Abstract

Instrumental variable identification is a concept in causal statistics for estimating the counterfactual effect of treatment $D$ on output $Y$ controlling for covariates $X$ using observational data. Even when measurements of $(Y, D)$ are confounded, the treatment effect on the subpopulation of compliers can nonetheless be identified if an instrumental variable $Z$ is available, which is independent of $(Y, D)$ conditional on $X$ and the unmeasured confounder. We introduce a de-biased machine learning (DML) approach to estimating complier parameters with high-dimensional data. Complier parameters include local average treatment effect, average complier characteristics, and complier counterfactual outcome distributions. In our approach, the de-biasing is itself performed by machine learning, a variant called de-biased machine learning via regularized Riesz representatives (DML-RRR). We prove our estimator is consistent, asymptotically normal, and semi-parametrically efficient. In experiments, our estimator outperforms state of the art alternatives. We use it to estimate the effect of 401(k) participation on the distribution of net financial assets.

1 Introduction

Instrumental variable (IV) identification is a concept in causal statistics for estimating the counterfactual effect of treatment $D$ on output $Y$ controlling for covariates $X$ using observational data [34]. Even when measurements of $(Y, D)$ are confounded, the treatment effect can nonetheless be identified if an instrumental variable $Z$ is available, which is independent of $(Y, D)$ conditional on $X$ and the unmeasured confounder. Intuitively, $Z$ only influences $Y$ via $D$, identifying the counterfactual relationship of interest.

This solution comes at a price; the analyst can no longer measure parameters of the entire population such as average treatment effect (ATE). Measuring population parameters requires a stronger assumption called selection on observables: conditional on covariates $X$, the relationship between treatment $D$ and outcome $Y$ is as good as random. Instead, the analyst can only measure parameters defined for the subpopulation of compliers such as local average treatment effect (LATE). A complier is an individual whose treatment status $D$ is affected by variation in the instrument $Z$. In public policy research, the instruments take the form of changes in eligibility criteria for social programs. Compliers are thus of policy interest as they are exactly the subpopulation to be affected by eligibility changes.

To fix ideas, we provide examples with continuous outcome $Y$, binary treatment $D$, and binary instrument $Z$. Randomized assignment of a drug ($Z$) only influences patient health ($Y$) via actual consumption of the drug ($D$), identifying the counterfactual effect of the drug on health even in the scenario of imperfect compliance [6]. However, the analyst can only learn the treatment effect on the subpopulation of complier patients: those who would consume the drug if assigned and who would not consume the drug if not assigned. Charter school admission by lottery ($Z$) only influences

*Equal contribution

Preprint. Under review.
student test scores ($Y$) via actually attending the charter school ($D$), identifying the counterfactual effect of the charter school on test scores even if there is selection bias in which students choose to accept an offer of admission. However, the analyst can only learn the treatment effect on the subpopulation of complier students: those who would attend the charter school if they won the lottery and who would not attend the charter school if they lost the lottery.

In the present work, we introduce a de-biased machine learning (DML) approach to estimating complier parameters with high-dimensional data. In our approach, the de-biasing is itself performed by machine learning, a variant called de-biased machine learning via regularized Riesz representers (DML-RRR). We present a general estimator, then specialize it to the tasks of learning LATE, average complier characteristics, and complier counterfactual outcome distributions. Counterfactual outcome distributions are particularly important in welfare analysis of schooling, subsidized training, union status, minimum wages, and transfer programs.

We make three contributions. First, we extend the theory of DML-RRR pioneered by Wang and Fong. Whereas consider parameters of the full population identified by selection on observables, we consider parameters of the complier subpopulation identified by instrumental variables. We prove our estimator is consistent, asymptotically normal, and semi-parametrically efficient, and we provide simultaneous confidence bands. Second, we re-interpret a widely-used algorithm for estimating complier parameters called $\kappa$-weighting as the Riesz representer in DML-RRR: it is in fact a component of the de-biasing term. Third, we show our approach outperforms alternative approaches to estimating complier parameters, suggesting DML-RRR may be an effective paradigm in high-dimensional causal inference.

## 2 Related Work

Several approaches have been proposed to estimate complier parameters by DML. Both and present a DML estimator for LATE. The justification in is via inverse propensity weighting, while the justification in is by interpreting LATE as a ratio of ATEs. In , the authors present a DML estimator for counterfactual outcome distributions with simultaneous confidence bands. All of these estimators involve plugging in an estimated propensity score in the denominator, which is numerically unstable. Unlike previous work, we present a general justification that covers a broad class of estimators, and we present a DML-RRR variant that eliminates the numerically unstable step of plugging in an estimated propensity score. As far as we know, ours is the first DML and DML-RRR estimator of complier characteristics. For a comparison between DML-RRR and other approaches to semi-parametric estimation that use ML—namely targeted maximum likelihood, efficient score, and approximate residual balancing—we recommend  and recommend  and .

Our work also relates to the literature on $\kappa$-weighting, an algorithm introduced by . In $\kappa$-weighting, any complier parameter can be expressed as a weighted average of the corresponding population parameter. For example, LATE can be expressed as a weighted average of ATE across covariate values. Likewise, and propose $\kappa$-weighting estimators of counterfactual outcome distributions. The weight involves an estimated propensity score in the denominator, which is numerically unstable. Theoretically, the literature has not yet justified the use of a black-box regularized ML algorithm to learn the propensity score in high dimensional settings. By elucidating the relationship between $\kappa$-weighting and DML, we provide this justification. Moreover, by introducing the DML-RRR variant, we are able to learn the $\kappa$-weight directly without estimating its components or even knowing its functional form.

Finally, our paper contributes to the growing literature on instrumental variables in machine learning. Both and consider the problem of nonparametric instrumental variable regression, where the target parameter is the structural function $h$ that summarizes the counterfactual relationship: $Y = h(D, X) + \epsilon$ where $\epsilon$ is confounding noise. In , the authors further assume the function $h$ can be decomposed as $h(D, X) = \mu(X) + \tau(X)D$. Importantly, and assume that the noise term $\epsilon$ is additively separable—a model proposed by . In this setting, introduce nonlinearity with neural networks, do so with RKHS methods, and with random forests. In our setting, $(D, Z)$ are binary and we do not assume additive separability of confounding noise—a model considered by . Our target parameters are functionals of the underlying regression $E[V|D, Z]$ where $V$ is a vector of relevant random variables. Such parameters are called semi-parametric. We allow black-box ML for nonlinear estimation of $E[V|D, Z]$.
3 Proof setting and definitions

Let $W = (Y, D, Z, X)$ concatenate the random variables. $Y \in \mathcal{Y} \subset \mathbb{R}$ is the continuous outcome, $D \in \{0, 1\}$ is the binary treatment, $Z \in \{0, 1\}$ is the binary instrumental variable, and $X \in \mathcal{X} \subset \mathbb{R}^d$ is the covariate. We observe $n$ i.i.d. observations $\{W_i\}_{i=1}^n$. Where possible, we suppress index $i$ to lighten notation.

Instrumental variable identification requires an assumption expressed in terms of potential outcomes. A potential outcome is a latent random variable expressing a counterfactual outcome given a hypothetical intervention. Following the notation of [6], we denote by $Y^{(z,d)}$ the potential outcome under the intervention $Z = z$ and $D = d$. We denote by $D(y)$ the potential treatment under the intervention $Z = y$. Compliers are the subpopulation for whom $D(1) > D(0)$.

We now formalize our causal assumption about the instrument $Z$, quoting [5]. This prior knowledge, described informally in the introduction, allows us to define and recover the counterfactual effect of treatment $D$ on outcome $Y$ for compliers.

**Assumption 1** (Identification). Assume

1. independence: $\{Y^{(z,d)}\}_{z,d \in \{0,1\}} \perp (D^{(z)})_{d \in \{0,1\}} | Z,X$
2. exclusion: $\mathbb{P}(Y^{(1,d)} = Y^{(0,d)} | X) = 1$ for $d \in \{0,1\}$
3. overlap: $\pi_0(X) := \mathbb{P}(Z = 1 | X) \in (0,1)$
4. monotonicity: $\mathbb{P}(D^{(1)} > D^{(0)} | X) = 1$ and $\mathbb{P}(D^{(1)} > D^{(0)} | X) > 0$

The independence condition states that the instrument $Z$ is as good as randomly assigned conditional on covariates $X$. The exclusion condition imposes that the instrument $Z$ only affects the outcome $Y$ via the treatment $D$. We can therefore simplify notation: $Y^{(d)} = Y^{(1,d)} = Y^{(0,d)}$. The overlap condition ensures that there are no covariate values for which the instrument is deterministic. The monotonicity condition rules out the possibility of defiers: individuals who will always pursue an opposite treatment status from their assignment.

**Definition 1** (Complier parameters). We define the following complier parameters

1. LATE is $\theta_0 = \mathbb{E}[Y^{(1)} - Y^{(0)} | D^{(1)} > D^{(0)}]$.
2. Average complier characteristics are $\theta_0 = \mathbb{E}[f(X) | D^{(1)} > D^{(0)}]$ for characteristics $f(X)$.
3. Complier counterfactual outcome distributions are $\theta_0 = \{ \theta_0^y \}_{y \in \mathcal{Y}}$ where

   $$\theta_0^y = \begin{bmatrix} \beta_0^y \\ \gamma_0^y \end{bmatrix} = \begin{bmatrix} \mathbb{P}(Y^{(0)} \leq y | D^{(1)} > D^{(0)}) \\ \mathbb{P}(Y^{(1)} \leq y | D^{(1)} > D^{(0)}) \end{bmatrix}.$$ 

Using the notation of [19], we denote the conditional expectation function (CEF) of a random vector $V = (V_1, ..., V_j)$ conditional on $(Z,X)$ as

$$\gamma_0(Z,X) = \begin{bmatrix} \gamma_0^{V_1}(Z,X) \\ \vdots \\ \gamma_0^{V_j}(Z,X) \end{bmatrix} = \mathbb{E}[V | Z,X]$$

where $\gamma_0^{V_j}(Z,X) = \mathbb{E}[V_j | Z,X]$. The random vector $V$ is observable and depends on the complier parameter of interest; we specify its components for LATE, complier characteristics, and counterfactual outcome distributions in Theorem 1. We denote the classic Horvitz-Thompson weight with $\alpha_0(z,x) = \frac{z}{\pi_0(x)} - \frac{1-z}{1-\pi_0(x)} = \frac{z - \pi_0(x)}{\pi_0(x)[1-\pi_0(x)]}$. Lastly, we denote by $\| \cdot \|_q$ the $\ell_q$ norm of a vector, and we denote by $\| \cdot \|$ the $L_2$ norm of a random variable, i.e. $\| V_j \| = \sqrt{\mathbb{E}[V_j^2]}$.

4 Learning problem and algorithm

DML is a method of moments approach to estimation with de-biasing and strong statistical guarantees. We review the DML algorithm: in stage 1, estimate the CEF $\hat{Y}$ and an additional nuisance
We derive the DR moment functions for complier parameters. We show that these moment functions share a common structure.

### 4.1 DML

Consider a causal parameter \( \theta_0 \) implicitly defined by

\[
E[m(W, \gamma_0, \theta)] = 0 \text{ iff } \theta = \theta_0
\]

Here \( m \) is called the moment function, and it defines the causal parameter \( \theta_0 \). \( \gamma_0 \) is the CEF, a nuisance parameter that must be estimated in order to estimate the parameter of interest \( \theta_0 \).

The plug-in approach involves estimating \( \hat{\gamma} \) in stage 1 by some black-box ML algorithm, and estimating \( \hat{\theta} \) in stage 2 by method of moments with moment function \( m \). The plug-in approach is badly biased [13].

The DML approach uses a more sophisticated moment function [24],

\[
E[\psi(W, \gamma_0, \alpha_0, \theta)] = 0 \text{ iff } \theta = \theta_0
\]

\[
\psi(w, \gamma, \alpha, \theta) = m(w, \gamma, \theta) + \phi(w, \gamma, \alpha, \theta)
\]

\( \phi \) is called the de-biasing term. We derive \( \phi \) such that \( \psi \) is doubly robust (DR). In particular, we derive \( \phi \) such that

\[
E[\psi(W, \gamma, \alpha, \theta_0)] = 0 \quad \forall \gamma \text{ s.t. } E[\gamma(Z, X)]^2 < \infty
\]

\[
E[\psi(W, \gamma_0, \alpha, \theta_0)] = 0 \quad \forall \alpha \text{ s.t. } E[\alpha(Z, X)]^2 < \infty
\]

so stage 2 estimation of \( \hat{\theta} \) by method of moments with moment function \( \psi \) is asymptotically invariant to estimation error of either \( \hat{\gamma} \) or \( \hat{\alpha} \). In this sense, introducing the additional term \( \phi \) serves to de-bias the original moment function \( m \).

Importantly, the DR moment function \( \psi \) introduces an additional nuisance parameter \( \alpha_0 \), a component of the RR, which must be estimated in stage 1. Whereas DML involves estimating \( \hat{\alpha} \) by estimating its components and knowing its functional form, we estimate \( \hat{\alpha} \) directly by DML-RRR.

### 4.2 DML for complier parameters

We derive the DR moment functions for complier parameters. We show that these moment functions share a common structure.

**Theorem 1 (DR moment functions).** Under Assumption[1] the DR moment functions for LATE, average complier characteristics, and complier counterfactual outcome distributions are of the form

\[
\psi(w, \gamma, \alpha, \theta) = m(w, \gamma, \theta) + \phi(w, \gamma, \alpha, \theta)
\]

\[
m(w, \gamma, \theta) = A(\theta)[\gamma(1, x) - \gamma(0, x)]
\]

\[
\phi(w, \gamma, \alpha, \theta) = \alpha(z, x) A(\theta)[v - \gamma(z, x)]
\]

where

1. for LATE, \( V = (Y, D)' \) and \( A(\theta) = [1 \quad -\theta] \)
2. for complier characteristics, \( V = (Df(X)' , D)' \) and \( A(\theta) = [1 \quad -\theta] \)
3. for complier counterfactual distributions, \( V^u = ((D - 1)1_{Y \leq y}, D1_{Y \leq y}, D)' \) and \( A(\theta^u) = \begin{bmatrix} 1 & 0 & -\beta y \\ 0 & 1 & -\delta y \end{bmatrix} \)

Formally, \( \alpha_0(z, x) A(\theta_0) \) is the RR to the continuous linear functional \( \gamma \mapsto E[A(\theta_0)[\gamma(1, x) - \gamma(0, x)]] \), i.e.

\[
E[A(\theta_0)[\gamma(1, X) - \gamma(0, X)]] = E[\alpha_0(Z, X) A(\theta_0) \gamma(Z, X)], \quad \forall \gamma \text{ s.t. } E[\gamma(Z, X)]^2 < \infty
\]
Indeed, this is obvious since we know from the classic Horvitz-Thompson derivation that \( \alpha_0(z, x) \) is the RR to the continuous linear functional \( \gamma \mapsto \mathbb{E}[\gamma(1, X) - \gamma(0, X)] \), i.e.

\[
\mathbb{E}[\gamma(1, X) - \gamma(0, X)] = \mathbb{E}[\alpha_0(Z, X)\gamma(Z, X)], \quad \forall \gamma \text{ s.t. } \mathbb{E}[\gamma(Z, X)]^2 < \infty
\]

In Appendix 8.2, we review the classic Horvitz-Thompson derivation. We also prove a more general version of Theorem 1 for the entire class of complier parameters, and we demonstrate that the \( \kappa \)-weight is a reparametrization of the RR \( \alpha_0(z, x)\hat{A}(\theta_0) \).

4.3 Algorithm

In [15], the authors show it is data-efficient and theoretically elegant to use sample splitting in DML [11, 32]. The DML-RRR algorithm of [18, 19] is as follows.

**Algorithm 1 (DML).** Partition the sample into subsets \( \{I_\ell\}_{\ell=1:L} \).

1. For each \( \ell \), estimate \( \hat{\gamma}_{-\ell} \) and \( \hat{\alpha}_{-\ell} \) from observations not in \( I_\ell \)

2. Estimate \( \hat{\theta} \) as the solution to

\[
\frac{1}{n} \sum_{\ell=1}^L \sum_{i\in I_\ell} \psi(W_i, \hat{\gamma}_{-\ell}, \hat{\alpha}_{-\ell}, \hat{\theta}) \bigg|_{\theta=\hat{\theta}} = 0
\]

Our theoretical guarantees apply to Lasso or Dantzig selector estimators of \( \hat{\alpha}_{-\ell} \), originally presented in [18] and [19], respectively. In what follows, we restrict attention to Lasso.

Consider the projection of \( \alpha_0(z, x) \) onto \( p \)-dimensional dictionary \( b(z, x) \). Extending the RR result component-wise,

\[
\mathbb{E}[b(1, X) - b(0, X)] = \mathbb{E}[\alpha_0(Z, X)b(Z, X)], \quad \forall b \text{ s.t. } \mathbb{E}[b(Z, X)]^2 < \infty
\]

With \( \ell_1 \)-regularization, the objective becomes

\[
\rho_L = \arg\min_{\rho} \mathbb{E}[\alpha_0(Z, X) - \rho b(Z, X)]^2 + 2\lambda_L|\rho|_1
\]

Expanding the square, ignoring terms without \( \rho \), and using the RR result,

\[
\rho_L = \arg\min_{\rho} -2\rho'\mathbb{E}[b(1, X) - b(0, X)] + \rho'\mathbb{E}[b(Z, X)b(Z, X)']\rho + 2\lambda_L|\rho|_1
\]

The empirical analogue to the above expression yields an estimator of \( \hat{\rho} \). In this paper, we consider \( \hat{\alpha}(z, x) = \hat{\rho}b(z, x) \).

**Algorithm 2 (RRR).** For observations in \( I_{-\ell} = \{1, ..., n\} \setminus I_\ell \)

1. Calculate \( p \times p \) matrix \( \hat{G}_{-\ell} = \frac{1}{n-n_\ell} \sum_{i\in I_{-\ell}} b(Z_i, X_i)b(Z_i, X_i)' \)

2. Calculate \( p \times 1 \) vector \( \hat{M}_{-\ell} = \frac{1}{n-n_\ell} \sum_{i\in I_{-\ell}} b(1, X_i) - b(0, X_i) \)

3. Set \( \hat{\alpha}_{-\ell}(z, x) = b(z, x)'\hat{\rho}_{-\ell} \) where \( \hat{\rho}_{-\ell} = \arg\min_\rho \rho'\hat{G}_{-\ell}\rho - 2\rho'\hat{M}_{-\ell} + 2\lambda_n|\rho|_1 \)

Likewise, we can project \( \gamma_0(z, x) \) onto \( p \)-dimensional dictionary \( b(z, x) \) using the functional \( b \mapsto \mathbb{E}[b(Z, X)W'] \). Our theoretical results are agnostic about the choice of estimator \( \hat{\gamma} \); it may be this estimator or any other black-box ML algorithm satisfying the rate condition specified in Assumption 4.

Suppose we wish to form a simultaneous confidence band for the components of \( \hat{\theta} \), particularly relevant for the estimation of counterfactual outcome distributions based on a grid \( \mathcal{U} \subseteq \mathcal{Y} \). The following algorithm allows us to do so from some estimator \( \hat{C} \) for the asymptotic variance of \( \hat{\theta} \).

**Algorithm 3 (Simultaneous confidence band).** Given \( \hat{C} \),

1. Calculate \( \hat{\Sigma} = S^{-1/2}\hat{C}S^{-1/2} \) where \( S = \text{diag}(\hat{C}) \).
2. Sample \( Q \) i.i.d. \( N(0, \hat{\Sigma}) \) and compute the value \( c \) as the \((1 - \alpha)\)-quantile of sampled \(|Q|_\infty\).

3. Form the confidence band \([\hat{y}, u] = \left[ \hat{y} - c\sqrt{\frac{\hat{C}yy}{n}}, \hat{y} + c\sqrt{\frac{\hat{C}yy}{n}} \right] \) where \( \hat{C}yy \) is the diagonal entry of \( \hat{C} \) corresponding to value \( y \in \mathcal{U} \).

5 Consistency and asymptotic normality

We adapt the assumptions of [19] to our setting. First, we place weak assumptions on the dictionary \( b \), propensity score \( \pi_0 \), conditional variance \( \text{var}(V|Z, X) \), and Jacobian \( J \). We allow the bound on the dictionary \( B_n^b \) to be a sequence that increases in \( n \).

**Assumption 2** (Bounded dictionary). \( \exists B_n^b \) s.t. \( \max_j |b_j(X)| \leq B_n^b \) a.s.

**Assumption 3** (Regularity). Assume

1. \( \pi_0(x) \in (\hat{c}, 1 - \hat{c}) \) for some \( \hat{c} > 0 \)
2. \( \text{var}(V|Z, X) \) is bounded
3. Jacobian \( J = E \left[ \frac{\partial \psi(W, \pi_0, \alpha, \theta)}{\partial \alpha} \bigg| \theta = \theta_0 \right] \) is nonsingular

Next we state our rate assumption on black-box estimator \( \hat{\gamma} \). We allow \( \hat{\gamma} \) to converge at a rate slower than \( n^{-2} \).

**Assumption 4** (CEF rate). \( \| \hat{\gamma} - \gamma_0 \| = O_p(n^{-d_\gamma}) \) s.t. \( d_\gamma \in (0, 1/2) \)

Let \( \epsilon_n = \max\{B_n^b, (B_n^b)^2\} \sqrt{\frac{\ln p}{n}} \). We articulate assumptions required for convergence of \( \hat{\alpha} \) under two regimes: the regime in which \( \alpha_0 \) is dense and the regime in which \( \alpha_0 \) is sparse.

**Assumption 5** (Dense RR). Assume

1. \( \exists \rho_n \) s.t. \( |\rho_n|_1 = B_n \) and \( \| \alpha_0 - b^\prime \rho_n \|^2 = O(\epsilon_n) \)
2. \( (1 + B_n)\lambda_n = o(n^{2d_\gamma - 1}) \)

**Assumption 6** (Sparse RR). Assume

1. \( \exists \bar{\rho} \) with \( \bar{s} \) nonzero elements s.t. \( |\bar{\rho}|_1 = B_n \) and \( \| \alpha_0 - b^\prime \bar{\rho} \|^2 = O(\bar{s}\epsilon_n^2) \)
2. \( G \) is nonsingular with largest eigenvalue uniformly bounded in \( n \)
3. \( \exists k > 3 \) s.t. \( RE(k) = \inf \{ \delta : \delta \neq 0, \sum_{j \in J_{\rho_L}} |\delta_j| \leq k \sum_{j \in J_{\rho_L}} |\delta_j| \} \frac{\delta^\prime \Sigma \delta}{\sum_{j \in J_{\rho_L}} \delta_j^2} > 0 \) where \( J_{\rho_L} = \text{supp}(\rho_L) \).
4. \( \bar{s}\lambda_n^2 = o(n^{2d_\gamma - 1}) \)

**Assumption 7** (Sufficient conditions). Assume

1. \( [B_n^b + (B_n^b)^2] \sqrt{\frac{\ln p}{n}} = o(\lambda_n) \)
2. \( (1 + B_n)B_n^b = o(n^{d_\gamma}) \)
We compare the performance of DML-RRR with original DML [13]. We obtain a slow rate for dense $\alpha_0$ and a fast rate for sparse $\alpha_0$.

**Theorem 2** (Dense RR rate). Under Assumptions [1, 2, 3, 5, 7] $\|\hat{\alpha} - \alpha_0\|^2 = O_p((1 + B_n)\lambda_n)$ and $|\hat{\rho}|_1 = O_{p}(1 + B_n)$

**Theorem 3** (Sparse RR rate). Under Assumptions [1, 2, 3, 6, 7] $\|\hat{\alpha} - \alpha_0\|^2 = O_p(\delta\lambda_n^2)$ and $|\hat{\rho}|_1 = O_{p}(1 + B_n)$

We now present the main theorem of this paper. We prove our DML-RRR estimator for complier parameters is consistent and asymptotically normal, appealing to the theory in [15] to generalize the main result in [19].

**Assumption 8.** $\theta_0, \hat{\theta} \in \Theta$, a compact parameter space

**Theorem 4** (DML-RRR asymptotic normality). Suppouse Assumptions [1, 2, 3, 4, either 5 or 6, 7] and 8 hold. Then $\hat{\theta} \xrightarrow{P} \theta_0$, $\sqrt{n}(\hat{\theta} - \theta_0) \xrightarrow{d} N(0, C)$, and $\hat{C} \xrightarrow{P} C$ where

$$J = E\left[\frac{\partial \psi_i(W)}{\partial \theta}\right], \quad \hat{J} = \frac{1}{n} \sum_{\ell=1}^{L} \sum_{i \in I_{\ell}} \frac{\partial \psi_i(\hat{\theta})}{\partial \theta}, \quad \Omega = E[\psi_i(W)\psi_i(W)^\prime], \quad \hat{\Omega} = \frac{1}{n} \sum_{\ell=1}^{L} \sum_{i \in I_{\ell}} \hat{\psi}_i(\hat{\theta})\hat{\psi}_i(\hat{\theta})^\prime$$

$$C = J^{-1}J^{-1}, \quad \hat{C} = \hat{J}^{-1}\hat{J}^{-1}, \quad \psi_0(W) = \psi(W, \gamma_0, \alpha_0, \theta_0), \quad \hat{\psi}_i(\theta) = \psi(W, \gamma_{-\ell}, \hat{\alpha}_{-\ell}, \theta)$$

It follows that $\hat{\theta}$ is semiparametrically efficient [15]. Finally, we prove the validity of simultaneous confidence bands for counterfactual distribution estimators.

**Theorem 5** (Simultaneous confidence band). Under the Assumptions of Theorem 4 the confidence band in Algorithm 3 jointly covers the true counterfactual distribution $\theta_0$ at all grid points $y \in \mathcal{U}$ with probability approaching the nominal level, i.e. $\lim_{n \to \infty} P(\theta_0^\alpha \in [y, \bar{y}] \forall y \in \mathcal{U}) = 1 - \alpha$.

### 6 Experiments

We compare the performance of DML-RRR with original DML [13] and $\kappa$-weighting [2] in simulations. We focus on counterfactual distributions as our choice of complier parameter. We then apply DML-RRR to real-world data to estimate the counterfactual distribution of employee net financial assets with and without 401(k) participation.

#### 6.1 Simulation

We apply DML-RRR, DML, and $\kappa$-weighting to a counterfactual distribution design detailed in Appendix 8.6. Each simulation consists of $n = 1000$ observations, and we use a dictionary $I$ with dimension $p = 10$. Both DML and $\kappa$-weighting involve inverting $\hat{\pi}$. To improve numerical stability for the DML estimator, we impose trimming according to [10], dropping observations with $\hat{\pi} \notin [10^{-12}, 1 - 10^{-12}]$.

For each algorithm, we implement 500 simulations and visualize the mean as well as the 2.5% and 97.5% quantiles for each value in the grid $\mathcal{U}$. Figure 1 summarizes results: DML-RRR performs best, though its improvement over DML is modest. However, one advantage of DML-RRR is that it does not require ad-hoc trimming. $\kappa$-weighting performs worst, perhaps because it does not use a regularized ML estimator of $\hat{\pi}$.
6.2 Effect of 401(k) on assets

Next, we use DML-RRR to investigate the effect of 401(k) participation on the distribution of net financial assets. We follow the identification strategy of \cite{30, 31}. The authors assume that when 401(k) was introduced, workers ignored whether a given job offered 401(k) and instead made employment decisions based on income and other observable job characteristics; after conditioning on income and job characteristics, 401(k) eligibility was exogenous at the time.

We use data from the 1991 US Survey of Income and Program Participation, studied in \cite{2, 16, 17, 28, 10}. We use sample selection and variable construction as in \cite{16}. The outcome $Y$ is net financial assets defined as the sum of IRA balances, 401(k) balances, checking accounts, US saving bonds, other interest-earning accounts, stocks, mutual funds, and other interest-earning assets minus non-mortgage debt. The treatment $D$ is participation in the 401(k) plan. The instrument $Z$ is eligibility to enroll in a 401(k) plan. The covariates $X$ are age, income, years of education, family size, marital status, two-earner status, benefit pension status, IRA participation, and home-ownership.

The data include $n = 9915$ observations. We follow \cite{10} in the choice of grid points $\mathcal{U}$ and the dictionary $b$. We take $\mathcal{U}$ as the 5th through 95th percentiles of $Y$, a total of 91 different values of $y$. We consider two dictionaries: low-$p$ with $p = 35$ and very-high-$p$ with $p = 1756$. See Appendix 8.7 for further details on the dictionaries and DML-RRR implementation.

Figure 2 visualizes point estimates and simultaneous 95% confidence bands. We find that 401(k) participation significantly shifts out the distribution of net financial assets, consistent with results reported in \cite{10}. Moreover, the DML-RRR algorithm is robust in the high dimensional setting, yielding similar results in the low-$p$ and very-high-$p$ specifications.
7 Conclusion

We extend DML-RRR to the task of learning causal parameters from confounded, high-dimensional data. DML-RRR is easily implemented and semiparametrically efficient. As a contribution to the IV literature, we reinterpret the $\kappa$-weight as the Riesz representer in the problem of learning complier parameters. As a contribution to the DML literature, we generalize the theory of DML-RRR and provide simultaneous confidence bands. In simulations, DML-RRR modestly outperforms DML and $\kappa$-weighting and eliminates the ad-hoc step of trimming, suggesting DML-RRR may be an effective paradigm in high-dimensional causal inference.

8.1 Notation glossary

Let \( W = (Y, D, Z, X) \) concatenate the random variables. \( Y \in \mathcal{Y} \subset \mathbb{R} \) is the continuous outcome, \( D \in \{0, 1\} \) is the binary treatment, \( Z \in \{0, 1\} \) is the binary instrumental variable, and \( X \in \mathcal{X} \subset \mathbb{R}^d \) is the covariate. We observe \( n \) i.i.d. observations \( \{W_i\}_{i=1}^n \). Where possible, we suppress index \( i \) to lighten notation.

Following the notation of [6], we denote by \( Y^{(z,d)} \) the potential outcome under the intervention \( Z = z \) and \( D = d \). Due to Assumption [11] we can simplify notation: \( Y^{(d)} = Y^{(1,d)} = Y^{(0,d)} \). We denote by \( D^{(z)} \) the potential treatment under the intervention \( Z = z \). Compliers are the subpopulation for whom \( D^{(1)} > D^{(0)} \).

Using the notation of [19], we denote the conditional expectation function (CEF) of random vector \( V = (V_1, ..., V_J)' \) conditional on \((Z, X)\) as

\[
\gamma_0(Z, X) = \begin{bmatrix}
\gamma_0^{V_1}(Z, X) \\
\vdots \\
\gamma_0^{V_J}(Z, X)
\end{bmatrix} = \mathbb{E}[V \mid Z, X]
\]

where \( \gamma_0^{V_j}(Z, X) = \mathbb{E}[V_j \mid Z, X] \). The random vector \( V \) is observable and depends on the complier parameter of interest; we specify its components for LATE, complier characteristics, and counterfactual outcome distributions in Theorem [11].

We denote the propensity score \( \pi_0(x) = \mathbb{P}(Z = 1 \mid X = x) \). We denote the classic Horvitz-Thompson weight with \( \alpha_0(z, x) = \frac{x}{\pi_0(x)} - \frac{1 - x}{1 - \pi_0(x)} = \frac{x - \pi_0(x)}{\pi_0(x)(1 - \pi_0(x))} \).

We denote by \( \| \cdot \|_q \) the \( \ell_q \) norm of a vector. We denote by \( \| \cdot \| \) the \( L_2 \) norm of a random variable \( V_j \), i.e. \( \| V_j \| = \sqrt{\mathbb{E}[V_j^2]} \). For random vector \( V = (V_1, ..., V_J)' \), we slightly abuse notation by writing

\[
\| V \| = \begin{bmatrix}
\| V_1 \| \\
\| V_2 \| \\
\vdots \\
\| V_J \|
\end{bmatrix}, \quad \mathbb{E}[V]^2 = \| V \|^2 = \begin{bmatrix}
\| V_1 \|^2 \\
\| V_2 \|^2 \\
\vdots \\
\| V_J \|^2
\end{bmatrix}
\]

Likewise, we write the element-wise absolute value as

\[
| V | = \begin{bmatrix}
| V_1 | \\
| V_2 | \\
\vdots \\
| V_J |
\end{bmatrix}
\]
Finally, we denote the true parameter value $\theta_0 \in \Theta$, where $\Theta$ is some compact parameter space.

### 8.2 Identification

We review the derivation of the classic Horvitz-Thompson weight, relate DML-RRR to $\kappa$-reweighting, prove a general identification result, and specialize this result to LATE, complier characteristics, and counterfactual outcome distributions.

**Proposition 1.** $\alpha_0(z, x)$ is the RR to the continuous linear functional $\gamma \mapsto E[\gamma(1, X) - \gamma(0, X)]$, i.e.

$$E[\gamma(1, X) - \gamma(0, X)] = E[\alpha_0(Z, X)\gamma(Z, X)], \quad \forall \gamma \text{ s.t. } E[\gamma(Z, X)]^2 < \infty$$

**Proof.** Observe that

$$E \left[ \gamma(Z, X) \frac{Z}{\pi_0(X)} \mid X \right] = E \left[ \gamma(Z, X) \frac{1}{\pi_0(X)} \mid X = 1, X \right] \mathbb{P}(Z = 1 \mid X)$$

$$= E \left[ \gamma(Z, X) \frac{1}{\pi_0(X)} \mid Z = 1, X \right] \pi_0(X)$$

and likewise

$$E \left[ \gamma(Z, X) \frac{1 - Z}{1 - \pi_0(X)} \mid X \right] = \gamma(0, X)$$

In summary, we can write

$$E[\gamma(1, X) - \gamma(0, X)] = \int \left\{ (\gamma(1, x) - \gamma(0, x)) d\mathbb{P}(x) \right\}$$

$$= \int \left\{ E \left[ \gamma(Z, X) \frac{Z}{\pi_0(X)} \mid X = x \right] - E \left[ \gamma(Z, X) \frac{1 - Z}{1 - \pi_0(X)} \mid X = x \right]\right\} d\mathbb{P}(x)$$

$$= E \left[ \gamma(Z, X) \frac{Z}{\pi_0(X)} \right] - E \left[ \gamma(Z, X) \frac{1 - Z}{1 - \pi_0(X)} \right]$$

\(\square\)

**Definition 2.** Define

$$\kappa^{(0)}(w) = (1 - d) \frac{(1 - z) - (1 - \pi_0(x))}{1 - \pi_0(x) \pi_0(x)}$$

$$\kappa^{(1)}(w) = d \frac{z - \pi_0(x)}{1 - \pi_0(x) \pi_0(x)}$$

$$\kappa(w) = (1 - \pi_0(x))\kappa^{(0)}(w) + \pi_0(x)\kappa^{(1)}(w)$$

These are the $\kappa$-weights introduced in \[2\].

**Proposition 2.** The $\kappa$-weights can be rewritten as

$$\kappa^{(0)}(w) = \alpha_0(z, x)[d - 1]$$

$$\kappa^{(1)}(w) = \alpha_0(z, x)d$$

$$\kappa(w) = \alpha_0(z, x)[d - 1 + \pi_0(x)]$$

**Proof.** $\alpha_0(z, x) = \frac{z}{\pi_0(x)} - \frac{1 - z}{1 - \pi_0(x)} = \frac{z - \pi_0(x)}{\pi_0(x)[1 - \pi_0(x)]}$

\(\square\)

**Theorem 6.** Suppose Assumption 4 holds. Let $g(y, d, x, \theta)$ be a measurable, real-valued function s.t. $E[g(Y, D, X, \theta)]^2 < \infty$ for all $\theta \in \Theta$.

1. If $\theta_0$ is defined by the moment condition $E[g(Y^{(0)}, X, \theta_0)]|D^{(1)} > D^{(0)}] = 0$, let

$$v(w, \theta) = [d - 1]g(y, x, \theta)$$
2. If \( \theta_0 \) is defined by the moment condition \( \mathbb{E}[g(Y^{(1)}, X, \theta_0)|D^{(1)} > D^{(0)}] = 0 \), let \( v(w, \theta) = d \cdot g(y, x, \theta) \)

3. If \( \theta_0 \) is defined by the moment condition \( \mathbb{E}[g(Y, D, X, \theta_0)|D^{(1)} > D^{(0)}] = 0 \), let \( v(w, \theta) = [d - 1 + \pi_0(x)]g(y, d, x, \theta) \)

Then the DR moment function for \( \theta_0 \) is of the form

\[
\psi(w, \gamma, \alpha, \theta) = \hat{n}(w, \gamma, \theta) + \phi(w, \gamma, \alpha, \theta)
\]

\[
\hat{n}(w, \gamma, \theta) = \gamma(1, x, \theta) - \gamma(0, x, \theta)
\]

\[
\phi(w, \gamma, \alpha, \theta) = \alpha(z, x)[v(w, \theta) - \gamma(z, x)]
\]

where \( \gamma_0(z, x, \theta) := \mathbb{E}[V(W, \theta)|z, x] \)

**Proof.** Consider the first case. Under Assumption\(^1\) we can appeal to \(^2\) Theorem 3.1.

\[
0 = \mathbb{E}[g(Y^{(0)}, X, \theta_0)|D^{(1)} > D^{(0)}] = \frac{\mathbb{E}[\kappa^{(0)}(W)g(Y^{(0)}, X, \theta_0)]}{\mathbb{P}(D^{(1)} > D^{(0)})}
\]

Hence

\[
0 = \mathbb{E}[\kappa^{(0)}(W)g(Y^{(0)}, X, \theta_0)]
\]

\[
= \mathbb{E}[\alpha_0(Z, X)|D - 1]g(Y^{(0)}, X, \theta_0)]
\]

\[
= \mathbb{E}[\alpha_0(Z, X)V(W, \theta_0)]
\]

\[
= \mathbb{E}[\alpha_0(Z, X)\gamma_0(Z, X, \theta_0)]
\]

\[
= \mathbb{E}[\gamma_0(1, X, \theta_0) - \gamma_0(0, X, \theta_0)]
\]

appealing to Assumption\(^1\) Proposition\(^2\) and the fact that \( \alpha_0 \) is the RR for \( \gamma \mapsto \mathbb{E}[\gamma(1, X, \theta_0) - \gamma(0, X, \theta_0)] \). Likewise for the second and third cases.

**Proof of Theorem\(^7\)** Suppose we can decompose \( v(w, \theta) = h(w, \theta) + a(\theta) \) for some function \( a(\cdot) \) that does not depend on data. Then we can replace \( v(w, \theta) \) with \( h(w, \theta) \) without changing \( \hat{n} \) and \( \phi \). This is because \( \gamma^v(z, x, \theta) = \gamma^h(z, x, \theta) + a(\theta) \) and hence \( v(w, \theta) - \gamma^v(z, x) = h(w, \theta) - \gamma^h(z, x) \). Whenever we use this reasoning, we write \( v(w, \theta) \propto h(w, \theta) \).

1. For LATE we can write \( \theta_0 = \delta_0 - \beta_0 \), where \( \delta_0 \) is defined by the moment condition \( \mathbb{E}[Y^{(1)} - \delta_0|D^{(1)} > D^{(0)}] = 0 \) and \( \beta_0 \) is defined by the moment condition \( \mathbb{E}[Y^{(0)} - \beta_0|D^{(1)} > D^{(0)}] = 0 \). Applying case 2 of Theorem\(^6\) to \( \delta_0 \), we have \( v(w, \delta) = d \cdot (y - \delta) \). Applying case 1 of Theorem\(^6\) to \( \beta_0 \), we have \( v(w, \beta) = (d - 1) \cdot (y - \beta) \cdot x \). Writing \( \theta = \delta - \beta \), the moment function for \( \theta_0 \) can thus be derived with \( v(w, \theta) = v(w, \delta) - v(w, \beta) = y - d \cdot \theta \). Note that this expression decomposes into \( V = (Y, D)' \) and \( A(\theta) = [1 - \theta] \) in Theorem\(^1\).

2. For average complier characteristics, \( \theta_0 \) is defined by the moment condition \( \mathbb{E}[f(X) - \theta_0|D^{(1)} > D^{(0)}] = 0 \). Applying case 2 of Theorem\(^6\) we have \( v(w, \theta) = d \cdot f(x) - \theta_0 \). This expression decomposes into \( V = (D f(X)', D)' \) and \( A(\theta) = [1 - \theta] \) in Theorem\(^1\).

3. For complier distribution of \( Y^{(0)}, \beta_0^\gamma \) is defined by the moment condition \( \mathbb{E}[\mathbb{1}_{Y^{(0)} < \beta_0^\gamma} - \beta_0^\gamma|D^{(1)} > D^{(0)}] = 0 \). Applying case 1 of Theorem\(^6\) to \( \beta_0^\gamma \), we have \( v(w, \beta^\gamma) = (d - 1) \cdot (1_{y < \beta^\gamma} - \beta^\gamma) \cdot x \cdot (d - 1) \cdot 1_{y < \beta^\gamma} - d \cdot \beta^\gamma \). For complier distribution of \( Y^{(1)}, \delta_0^\gamma \) is defined by the moment condition \( \mathbb{E}[\mathbb{1}_{Y^{(1)} < \delta_0^\gamma} - \delta_0^\gamma|D^{(1)} > D^{(0)}] = 0 \). Applying case 2 of Theorem\(^6\) to \( \delta_0 \), we have \( v(w, \delta^\gamma) = d \cdot (1_{y < \delta^\gamma} - \delta^\gamma) \). Concatenating \( v(w, \beta^\gamma) \) and \( v(w, \delta^\gamma) \), we arrive at the decomposition in Theorem\(^1\).

\(\square\)
8.3 Lemmas

Definition 3.

\[ G = E[b(Z, X) b(Z, X)'] \]
\[ M = E[m(W, b, \theta_0)] \]

Proposition 3. Under Assumption 2

\[ \hat{G} - G \sim O_p \left( (B^b_n)^2 \sqrt{\frac{\ln p}{n}} \right) \]

Proof. [19 Lemma A1]

Denote \( \hat{m}(w, \gamma) := \gamma(1, x) - \gamma(0, x) \).

Proposition 4. Under Assumptions 1 and 3

1. \( E[\hat{m}(W, \gamma_0)^2] < \infty \)
2. \( E[\hat{m}(W, \gamma) - \hat{m}(W, \gamma_0)]^2 \) is continuous at \( \gamma_0 \) w.r.t. \( \| \gamma - \gamma_0 \| \)
3. \( \max_j |\hat{m}(W, b_j) - \hat{m}(W, 0)| \leq B^b_n \)

Proof. [19 Theorem 6]

Proposition 5. Under Assumptions 1 and 3

\[ |\hat{M} - M| \sim O_p \left( B^b_n \sqrt{\frac{\ln p}{n}} \right) \]

Proof. Proposition 4 and [19, Lemma 4]

Proposition 6. Under Assumption 3

1. \( E[\gamma_0(d, Z)]^2 \leq C E[\gamma_0(D, Z)]^2 \) for \( d \in \{0, 1\} \)
2. \( E[\gamma(d, Z) - \gamma_0(d, Z)]^2 \leq C \| \gamma - \gamma_0 \|^2 \) for \( d \in \{0, 1\} \)

Proof. [19 Theorem 6]

Proposition 7. Consider the estimator \( \hat{\theta} = \arg\min_{\theta \in \Theta} \hat{Q}(\theta) \), where \( \hat{Q} : \Theta \rightarrow \mathbb{R} \) estimates \( Q_0 : \Theta \rightarrow \mathbb{R} \). If

1. \( \Theta \) is compact
2. \( Q_0 \) is continuous in \( \theta \in \Theta \)
3. \( Q_0 \) is uniquely maximized at \( \theta_0 \)
4. \( \sup_{\theta \in \Theta} |\hat{Q}(\theta) - Q_0(\theta)| \overset{p}{\rightarrow} 0 \)

then \( \hat{\theta} \overset{p}{\rightarrow} \theta_0 \)

Proof. [25, Theorem 2.1]

8.4 Stage 1

Proof of Theorem 2.

Proposition 3, Proposition 5, and [19, Theorem 1]

Proof of Theorem 3.

Proposition 8. Under Assumptions 1, 2, 3, 4, either 5 or 6, and 7

\[ \| \hat{\alpha} - \alpha_0 \| \cdot \| \hat{\gamma} - \gamma_0 \| = o_p(n^{-\frac{1}{2}}) \]

Proof. Corollary of Theorems 2 and 5
8.5 Stage 2

\[ \frac{1}{\sqrt{n}} \sum_{\ell=1}^{L} \sum_{i \in \ell} \psi(W_i, \hat{\gamma}_{-\ell}, \hat{\alpha}_{-\ell}, \hat{\theta}) \overset{p}{\to} \frac{1}{\sqrt{n}} \sum_{i=1}^{n} \psi_0(W_i) \]

Proof. [19, Theorem 5]

1. \( \mathbb{E}[m(W_i, \hat{\gamma}_{-\ell}, \theta) - m(W_i, \gamma_0, \theta)]^2 \overset{p}{\to} 0 \)
2. \( \mathbb{E}[\phi(W_i, \hat{\gamma}_{-\ell}, \alpha_0, \theta) - \phi(W_i, \gamma_0, \alpha_0, \theta)]^2 \overset{p}{\to} 0 \)
3. \( \mathbb{E}[\phi(W_i, \gamma_0, \hat{\alpha}_{-\ell}, \theta) - \phi(W_i, \gamma_0, \alpha_0, \theta)]^2 \overset{p}{\to} 0 \)

Proof. First note that

\( \phi(W_i, \hat{\gamma}_{-\ell}, \alpha_0, \theta) - \phi(W_i, \gamma_0, \alpha_0, \theta) = \alpha_0(z, x)A(\theta_0)[\gamma_0(z, x) - \hat{\gamma}_{-\ell}(z, x)] \)

\( \phi(W_i, \gamma_0, \hat{\alpha}_{-\ell}, \theta) - \phi(W_i, \gamma_0, \alpha_0, \theta) = [\hat{\alpha}_{-\ell}(z, x) - \alpha_0(z, x)]A(\theta_0)[v - \gamma_0(z, x)] \)

\( \|\alpha_0A(\theta_0)[\gamma_0 - \hat{\gamma}_{-\ell}]\| \leq CA(\theta_0)\|\gamma_0 - \hat{\gamma}_{-\ell}\| \overset{p}{\to} 0 \)

\( \|\hat{\alpha}_{-\ell} - \alpha_0\|A(\theta_0)[v - \gamma_0(z, x)] \| \leq \|\hat{\alpha}_{-\ell} - \alpha_0\|A(\theta_0)C \cdot 1 \overset{p}{\to} 0 \)

\[ \frac{1}{\sqrt{n}} \sum_{i=1}^{L} \sum_{i \in \ell} [\phi(W_i, \hat{\gamma}_{-\ell}, \hat{\alpha}_{-\ell}, \theta) - \phi(W_i, \hat{\gamma}_{-\ell}, \alpha_0, \theta) - \phi(W_i, \gamma_0, \hat{\alpha}_{-\ell}, \theta) + \phi(W_i, \gamma_0, \alpha_0, \theta)] \overset{p}{\to} 0 \]

Proof. Note that

\( \phi(W_i, \hat{\gamma}_{-\ell}, \hat{\alpha}_{-\ell}, \theta) - \phi(W_i, \hat{\gamma}_{-\ell}, \alpha_0, \theta) - \phi(W_i, \gamma_0, \hat{\alpha}_{-\ell}, \theta) + \phi(W_i, \gamma_0, \alpha_0, \theta) \)

\( = -[\hat{\alpha}_{-\ell}(z, x) - \alpha_0(z, x)]A(\theta_0)[\gamma_0(z, x) - \hat{\gamma}_{-\ell}(z, x)] \)

Because convergence in first mean implies convergence in probability, it suffices to analyze

\( \mathbb{E} \left[ \left| \frac{1}{\sqrt{n}} \sum_{i=1}^{L} \sum_{i \in \ell} [\hat{\alpha}_{-\ell}(Z_i, X_i) - \alpha_0(Z_i, X_i)]A(\theta_0)[\gamma_0(Z_i, X_i) - \hat{\gamma}_{-\ell}(Z_i, X_i)] \right| \right] \)

\( \leq \sum_{\ell=1}^{L} \mathbb{E} \left[ \sqrt{n} \frac{1}{\sqrt{n}} \sum_{i \in \ell} \left| [\hat{\alpha}_{-\ell}(Z_i, X_i) - \alpha_0(Z_i, X_i)]A(\theta_0)[\gamma_0(Z_i, X_i) - \hat{\gamma}_{-\ell}(Z_i, X_i)] \right| W_{-\ell} \right] \)

\( = \sum_{\ell=1}^{L} \mathbb{E} \left[ \sqrt{n} \frac{1}{\sqrt{n}} \sum_{i \in \ell} \left| [\hat{\alpha}_{-\ell}(Z_i, X_i) - \alpha_0(Z_i, X_i)]A(\theta_0)[\gamma_0(Z_i, X_i) - \hat{\gamma}_{-\ell}(Z_i, X_i)] \right| W_{-\ell} \right] \)

16
By element-wise Hölder and Proposition 8 we have convergence for each summand as
\[
\mathbb{E} \left[ \sqrt{n} \frac{\partial A}{\partial \theta} (Z_i, X_i) - \alpha_0 (Z_i, X_i) \right] A(\theta_0) [\gamma - \gamma_0 (Z_i, X_i)] \bigg| W - \ell \right] \\
\leq \mathbb{E} \left[ \sqrt{n} \frac{\partial A}{\partial \theta} (Z_i, X_i) - \alpha_0 (Z_i, X_i) \right] A(\theta_0) [\gamma - \gamma_0 (Z_i, X_i)] \bigg| W - \ell \right] \\
\leq \sqrt{n} \| \frac{\partial A}{\partial \theta} - \alpha_0 \| A(\theta_0) \| \gamma - \gamma_0 \| 
\xrightarrow{P} 0
\]

**Proposition 12.** Under Assumption 1 for each \( \ell \)
\begin{enumerate}
\item \( \sqrt{n} \mathbb{E} [\psi (W, \gamma - \ell, \alpha_0, \theta_0)] \xrightarrow{P} 0 \)
\item \( \sqrt{n} \mathbb{E} [\phi (W, \gamma_0, \alpha - \ell, \theta_0)] \xrightarrow{P} 0 \)
\end{enumerate}

**Proof.** Note that
\[
\mathbb{E}[\psi (W, \gamma - \ell, \alpha_0, \theta_0)] = \mathbb{E}[A(\theta_0) [\gamma - \ell (1, X) - \gamma_0 (0, X)] + \alpha_0 (Z, X) A(\theta_0) [V - \gamma - \ell (Z, X)]] \\
\mathbb{E}[\phi (W, \gamma_0, \alpha - \ell, \theta_0)] = \mathbb{E}[\frac{\partial A}{\partial \theta} (Z, X) A(\theta_0) [V - \gamma_0 (Z, X)]]
\]

1. The LHS is exactly 0 by Theorem 1 as well as LIE w.r.t. \( W - \ell \)
2. The LHS is exactly 0 by Theorem 1 as well as LIE w.r.t. \( W - \ell \)

\[\square\]

**Proposition 13.** Under Assumptions 1, 2, 3, 4, either 5 or 6 and 7
\begin{enumerate}
\item \( J \) exists.
\item \( \exists \) neighborhood \( \mathcal{N} \) of \( \theta_0 \) w.r.t. \( \| \cdot \| \) s.t.
\begin{enumerate}
\item \( \| \gamma - \gamma_0 \| \xrightarrow{P} 0 \)
\item \( \| \alpha - \alpha_0 \| \xrightarrow{P} 0 \)
\item \( \| \gamma - \gamma_0 \| \) and \( \| \alpha - \alpha_0 \| \) small enough, \( \psi (W_i, \gamma, \alpha, \theta) \) is diff. in \( \theta \) w.p.a. 1
\item \( \exists C > 0 \) and \( d(W) \) s.t. \( \mathbb{E}[d(W)] < \infty \) and for \( \| \gamma - \gamma_0 \| \) small enough,
\begin{equation}
\left\| \frac{\partial \psi (w, \gamma, \alpha, \theta_0)}{\partial \theta} - \frac{\partial \psi (w, \gamma, \alpha, \theta_0)}{\partial \theta} \right\|_2 \leq C \| d(W) \| < \infty \text{ and for } \| \gamma - \gamma_0 \| \text{ small enough,}
\end{equation}
\end{enumerate}
\item \( \mathbb{E} \left[ \left| \frac{\partial \psi (w, \gamma, \alpha, \theta_0)}{\partial \theta} - \frac{\partial \psi (w, \gamma_0, \alpha, \theta_0)}{\partial \theta} \right| \right] \xrightarrow{P} 0, \forall \ell, j, k \)
\end{enumerate}

**Proof.** Note that
\[
\frac{\partial \psi (w, \gamma, \alpha, \theta)}{\partial \theta} = \frac{\partial A(\theta)}{\partial \theta} [\gamma (1, x) - \gamma (0, x)] + \alpha (z, x) \frac{\partial A(\theta)}{\partial \theta} [v - \gamma (z, x)]
\]
where \( \frac{\partial A(\theta)}{\partial \theta} \) is a tensor consisting of 1s and 0s.

1. It suffices to show finite second moment. By triangle inequality and Assumption 5
\[
\left\| \frac{\partial A(\theta_0)}{\partial \theta} [\gamma (1, x) - \gamma (0, x)] + \alpha (z, x) \frac{\partial A(\theta_0)}{\partial \theta} [v - \gamma (z, x)] \right\| \leq \frac{\partial A(\theta_0)}{\partial \theta} \left\| \gamma (1, x) - \gamma (0, x) \right\| + C
\]
To bound the RHS, appeal to Proposition 6
\[
\| \gamma (1, x) - \gamma (0, x) \| \leq \| \gamma (1, x) \| + \| \gamma (0, x) \| \leq C \| \gamma \| < \infty
\]
2. (a) Assumption 4

\[\square\]
We verify the conditions of Proposition 7 with

\[E|\xi| \leq E|\hat{\gamma}_e(1, X) - \gamma_0(1, X)|
\]

\[\quad + E|\hat{\gamma}_e(0, X) - \gamma_0(0, X)|
\]

\[\quad + E|[\hat{\alpha}_e(Z, X) - \alpha_0(Z, X)][V - \gamma_0(Z, X)]|
\]

\[\quad + E|[\hat{\alpha}_e(Z, X) - \alpha_0(Z, X)][\gamma_0(Z, X) - \hat{\gamma}_e(Z, X)]|
\]

\[\quad + E|\alpha_0(Z, X)[\gamma_0(Z, X) - \hat{\gamma}_e(Z, X)]|
\]

Consider the first two terms. By Jensen, Proposition 6 and Assumption 3

\[E|\hat{\gamma}_e(1, X) - \gamma_0(1, X)| \leq ||\hat{\gamma}_e(1, x) - \gamma_0(1, x)|| \leq C||\hat{\gamma}_e - \gamma_0|| \overset{p}{\to} 0
\]

\[E|\hat{\gamma}_e(0, X) - \gamma_0(0, X)| \leq ||\hat{\gamma}_e(0, x) - \gamma_0(0, x)|| \leq C||\hat{\gamma}_e - \gamma_0|| \overset{p}{\to} 0
\]

Consider the third term. By Hölder, Theorem 2 or Theorem 3, Assumption 3 and LIE w.r.t. \( W_e \)

\[E|[\hat{\alpha}_e(Z, X) - \alpha_0(Z, X)][V - \gamma_0(Z, X)]| \leq ||\hat{\alpha}_e - \alpha_0|| C||v - \gamma_0(z, x)|| \overset{p}{\to} 0
\]

Consider the fourth term. By Hölder and Proposition 8

\[E|[\hat{\alpha}_e(Z, X) - \alpha_0(Z, X)][\gamma_0(Z, X) - \hat{\gamma}_e(Z, X)]| \leq ||\hat{\alpha}_e - \alpha_0|| C||\gamma_0 - \hat{\gamma}_e|| \overset{p}{\to} 0
\]

Consider the fifth term. By Assumption 3, Jensen, and Assumption 4

\[E|\alpha_0(Z, X)[\gamma_0(Z, X) - \hat{\gamma}_e(Z, X)]| \leq C E|\gamma_0(Z, X) - \hat{\gamma}_e(Z, X)| \leq C||\gamma_0 - \hat{\gamma}_e|| \overset{p}{\to} 0
\]

\[\square
\]

**Proposition 14.** Suppose Assumptions 1, 2, 3, 4, either 5 or 6, 7, and 8 hold. Then \( \hat{\theta} \overset{p}{\to} \theta_0 \)

**Proof.** We verify the conditions of Proposition 7 with

\[Q_0(\theta) = E[\psi_0(\theta)] E[\psi_0(\theta)]
\]

\[\hat{Q}(\theta) = \left[ \frac{1}{n} \sum_{\ell=1}^{L} \sum_{i \in I_\ell} \hat{\psi}_i(\theta) \right]' \frac{1}{n} \sum_{\ell=1}^{L} \sum_{i \in I_\ell} \hat{\psi}_i(\theta)
\]

\[\psi_0(\theta) = \psi(W, \gamma_0, \alpha_0, \theta)
\]

\[\hat{\psi}_i(\theta) = \psi(W, \hat{\gamma}_e, \hat{\alpha}_e, \theta)
\]

18
1. Assumption 
2. Theorem
3. Theorem
4. Define

\[
\eta_0(w) = \gamma_0(1, x) - \gamma_0(0, x) + \alpha_0(z, x)[v - \gamma_0(z, x)]
\]

\[
\hat{\eta}_{-\ell}(w) = \hat{\gamma}_{-\ell}(1, x) - \hat{\gamma}_{-\ell}(0, x) + \hat{\alpha}_{-\ell}(z, x)[v - \hat{\gamma}_{-\ell}(z, x)]
\]

It follows that

\[
\psi_0(\theta) = A(\theta)\eta_0(W), \quad \mathbb{E}\psi_0(\theta) = A(\theta)\mathbb{E}\eta_0(W)
\]

\[
\hat{\psi}_i(\theta) = A(\theta)\hat{\eta}_{-\ell}(W_i), \quad \frac{1}{n} \sum_{\ell=1}^{L} \sum_{i \in I_\ell} \hat{\psi}_i(\theta) = A(\theta) \frac{1}{n} \sum_{\ell=1}^{L} \sum_{i \in I_\ell} \hat{\eta}_{-\ell}(W_i)
\]

It suffices to show \( \frac{1}{n} \sum_{\ell=1}^{L} \sum_{i \in I_\ell} \hat{\eta}_{-\ell}(W_i) \xrightarrow{P} \mathbb{E}\eta_0(W) \) since by continuous mapping theorem this implies that \( \forall \theta \in \Theta, \frac{1}{n} \sum_{\ell=1}^{L} \sum_{i \in I_\ell} \hat{\psi}_i(\theta) \xrightarrow{P} \mathbb{E}\psi_0(\theta) \) and hence \( Q(\theta) \xrightarrow{P} Q_0(\theta) \) uniformly.

We therefore turn to arguing the sufficient condition. Write

\[
\frac{1}{n} \sum_{\ell=1}^{L} \sum_{i \in I_\ell} \hat{\eta}_{-\ell}(W_i) - \mathbb{E}\eta_0(W) = \frac{1}{n} \sum_{\ell=1}^{L} \sum_{i \in I_\ell} [\hat{\eta}_{-\ell}(W_i) - \eta_0(W_i)] + \frac{1}{n} \sum_{\ell=1}^{L} \sum_{i \in I_\ell} \eta_0(W_i) - \mathbb{E}\eta_0(W)
\]

Consider the first and second term. Denote \( \xi_i = \hat{\eta}_{-\ell}(W_i) - \eta_0(W_i) \) as in Proposition 13.3. Since convergence in mean implies convergence in probability, it suffices to analyze

\[
\mathbb{E}\left|\frac{1}{n} \sum_{\ell=1}^{L} \sum_{i \in I_\ell} \xi_i\right| \leq \sum_{\ell=1}^{L} \mathbb{E}\left[\frac{1}{n} \sum_{i \in I_\ell} |\xi_i| |W_{-\ell}|\right] = \sum_{\ell=1}^{L} \frac{\mathbb{E}n_\ell}{n} \mathbb{E}[|\xi_i||W_{-\ell}|] \leq \sum_{\ell=1}^{L} \mathbb{E}[|\xi_i||W_{-\ell}|] \to 0
\]

by triangle inequality, LIE, and the proof of Proposition 13.3.

Consider the third and fourth term.

\[
\frac{1}{n} \sum_{\ell=1}^{L} \sum_{i \in I_\ell} \eta_0(W_i) - \mathbb{E}\eta_0(W) = \frac{1}{n} \sum_{i=1}^{n} \eta_0(W_i) - \mathbb{E}\eta_0(W) \xrightarrow{P} 0
\]

by WLLN and the fact that \( \mathbb{E}[\hat{\eta}_0(W)]^2 < \infty \), guaranteed by the argument in Proposition 15.3 below.

\[ \square \]

**Proposition 15.** Under Assumptions 1, 2, 3, 4, either 5 or 6, 7, and 8,

1. \( \hat{\theta} \xrightarrow{P} \theta_0 \)
2. \( J'J \) is nonsingular
3. $\mathbb{E}[\psi_0(W)]^2 < \infty$

4. $\mathbb{E}[\phi(W, \hat{\gamma}_{-\ell}, \hat{\alpha}_{-\ell}, \theta_0) - \phi(W, \hat{\gamma}_{-\ell}, \alpha_0, \theta_0) - \phi(W, \gamma_0, \hat{\alpha}_{-\ell}, \theta_0) + \phi(W, \gamma_0, \alpha_0, \theta_0)]^2 \overset{P}{\rightarrow} 0$

Proof. As before

\[
\phi(w, \hat{\gamma}_{-\ell}, \hat{\alpha}_{-\ell}, \theta_0) - \phi(w, \hat{\gamma}_{-\ell}, \alpha_0, \theta_0) - \phi(w, \gamma_0, \hat{\alpha}_{-\ell}, \theta_0) + \phi(w, \gamma_0, \alpha_0, \theta_0) = -[\hat{\alpha}_{-\ell}(z, x) - \alpha_0(z, x)]A(\theta_0)[\hat{\gamma}_{-\ell}(z, x) - \gamma_0(z, x)]
\]

1. Proposition [14]

\[
\|\gamma_0(1, x) - \gamma_0(0, x) + \alpha_0(z, x)[v - \gamma_0(z, x)]\| \leq \|\gamma_0(1, x) - \gamma_0(0, x)\| + CC'
\]

To bound the RHS, appeal to Proposition [6]

\[
\|\gamma_0(1, x) - \gamma_0(0, x)\| \leq \|\gamma_0(1, x)\| + \|\gamma_0(0, x)\| \leq C\|\gamma_0\| < \infty
\]

4. It suffices to analyze

\[
\| - [\hat{\alpha}_{-\ell} - \alpha_0]A(\theta_0)[\hat{\gamma}_{-\ell} - \gamma_0]\| \leq \|\hat{\alpha}_{-\ell}A(\theta_0)[\hat{\gamma}_{-\ell} - \gamma_0]\| + \|\alpha_0A(\theta_0)[\hat{\gamma}_{-\ell} - \gamma_0]\|
\]

\[
|\hat{\alpha}_{-\ell}(z, x)| = |\hat{\beta}(z, x)| \leq |\hat{\beta}(z, x)|_\infty = O_p((1 + B_n)B'_n)
\]

It follows by Assumptions [3] and [7]

\[
\|\hat{\alpha}_{-\ell}A(\theta_0)[\hat{\gamma}_{-\ell} - \gamma_0]\| = O_p((1 + B_n)B'_n)\|\hat{\gamma}_{-\ell} - \gamma_0\| = O_p((1 + B_n)B'_n n^{-d\gamma}) \overset{P}{\rightarrow} 0
\]

\[
\|\alpha_0A(\theta_0)[\hat{\gamma}_{-\ell} - \gamma_0]\| \leq CA(\theta_0)\|\hat{\gamma}_{-\ell} - \gamma_0\| \overset{P}{\rightarrow} 0
\]

Proof of Theorem [5] Let $c_0$ be the $(1 - \alpha)$-quantile of $|\mathcal{N}(0, \Sigma)|$ where $\Sigma = S_0^{-1/2}C S_0^{-1/2}$ and $S_0 = \text{diag}(C)$. This critical value ensures correct (asymptotic) simultaneous coverage of confidence bands in the form of the rectangle

\[
[l_0 y, u_0 y] = \left[\hat{\theta}^y - c_0 \frac{C_{yy}}{n}, \hat{\theta}^y + c_0 \frac{C_{yy}}{n}\right]
\]

where $C_{yy}$ is the diagonal entry of $C$ corresponding to value $y \in \mathcal{U}$. To see that, denote by $[l_0, u_0] = \times_{y \in \mathcal{U}} [l_0 y, u_0 y]$ and $d = \text{dim}(\mathcal{U})$. Then note the simultaneous coverage probability is

\[
P(\theta_0 \in [l_0 y, u_0 y]) = P((\sqrt{n}(\hat{\theta}_y - \theta_0)) \in S_0^{1/2}[-c_0, c_0]^d)
\]

\[
= P(\mathcal{N}(0, C) \in S_0^{1/2}[-c_0, c_0]^d) + o(1)
\]

\[
= P(S_0^{-1/2}\mathcal{N}(0, C) \in [-c_0, c_0]^d) + o(1)
\]

\[
= P(|\mathcal{N}(0, S_0^{-1/2}C S_0^{-1/2})| \leq c_0) + o(1)
\]

\[
= 1 - \alpha + o(1)
\]

[14] Theorem 3.1] proves the validity of Gaussian multiplier bootstrap for approximating this $c_0$. Gaussian multiplier bootstrap is operationally equivalent to calculating $c$ by our Algorithm [3] since conditional on the data, the Gaussian multipliers are distributed $\mathcal{N}(0, C)$. [15]
8.6 Simulations

8.6.1 Design

We implement 500 simulations. One simulation consists of a sample of \( n = 1000 \) observations. A given observation is generated from the following IV model:

\[
X \overset{i.i.d.}{\sim} \text{Unif}[0, 1], \quad Z \overset{i.i.d.}{\sim} \text{Bern}(\pi_0(x)), \\
D | Z = z, X \overset{i.i.d.}{\sim} \text{Bern}(\gamma_0^V(z, x)), \\
Y | Z = z, X \overset{i.i.d.}{\sim} \mathcal{N}(\gamma_0^Z(z, x), 1)
\]

where \( Y \) is the continuous outcome, \( D \) is the binary treatment, \( Z \) is the binary instrumental variable, and \( X \) is the covariate. \( Y \) and \( D \) are drawn independently given \( Z \) and \( X \). In particular,

\[
\pi_0(x) = 0.05 \cdot 1_{x \leq 0.5} + 0.95 \cdot 1_{x > 0.5}, \quad \gamma_0^V(z, x) = 2zx^2, \quad \gamma_0^Z(z, x) = zx
\]

From observations of \( W = (Y, D, Z, X) \), we estimate complier counterfactual outcome distributions \( \hat{\pi} = (\hat{\beta}', \hat{\delta}') \) at a few grid points. For \( \beta_0 = \{\beta_0^y\} = \{\mathbb{P}(Y^{(0)} \leq y | D^{(1)} > D^{(0)})\} \), we set \( y \in \{-3, -2, \ldots, 3, 4\} \). For \( \delta_0 = \{\delta_0^y\} = \{\mathbb{P}(Y^{(1)} \leq y | D^{(1)} > D^{(0)})\} \), we set \( y \in \{-2, -1, \ldots, 4, 5\} \). The true parameter values are

\[
\beta_0^y = \frac{\int_0^1 \Phi(y - 2x^2)(x - 1) + \Phi(y)dx}{\int_0^1 xdx}, \\
\delta_0^y = \frac{\int_0^1 \Phi(y - 2x^2)x dx}{\int_0^1 x dx}
\]

8.6.2 Algorithms

We estimate \( \hat{\pi} \) and \( \hat{\alpha} \) with a dictionary \( b(Z, X) \) consisting of fourth-order polynomials of \( X \) and interactions between \( Z \) and the polynomials. We estimate \( \hat{\pi} \) with a dictionary \( b(X) \) consisting of fourth-order polynomials of \( X \). We set \( L = 5 \) and \( n_t = n/L \) for sample splitting.

DML-RRR. For stage 1 parameters, we estimate \( \hat{\alpha}_{-\ell} \) according to Algorithms 1 and 2. We tune the \( \ell_1 \)-regularization parameter over a simple grid of \( \lambda_n \in \{0, 0.05, 0.1\} \) with an 80/20 split for training/validation. We estimate \( \hat{\gamma}_V \), by \( \ell_1 \)-regularized logistic regression when \( V \) is binary, and by Lasso when \( V \) is continuous. We implement \( \ell_1 \)-regularization under default settings in MATLAB’s lassoglm library.

DML-plugin. The only difference from DML-RRR is how we estimate \( \hat{\alpha}_{-\ell} \). For DML-plugin, we first estimate \( \hat{\pi}_{-\ell} \) by \( \ell_1 \)-regularized logistic regression, and then form \( \hat{\alpha}_{-\ell} \) by plugging \( \hat{\pi}_{-\ell} \) into its formula. We discard observations with \( \hat{\pi}_{-\ell} \notin [10^{-12}, 1 - 10^{-12}] \).

kappa-weight. We estimate \( \hat{\pi} \) by logistic regression using the full sample, without regularization and without trimming. We then plug \( \hat{\pi} \) into Definition 2 to obtain \( \hat{\kappa}^{(0)}(w) \), \( \hat{\kappa}^{(1)}(w) \), or \( \hat{\kappa}(w) \). The \( \kappa \)-weighted estimator is then the sample analog of formula given in 2. For example for \( \theta_0 = \mathbb{E}[g(Y^{(0)}, X) | D^{(1)} > D^{(0)}] \), the \( \kappa \)-weighted estimator is

\[
\hat{\theta}_\kappa = \frac{1}{n} \sum_{i=1}^n \hat{\kappa}^{(0)}(W_i) \cdot g(Y_i, X_i)
\]

MATLAB code for replicating the simulations is available at the following directory: https://anonymous.4open.science/r/ff19c7b5-bb5c-4af2-94cb-2cb7e56a2199/.

8.7 401(k)

8.7.1 Dictionaries

We follow 10 in constructing the low-\( p \) and very-high-\( p \) dictionaries. The low-\( p \) dictionary includes interactions between \( Z \) and the following transformations of covariate \( X \): indicators of marital status, two-earner status, defined benefit pension status, IRA participation status, and home ownership status, second-order polynomials in family size and education, a third-order polynomial in age, and a quadratic spline in income with six break points. The very-high-\( p \) dictionary includes the low-\( p \) dictionary, plus two-way interactions between all of the transformed income variables, and all of the transformed non-income variables.
8.7.2 Algorithm

We implement DML-RRR exactly as described in Appendix 8.6.2 except the $\ell_1$-regularization parameter for $\hat{\gamma}^{V}_{\ell}$ follows [10] to account for a continuum of target parameters. MATLAB code for replicating the empirical illustration is available at https://anonymous.4open.science/r/ff19c7b5-bb5c-4af2-94cb-2cb7e56a2199/.
