \Theta$, and define the matrix representations of these appropriately - see Supplemental Material (SM) [5]. The Hamiltonian transforms to:

$$H(I, \Theta) = H_{\text{int}}(I) + \epsilon^{1/2}q(I, e^{i\Theta})\eta(t). \quad (2)$$

We now briefly review the behavior of the classical model. A comprehensive analysis is given in Ref. [3], and a complete summary in the Extended Paper [5].

The classical Lyapunov exponent reads

$$\lambda_{\text{cl}} \sim \epsilon^{1/3} \left[ \left\langle \frac{q'^2}{\alpha^2} \right\rangle (H_{\text{int}}''(J_0))^2 \right]^{1/3}, \quad (3)$$

where $q'$ is the derivative of $q$ with respect to $\Theta$, and $\alpha$ is a parameter that depends on the power of the potential.
where \( I_0 \) is the initial value of the action, derivatives with respect to \( I \) are marked with \( ' \), and \( \tilde{T}_n(I_0) \) is the mean squared of \( g(I,e^{i\Theta}) \) with average taken over the torus \( 0 < \Theta < 2\pi \). The result in Eq. (3) is derived under the assumption of weak perturbation so that the action variable diffuses little during a Lyapunov time \( t_{\text{Lyp}} = \frac{\lambda_{ci}^{-1}}{\epsilon} \).

\[
t_{\text{Lyp}} \ll I_0^2/(e\sigma^2(I_0)).
\]

Since \( t_{\text{Lyp}} \sim \epsilon^{-1/3} \) and the diffusion time \( \sim \epsilon^{-1} \), this regime may always be realized by decreasing the perturbation magnitude. For large values of \( \epsilon \), the \( \epsilon^{1/3} \) scaling breaks down, e.g., \( 3, 4 \).

Turning to the quantum version, since we consider a single power-law potential, the Hamiltonian can be rescaled from the one in Eq. (1).

\[
H(N,\Theta) = \omega_0 \hbar \left( \tilde{H}_\text{int}(N) + \epsilon^{1/2} \bar{q}(N,e^{i\Theta}) \eta(t) \right),
\]

where \( \omega_0 = (a^2 m^{-\nu} h^{-2})^{1/(2+\nu)} \) has units of time\(^{-1} \) and \( \epsilon = \epsilon / (m^{2-\nu} a^1 h^{3 \nu - 2})^{1/(2+\nu)} \) is adimensional. The time variable, which appears explicitly in the white noise, is rescaled with \( \omega_0 \). The number operator \( N \) indicates the number \( n \) of energy level for the integrable part \( N|n\rangle = n|n\rangle \). This form of the quantum Hamiltonian is obtained regardless of the explicit functionality of the classical integrable Hamiltonian \( \tilde{H}_\text{int}(I) \).

The quantum Lyapunov exponent is adimensional as: \( \lambda = \frac{1}{\tilde{\lambda}} \), with \( \tilde{\lambda} \) defined by the (adimensional) time dependence of the OTOC associated with the evolution generated by the adimensional \( H/(\omega_0 \hbar) \):

\[
C^2(t) = \langle \psi_0 | 2 \cos \Theta, N_0 |^2 \rangle \psi_0 \sim \epsilon^{2 \tilde{\lambda} t}.
\]

The initial state, \( |\psi_0\rangle = \sum_n c_n |n\rangle \), is assumed to be concentrated around some \( n_0 \), here we take directly \( |\psi_0\rangle = |n_0\rangle \).

We could alternatively write the Lyapunov exponent in canonical form (such as in the quantum bound \( 10 \)), for this we need to introduce a canonical ensemble calculating \( \lambda_T = \frac{1}{2} \ln \text{Tr} \left\{ A(t), B_0 \right\} \epsilon^{-\beta_0 \omega_H \tilde{H}_\text{int}(N)} / Z \), where the long time limit has to be taken with care in this annealed version, or make a ‘quenched’ calculation by taking the expectation of the logarithm of the squared commutator. Inserting \( \tilde{\lambda} = \frac{1}{\lambda_{ci}} \), and eliminating the parameters in favor of

\[
n_T(\beta_0 \omega_H h) = \text{Tr} \left\{ N e^{-\beta_0 \omega_H \tilde{H}_\text{int}(N)} \right\} / Z,
\]

which also implies that \( \beta_0 \omega_H h \) is a function of \( n_T \), we obtain:

\[
\beta_0 \omega_H h = g(n_T, \epsilon).
\]

We shall see below that the adimensional function \( g(n_T, \epsilon) \) grows, for a given \( \epsilon \), as \( n_T \) decreases: the quantization of \( n_T \) will provide a bound. The system is then a relatively good scrambler, in the sense that \( \beta_0 \lambda_{ci} \) reaches, at low \( T \), a finite (albeit small) \( \epsilon \)-dependent value. Note that although \( \epsilon \) depends on \( \hbar \) and \( \omega_0 \), we can change \( n_T \) independently by varying the temperature.

**QUANTUM TANGENT SPACE**

In the Extended Paper we show explicitly how the quantum Lyapunov exponent can be determined in analogy to the classical one. It is sufficient to focus on the dynamics of two operators, \( C^\Theta = [e^{i\Theta}, A_0] e^{-i\Theta} \) and \( C^N = i[N, A_0] \), with \( A_0 \) being some initial Hermitian operator. The time derivatives of these operators follows a linear super-operator equations, which are the analogue of those of the tangent space in classical mechanics (written by Poisson brackets \( \{ \} \)), of the form

\[
\left( \begin{array}{c} C^N \\ C^\Theta \end{array} \right) = \left( \begin{array}{cc} 0 & iJ \\ i\mathcal{J} & N \times K \end{array} \right) \left( \begin{array}{c} C^N \\ C^\Theta \end{array} \right),
\]

where \( \mathcal{L}, J, M, F, N, K \) are super-operators easily obtained by using the ‘chain-rule’ for commutators \( \{ \} \). The super-operator \( J \) comes from factor reorderings, and thus vanishes in the classical case. When this is so, we may rescale \( C^N \to C^N, \ C^\Theta \to \epsilon^{-1/3} C^\Theta \) and \( t \to \epsilon^{-1/3} t \), and conclude that \( M, N, K \) may be neglected for small \( \epsilon \), and that the Lyapunov exponent \( \tilde{\lambda} \) scales like \( \epsilon^{1/3} \). In the quantum case \( J \neq 0 \), and time cannot be rescaled with \( \epsilon \).

**PRESCRAMBLING TIMES**

Consider, for the classical case, two trajectories with small but finite initial separation \( u_0 \), submitted to the same noise realization. We follow their relative distance in time \( u^2(t) \equiv u_1^2(t) + u_2^2(t) \), where \( u_1(t) \) and \( u_2(t) \) are the differences in the action and angle variables of the two copies. The natural expectation is that there will be a saturation time \( t_{\text{sat}} \), dependent on the initial separation, reached when the angles of two trajectories differ by \( O(1) \): \( |u_0| e^{\lambda_{\text{eff}} t_{\text{sat}}} \sim 1 \). The situation here is actually more complicated: we find that this estimate is correct only if we modify it as \( \ell_0(|u_0|, \epsilon) e^{\lambda_{\text{eff}} t_{\text{sat}}} \sim O(1) \), where \( \ell_0 \) is an initial effective separation that depends on \( \epsilon \), but of course goes to zero as \( |u_0| \to 0 \). We may understand this if we suppose that there are in fact three regimes: (1) during a time-interval contained within \([0, t_{\text{Lyp}}]\) the actions are essentially constant, \( u_j \approx u_j(0) \), while the angles separate ballistically \( u_\Theta \approx H_{\text{int}}^n(I_0) u_\Theta(0) \) up to a value \( \ell_0 \), then (2) the trajectories diverge exponentially \( u_j \sim u_j(0) e^{\lambda_{ci} t} \), \( u_\Theta \sim \ell_0 e^{\lambda_{ci} t} \), until (3) the angular separation saturates at time \( t_{\text{sat}} \) defined above by \( u_\Theta(t_{\text{sat}}) = 1 \): the trajectories have spanned a torus. From that time onward the action variables follow a simple diffusion from torus to torus.
If we further assume that the ballistic regime (1) lasts for a time of the order of the Lyapunov time, then \( t_0 \propto t_{\text{Lyp}} \sim \epsilon^{-1/3} \). Thus, for a given initial separation, a smaller perturbation results in a larger effective separation \( t_0 \) at the onset of the Lyapunov regime (see Fig. 1), leading to logarithmic corrections for \( t_{\text{sat}} \). If the perturbation \( \epsilon \) is so small that \( t_0(\epsilon_t, \epsilon) \) is itself of order one, then the Lyapunov regime on the torus disappears altogether. We shall check numerically these predictions in the next section.

In the quantum problem, even if we are considering the tangent space dynamics for an OTOC (Eq. (9)), we cannot avoid an initial uncertainty given by quantum fluctuations. A semiclassical argument is then to imagine that the initial wavepacket of size \( \ell_q \) is stretched by the Lyapunov instability, until it spreads in the whole available space: this is the Ehrenfest/scrambling-on-the-torus time, which we term hereafter as \( \text{prescrambling time} \). In our case here there are two grains of salt: (i) from the discussion above we may expect that not only \( \hbar \) but also \( \epsilon \) enters in the estimate of the effective initial packet \( \ell_q(\epsilon, h) \), where, if the classical estimate holds, the dependence for small \( \epsilon \) is \( \ell_q \propto \epsilon^{-1/3} \) and (ii) Again, if \( \epsilon \) is so small that \( \ell_q(\epsilon, h) \sim 1 \), the Lyapunov regime within prescrambling times is absent. Finally, if \( \epsilon \) is large, the initial size of the packet is in any case bounded by \( n_0 \), since this is its initial size \([11–13]\) (this is best understood by considering the Bohr-Sommerfeld quantization (BS), which imposes that \( n \) is integer, fixing a wavenumber around the torus).

During the time in which an exponential growth of the OTOC exists, a simple semiclassical argument based on the BS shows that \([3]\), not surprisingly, the quantum Lyapunov exponent coincides with the classical one for \( n_0 \) large enough. We shall check this below.

**AN EVEN SIMPLER MODEL, NUMERICS**

The Hamiltonian \([5]\) may be treated as it is, but in fact we may learn the same lessons with a simplification that implies no loss of physical generality. We choose for \( \tilde{H}_{\text{int}}(N) = N^2/2 \) and simplify for \( \tilde{q}(\tilde{N}, e^{i\Theta}) = 2 \cos \Theta \) (we omit the \( N \) dependence in \( \tilde{q} \) but this is inessential since \( N \) is almost constant during the times involved). Hence we have

\[
H = \hbar \omega_0 \left[ \frac{N^2}{2} + 2\epsilon^{1/2} \cos \Theta \sum_{k=-\infty}^{\infty} r_k \delta(t - k\tau) \right],
\]

(10)

where the random external noise \( \eta(t) \) is taken as a limit of frequent random kicking with some fast kicking rate \( \tau^{-1} \) and where \( r_k \) are taken from a normal distribution of zero mean and variance \( \tau \). (This is how we introduce the noise in the simulations below). The predicted Lyapunov exponent for this system is \( 2\lambda = 2^{1/3} \epsilon^{1/3} \) (see Eq. (3)), where it is only the prefactor that we determine a posteriori from the simulations.

The system is then the so-called Chirikov Typical map \([14, 15]\), which differs from the, more usual, `Standard Map' \([16, 17]\) in that the kicks have zero mean and random sign. In the former map, there is no KAM regime, and the classical version has a Lyapunov exponent \( \lambda_{cl} \sim \epsilon^{1/3} \). Thus, the regime we are studying here, nonlocalized and fully chaotic but with small \( \epsilon \), does not in fact exist if the kicks are non-random.

Below we report numerical solutions to a classical and quantum rotor subjected to periodic kicking of random magnitude and sign. We focus on the case of weak relative perturbation. Technical details of the numerics are given in the SM.

**CLASSICAL CASE**

Let us start with the classical Hamiltonian, with the same functionality of the one appearing in Eq. (10), \( H = \frac{p^2}{2} + 2\epsilon^{1/2}\eta(t) \cos \Theta \) (namely, according to BS \( I = hN \)). The corresponding Hamilton equations lead to a random map which we iterate numerically.

Fig. 1 shows the quenched separation \( \langle \log u^2(t) \rangle \) for different perturbation strengths \( \epsilon \), and fixed initial separation \( |u_0| = 10^{-8} \). One can see all the three regimes mentioned above. The exponential growth, with \( \lambda_{cl} \sim \epsilon^{1/3} \), starts after \( \sim 1 \) Lyapunov time and saturates at later times. As can be seen by the inset of Fig. 2, the separation along the action direction is small. When decreasing the perturbation, the effective initial separation \( t_0(\epsilon) \) becomes larger, and as a result the saturation time, measured in Lyapunov times, is shorter.

**QUANTUM CASE**

All numerics in what follows involve an initial eigenstate, \( |\psi_0\rangle = |n_0\rangle \), where we measure the OTOC which is defined in Eq. (6). The numerical pro-
procedure is performed by evolving the system in time with consecutive unitary operation between kicks \[\tilde{\varepsilon}\]. We treat a system of a fixed size \(M = 2^{14}\), and vary the initial state \(n_0\) and the perturbation strength \(\tilde{\varepsilon}\).

In Fig. 2a) we show the growth of the OTOC for different initial energy levels \(n_0\) and fixed relative perturbation \(\tilde{\varepsilon}^{1/2} = 5 \times 10^{-3} n_0\) [21]. The OTOCs show an exponential growth with essentially the classical Lyapunov exponent for a time window—the Lyapunov regime—that roughly starts at one Lyapunov time and ends at the preescaping time \(t_E\). In the inset of Fig. 2a) we show that the latter is proportional to \(\log n_0\) Lyapunov times. For \(\log n_0 \sim 1\) there is no Lyapunov regime. This is the usual situation for large \(\tilde{\varepsilon}\). For smaller \(\tilde{\varepsilon}\) the Lyapunov time becomes large, and we must correct the initial size \(\ell_g(\tilde{\varepsilon}) \sim \tilde{\varepsilon}^{-1/3}\), according to the estimate above.

We check how the preescaping time depends on the perturbation strength. In Fig. 2b) we show the evolution of \(C^2(t)\) for various magnitudes of external noise and fixed initial condition. The Lyapunov regime gets shorter with decreasing \(\tilde{\varepsilon}\), and for small enough perturbation it vanishes. This behavior resembles the one observed in Fig. 1 for the classical model.

In analogy to the classical case, we find that during the Lyapunov regime the energy diffuses little around \(|n_0\) [3]. It would be interesting to check that a wavepacket in the coherent-state or Wigner representation indeed fills the torus in an Ehrenfest time, and diffuses subsequently [3, 22].

**QUANTUM LIMITS TO CHAOS**

The fact that there should be at all a Lyapunov regime at a given finite value of \(n_0\) already implies that the adimensional quantity \(\beta \hbar \lambda_f\) scales as a finite number, and the system is a ‘rather good scrambler’ between Lyapunov and prescrambling times. We now derive a general semiclassical expression for the adimensional function \(g(n_T, \tilde{\varepsilon})\) in Eq. (8).

For a general Hamiltonian in Eq. (6), the scalings for the adimensional Lyapunov and the assumption of weak perturbation are given respectively according Eq. (3) and Eq. (4), replacing \(I_0 \rightarrow n_0\) [4]. Switching to the canonical averaging, let us define from Eq. (7) \(\beta \hbar \omega_0 = k(n_T)\), which is a decreasing function of \(n_T\). The adimensional relation in Eq. (8) then reads

\[
\beta \hbar \lambda_f = \frac{\tilde{\lambda}(n_T, \tilde{\varepsilon})}{k^{-1}(n_T)} = \left( \frac{\tilde{\varepsilon}^2(n_T)}{H''_{\text{int}}(n_T) n_T^2} \right)^{1/3} \left( \frac{n_T H''_{\text{int}}(n_T)}{k^{-1}(n_T)} \right).
\]

(11)

Now, the first brackets cannot be too large according to Eq. (3), and, if we do not want to violate the bound [10], then the second bracket must be a decreasing function of \(n_T\). Hence, the most chaotic system corresponds for \(n_T = O(1)\), at which the Lyapunov regime also vanishes. We can verify this explicitly for the BS of \(\tilde{H}_{\text{int}}\), for which we find \(\beta \hbar \lambda_f = \tilde{\varepsilon}^{13/2} k(n_T) n_T^{-2/3}\) with \(0 < \gamma \leq 2\) [3].

Let us go further, and consider a system consisting of \(M\) very weakly coupled copies of our integrable model, having values of \(\omega_0 = \omega_0^{(1)} > ... > \omega_0^{(M)} \sim 0\), with \(\omega_0^{(i)}\) spanning an interval that goes down to zero. The system is at temperature \(T\), so that the corresponding average quantum numbers are \(n_T^{(1)} < ... < n_T^{(M)}\). The coupling introduces perturbations with \(\tilde{\varepsilon}^{(i)}\). As in any system that is a collection of uncoupled subsystems, the global Lyapunov exponent is dominated by the largest of individual ones. Consider, for example, choosing the adimensional \(\tilde{\varepsilon}^{(i)} = \tilde{\varepsilon}^{(1)}\), the same \(\forall i\). Then, at each (low) temperature some subsystems will have \(n_T^{(i)} < 1\), and will thus not contribute with a Lyapunov regime. Hence, the global Lyapunov exponent corresponds to the one of the systems \(n_T^{(i)} \sim 1\) that is just about to lose its Lyapunov regime because of quantum effects, which one depends on the value of \(T\). This will also be the case if the \(\tilde{\varepsilon}^{(i)}\) increase with \(i\). If, instead, \(\tilde{\varepsilon}^{(i)}\) decrease and go to zero as \(\omega_0^{(i)}\) goes to zero, the scaling with temperature becomes different.

**CONCLUSION**

In this Letter we have presented one example of weakly driven integrable model. A more complete study is given in the Extended Paper. The same behavior is expected for systems with many degrees of freedom. The noise plays the role of the sum of all weak integrability-breaking terms in a true quasi-integrable model with many dimensions. There is however a caveat: in the situation we discuss the noise acting on the quantum system is classical, which might not be suitable to fully capture quantum couplings. A rigorous way to account for noise with quantum origins might be to consider a model with one degree of freedom coupled to an ensemble of linear oscillators and employ the Feynman-Vernon, Caldeira Leggett method (as in Ref. 22).

Finally, it will be interesting to test the implications of our model to real isolated quasi-integrable systems in equilibrium. Another interesting future direction is to consider an initial ensemble that is a Generalized-Gibbs-Ensemble [24]. The latter can be relevant to study the so-called prethermalized state [25].

We thank Laura Foini, Eduardo Fradkin, Andrea Gambassi, Stefano Ruffo, Dima Shepelyansky, Alessandro Silva, and Denis Ullmo for helpful discussions. We also thank Doron Cohen for pointing out relevant references for this work. TG and JK are supported by the Simons Foundation Grant No. 454943.
FIG. 2. (a) The (quenched) growth rate of the OTOC for a fixed relative perturbation strength $\bar{\epsilon}^{1/2}/n_0$ as a function of time rescaled by the classical Lyapunov exponent (averaged over 86 noise realizations). For larger initial energy level $n_0$ the Lyapunov regime is longer, below a certain $n_0$ the Lyapunov regime disappears. The inset shows how $\hat{\lambda} t_F$, with $t_F$ being the prescrambling time (stars in the main figure), increases with the logarithm scale of $n_0$, indicating a linear trend. (b) The growth of the OTOC (one noise realization) for different relative perturbation strength and fixed initial state $n_0 = 8191$.

We choose to keep $\bar{\epsilon}/n_0^3$ fixed rather than $\bar{\epsilon}$, since this parameter controls the smallness of the perturbation, as the energy is almost constant throughout the evolution. We have verified that the Ehrenfest time also decreases for fixed $\bar{\epsilon}$ and decreasing $n_0$.

[21] We choose to keep $\bar{\epsilon}/n_0^3$ fixed rather than $\bar{\epsilon}$, since this parameter controls the smallness of the perturbation, as the energy is almost constant throughout the evolution. We have verified that the Ehrenfest time also decreases for fixed $\bar{\epsilon}$ and decreasing $n_0$.
Supplemental Material

This Supplemental Material contains more details on the numerical simulations presented in the main text.

Classical model

We treat the classical Hamiltonian:

\[ H = \frac{T^2}{2} + 2\epsilon^{1/2} \eta(t) \cos \Theta, \]

(12)

where the random external noise \( \eta(t) \) can be thought as a limit of frequent random kicking

\[ \eta(t) = \sum_{k=-\infty}^{\infty} r_k \delta(t - k\tau), \]

(13)

with kicking rate \( \tau^{-1} \). The kicks are of magnitude \( r_k \) taken from a normal distribution of zero mean and variance \( \tau \). The corresponding Hamilton equations lead to the random map

\[ I_{t+\tau} = I_t + 2r \sin \Theta_t, \]

(14)

\[ \Theta_{t+\tau} = \Theta_t + I_t \tau \pmod{2\pi}, \]

(15)

where \( r \) is a random number drawn from a Gaussian distribution with zero mean and variance \( \epsilon \tau \). The kicking rate is taken as \( \tau = 0.1 \lambda^{-1}(\epsilon) \).

Quantum model

We study the quantum Hamiltonian

\[ H = \hbar \omega_0 \left[ \frac{N^2}{2} + 2\epsilon^{1/2} \eta(t) \cos \Theta \right], \]

(16)

where \( \eta(t) \) is given by Eq. (13). We start with an initial eigenstate, \( |\psi_0\rangle = |n_0\rangle \), and calculate the OTOC

\[ C^2(t) \equiv \langle n_0| [2\cos \Theta, N_0]^2 |n_0\rangle = \sum_n (n - n_0)^2 |C_n(t)|^2, \]

(17)

with \( C_n(t) \equiv \langle n|2\cos \Theta|n_0\rangle \). The unitary evolution between kicks is given by \( U_{\tau}(r) = e^{-iN^2/2\tau}e^{-2ir \cos \Theta} \). The operation in \( \Theta \) space is done in Fourier space. As in the classical case, the rate of kicks is kept fixed with respect to the expected Lyapunov time, \( \tau = 0.01 \lambda^{-1}(\epsilon) \).

There are two choices for the operator \( \cos \Theta \): the usual one, \( 2\langle n| \cos \Theta |n'\rangle = \delta_{n,n'+1} + \delta_{n+1,n'} \) for \( n, n' \) integer, or the one coming from the quantum action-angle construction, \( 2\langle n| \hat{\cos} \Theta |n'\rangle = \delta_{n,n'+1} + \delta_{n+1,n'} \) for \( n, n' \) nonnegative, only the space with positive \( n \) counts, as one would expect from an action variable. We verified that these two alternatives give similar behavior of the OTOC, so we shall disregard the difference.
