(Dated: September 13, 2019)

Odd-angular momentum exciton states are dark to light in monolayers of transition-metal dichalcogenides and can be addressed only by two-photon probes. Besides, 2p excitons states are expected to show a fine splitting that arises from the peculiar electronic band structure of the material, characterized by a finite Berry curvature around each valley. In this work we study in detail the coupling of cavity photons to p exciton states and we find that the introduction of a Skyrmion in the TMD substrate modifies the selection rules via a matching of the exciton angular momentum with the Skyrmion topological charge, thus providing a useful tool to detect exciton fine-splitting via single photon probes.

I. INTRODUCTION

The generic impact of dimensionality and crystal symmetries in the excitonic spectrum and the associated optical selection rules in two-dimensional (2D) crystals has recently become evident. The rich band structure displaying band topology and winding numbers has been shown to be at the origin of novel selection rules for optical transitions and spectral modifications in 2D crystals. Among different instances of two-dimensional material, monolayers of group VI semiconductor TMDs have shown remarkable optical properties, that led to a grown interest in excitons in these materials. Below the gap the strong Coulomb interaction leads to a dense series of exciton level, whose most prominent peaks are the so called A and B excitons. Besides, several other s-wave exciton lines have been detected, that strongly deviate from the expected hydrogenic series. Higher angular momentum exciton states are also predicted to occur, such as p-wave states, that are dark to light, due to a mismatch of quantum numbers, and are expected to show a splitting between 2p+ and 2p− due to a non-zero Berry curvature effect. These findings open the way to the engineering of novel selection rules by playing with the fundamental topological properties of the electronic carriers and the possibility to suitably tailor light-matter interaction to generate novel topological polaritons.

The quest for topological states of matter have prompted the relevant role of the Rashba spin-orbit interaction (SOI) as a fundamental ingredient capable to provide the electronic carriers with a topologically non-trivial character (see Refs. for a review and references therein). An analogous object capable of breaking spin degeneracy and simultaneously imparting a winding to the electronic carriers is provided by a Skyrmion. Skyrmions are magnetic coplanar spin textures characterized by a topological charge, that arise in magnetic systems by virtue of the competing tendency of neighbouring spins to align perpendicularly or parallel, that favours a chiral order. Several distinct mechanisms can lead to the formation of Skyrmions, such as the Dzyaloshinskii-Moryia interaction or dipolar interaction, and the typical size can range from nm to μm. Based on a mapping between spatially varying in-plane magnetic fields and the Rashba spin-orbit interaction, a configuration realized by a graphene flake on top of a substrate containing the Skyrmion has been shown to effectively generate a Rashba SOI on the top layer carriers.

In this work we study how to address the predicted 2p± splitting in TMDs and look for a way to resolve it experimentally by single-photon probes. Since the coupling is expected to be very small, we embed the monolayer in an optical cavity that allows to enhance the light-matter coupling strength and to study finite momentum deviations from the optical selection rules. The results thus naturally extends to systems with cavity polaritons.

We first review the impact of the C3 crystal symmetry, that manifests in trigonal warping corrections in an effective gapped Dirac Hamiltonian and results in a mixing between optically bright and dark exciton states in biased bilayer graphene. Consistently with previous findings based on group theory, we show that parity-mixing in the spectrum of TMDs due to C3 symmetry allows coupling of photons to two out of the four 2p states, so that it cannot be exploited to resolve the 2p± splitting.

We then consider a possible Rashba spin-orbit interaction that can be engineered in the material and show that the winding of the spin imparted by the Rashba SOI to the carriers, combined with an in-plane magnetic...
field, allows coupling of light to $2p^\pm$ excitons states, albeit with very small strength due to the weak strength of the Rashba SOI. In order to overcome the weakness of the Rashba spin-orbit interaction we suggest to introduce a Skyrmion in the substrate of the system. The latter generates a spatially varying Zeeman field for the carriers in the TMD monolayer that is rotational invariant along the $z$ direction. Analogously to the case of Rashba SOI, a Skyrmion characterized by a unit winding number can modify the selection rules and mediate the coupling between photons and $p$ excitons through its topological charge, that can match the internal angular momentum of the excitons.

The work is structured as follows: in Sec. II we introduce the excitonic model, by first considering a minimal electronic model describing low energy physics at the $K'/K$ points in the Brillouin zone in TMDs, and by introducing the exciton wave functions. In Sec. III we introduce cavity photons and describe the light matter function. In Sec. IV we address the $2p^\pm$ exciton splitting by first studying the effect of a Rashba SOI and then considering a setup including a Skyrmion in the substrate. We derive the novel selection rules and calculate the relevant matrix elements. In Sec. V we consider the case of spin-unlike excitons and derive the matrix element for coupling of polarized photons to $2p^\pm$ excitons. In Sec. VI we conclude the work with a summary and some final remarks.

II. EXCITON MODEL

We consider 2D excitons in a monolayer TMD. The latter has a direct semiconductor gap between conduction and valence bands located at the $K$ and $K'$ points of the Brillouin zone. Excitons in valley $K'/K$ ($\tau = \pm 1$) at finite momentum $q$, principal quantum number $n$, and angular momentum $\ell$ are described by the state

$$|\Phi_{\tau,n,\ell}\rangle = \sum_k \Phi_{k,\alpha}^{\tau,n} e^{-i\epsilon_{n,\tau,k}q/2} \Phi_{n,\tau,k}^{\ell,\tau} |0\rangle, \quad (1)$$

where $c_{\alpha,\tau,k}$ ($c_{\alpha,\tau,k}^\dagger$) are fermionic annihilation (creation) operators that remove (add) an electron in the Bloch state $|\epsilon_{\alpha,k}\rangle$ in valley $\tau$, band $\alpha = c,v$, and momentum $k$, $|0\rangle$ is the neutral filled Fermi sea, and $\Phi_{n,\tau,k}^{\ell,\tau}$ is the $k$-space exciton wavefunction. The latter is determined by the electronic Hamiltonian and the Coulomb interaction.

The minimal model describing a monolayer TMD is given by a gapped Dirac Hamiltonian and accounts for a direct gap located at the $K$ and $K'$ points, as well as direct transitions between conduction and valence band. It has been recently shown\cite{12,13} that the $C_3$ crystal symmetry allows mixing of even-odd parity selection rules. This can be seen by noticing that the rich band structure of the TMDs allows interband transitions at finite momentum via second order processes involving bands higher in energy. Once projected on the conduction and valence bands, these processes result in trigonal warping terms, a reflection of the $C_3$ symmetry of the crystal\cite{13,33}. We then consider an effective two-band model, that at the $K$ point reads ($\hbar = 1$)

$$H_0(k) = \begin{pmatrix} \Delta & v_F (k_+ + \lambda_{tw} k_z^2) \\ v_F (k_+ + \lambda_{tw} k_z^2) & -\Delta \end{pmatrix}, \quad (2)$$

with $k_{\pm} = k_x \pm i k_y$. The Hamiltonian at the $K'$ point is obtained by replacing $k_{\pm} \rightarrow -k_{\mp}$ and $\lambda_{tw} \rightarrow -\lambda_{tw}$. Due to its microscopic origin the scale $\lambda_{tw}$ is on order of the lattice constant $a$. Additionally, TMDs are characterized by a strong intrinsic SOI, that spin-splits the conduction and valence bands and it is at the origin of the A and B exciton peaks in the photoluminescence spectra. It is described by the term

$$H_{\text{SOI}} = -\frac{\tau s}{4} \left[ \delta_v (\Pi + \sigma_z) - \delta_c (\Pi - \sigma_z) \right], \quad (3)$$

with $\delta_c, \delta_v > 0$ for the case of MoS$_2$ and MoSe$_2$. The valence band splitting is much larger than the conduction band one. Taking as reference the values determined in Ref. $33$, we have that $\delta_v = 146$ meV and $\delta_c = 6$ meV for MoS$_2$. The strong character of the intrinsic SOI promotes the eigenvalue $s$ of the $s$ spin component to be a good quantum number and locks spin and valley. Depending on the sign of the conduction band spin splitting, spin-like excitons are the ground states (for Mo-based compounds) or the excited states (for W-based compounds).

Focusing on A excitons, that involve the upper most spin-polarized excitons through its microscopic origin the scale $\lambda_{tw}$ is on order of the lattice constant $a$. The exciton wavefunction $\Phi_{n,\tau,k}^{\ell,\tau}$ entering the state Eq. (1) is solution of the Bethe-Salpeter equation, that is obtained by projecting the full Hamiltonian including the Coulomb interaction onto two-particle states $c_{c,k+q/2}^\dagger c_{c,k-q/2}|0\rangle$. Assuming a bare Coulomb interaction $V_Q = \frac{2\pi e^2}{\epsilon a}$, characterized by the material dielectric constant $\epsilon$, the exciton eigenstates are given by the 2D hydrogen wavefunctions\cite{12,13}, with an effective Bohr radius $a_{ex} \approx 1$ nm.

The 2D hydrogen wavefunctions capture only partially the problem. First of all, the finite thickness of the monolayer results in a screening of the Coulomb interaction, that is described by a momentum dependent dielectric function $\varepsilon(q) = \varepsilon(1 + r_0 q)$, with $r_0$ a length scale on order of the monolayer thickness\cite{10,11,12}. This generates matrix elements between excitonic states characterized by different principal quantum number $n$ and a consequent deviation from the $1/(n-1/2)^2$ 2D hydrogen series. Furthermore, Berry curvature effects originating from the microscopic Hamiltonian $H_0$ Eq. (2), have been shown to be at the origin of fine structure splittings in the exciton spectrum of TMDs\cite{14,10}. Due to the pseudospinorial character of the eigenstates of the microscopic Hamiltonian $H_0$, a correction to the Coulomb potential arises, that produces a splitting between $2s$ and $2p$ solutions and a further fine splitting between $2p^\pm$ states,
both proportional to the Berry curvature of the bands $\Omega_0 \equiv \Omega(q = 0) = (\nu_F/D)^2$. Finally, the presence of the trigonal warping terms gives rise to a mixing between exciton states differing by $\pm 3$ units of angular momentum. This effect is expected to be very small and can be safely neglected.

### III. LIGHT-MATTER COUPLING

We consider a planar cavity of height $L_z$ with perfectly conducting mirrors, in which photons have quantised out-of-plane momentum $k_z$ and carry in-plane momentum $q = (q_x, q_y)$. In the lowest subband the momentum takes the value $k_z = \pi/L_z$. For a cavity with perfectly conducting mirrors, the TE and TM modes are degenerate. In the basis of circularly polarised light, for which we define the bosonic operators $a_{\nu, q}$ with polarisations $\nu = \pm$, the photonic Hamiltonian reads

$$H_{ph} = \sum_{\nu, q} \hbar \omega_q a^\dagger_{\nu, q} a_{\nu, q}, \tag{4}$$

where $\omega_q$ denotes the photon frequency.

The Hamiltonian for the light-matter coupling is as usual obtained by minimal coupling substitution $k \rightarrow k + eA$ in Eq. (2). The vector potential $A$ couples at first order to the velocity $V^r_i = \partial H^r_i(k)/\partial k_i$ and the Hamiltonian for the light-matter coupling in valley $\tau$ reads

$$H_{lm} = \frac{1}{2} \sum_{\tau, i=x,y} \int d\mathbf{r} \hat{\psi}^{\dagger}_{\tau}(\mathbf{r}) \{ A_i(\mathbf{r}), V^r_i(\mathbf{r}) \} \hat{\psi}_{\tau}(\mathbf{r}) \tag{5}$$

with $\hat{\psi}_{\tau}(\mathbf{r}) = \sum_{\mathbf{k}, \alpha} e^{i\mathbf{k} \cdot \mathbf{r}} u^\tau_{\mathbf{k}, \alpha} c_{\tau, \alpha, \mathbf{k}}$ electronic field operators, with $u_{\mathbf{k}}$ eigenstates of the Hamiltonian Eq. (2), $\{ A, B \} = AB + BA$, and

$$V^r_x(\mathbf{k}) = v_F \left[ \sigma_x + 2\lambda_{tw}(k_x \sigma_x - \tau k_y \sigma_y) \right], \tag{6}$$

$$V^r_y(\mathbf{k}) = v_F \left[ \sigma_y - 2\lambda_{tw}(\tau k_x \sigma_x + k_y \sigma_x) \right]. \tag{7}$$

Integrating over the spatial distribution of the cavity vector potential, the light-matter coupling Hamiltonian takes the form

$$H_{lm} = \frac{ie}{2} \sum_{\nu, q, \alpha, \beta} |A_q| \langle u^{\tau, \beta}_{\mathbf{k} + \mathbf{q}/2} | \hat{P}_{\nu, \tau}(q, \mathbf{k}) | u^{\tau, \alpha}_{\mathbf{k} - \mathbf{q}/2} \rangle \times c^{\dagger}_{\alpha, \mathbf{k} - \mathbf{q}/2} c_{\beta, \mathbf{k} + \mathbf{q}/2} (a^{\dagger}_{\nu, q} - a_{-\nu, -q}), \tag{8}$$

where $\hat{P}_{\nu, \tau}(q, \mathbf{k}) = c_q (V^r_{x} - iu^r_{y}V^r_{z}) - s_q e^{-2i\theta_q} (V^r_{x} + iu^r_{y}V^r_{z}) |A_q| = 1/\sqrt{\pi \omega_q} \nu, V$ is the cavity volume, $\tan \theta_q = q_y/q_x, c_q = \cos^2(q_y/2), s_q = \sin^2(q_y/2), \cos(q_y) = k_z/\sqrt{k_z^2 + q^2}$ is the angle between the TM mode and the out-of-plane direction. Introducing $\sigma_{\nu, \tau} = (\sigma_x + i\nu \sigma_y)/2$ we have

$$\hat{P}_{\nu, \tau}(q, \mathbf{k}) = \sqrt{2} v_F (\sigma_{\tau \tau} + 2\lambda_{tw} k_x \sigma_{\nu \nu}) c_q - \sqrt{2} v_F (\tau \sigma_{\nu \nu} + 2\lambda_{tw} k_x \sigma_{\nu \nu}) s_q e^{-2i\theta_q}. \tag{9}$$

The coupling matrix element $\langle \nu q | H_{lm} | \Phi^{n, \ell}_{\mathbf{k}} \rangle$ at momentum $\mathbf{q}$ between an exciton with quantum numbers $n$ and $\ell$ in valley $\tau$, and a photon of polarisation $\nu$ reads

$$\Gamma_{\nu, \tau}^{n, \ell} = e A_q \sum_{\mathbf{k}} \Phi^{n, \ell}_{\mathbf{k}} (\hat{P}_{\nu, \tau}(q, \mathbf{k}) | \Phi^{n, \ell}_{\mathbf{k}} \rangle. \tag{10}$$

where we neglected the dependence on $\mathbf{q}$ of the exciton wavefunction and the band eigenstates, that give a negligibly small correction.

For $\mathbf{q} = 0$ and $\lambda_{tw} = 0$ we recover the characteristic optical selection rules, that selectively couple polarized photons to $s$ excitons satisfying $\nu = \tau$ and $d$ excitons satisfying $\nu = -\tau$. In particular, $\Gamma_{\nu, \tau}^{n, \ell} = 0$ for $\ell$ odd. However, the rich band structure of the TMDs allows finite coupling via transitions through bands higher in energy. The additional $k_{\pm}$ dependence of the velocity operator $\hat{P}_{\nu, \tau}$ at finite $\lambda_{tw}$ can compensate the angular momentum of $2p$ excitons and the matrix elements $\Gamma_{\nu, \tau}^{n, \ell}$ acquire finite value for $\ell = \pm 1$. The linear dependence in $\lambda_{tw} k$ produces, once integrated over the exciton wave function, a coefficient $\lambda_{tw}/a_B$. Second order corrections, that can be obtained by expanding both conduction and valence band eigenstates at first order $\lambda_{tw} \xi/a_B^2$, with $\xi = v_F/\Delta$, necessarily bring a factor $(\lambda_{tw} \xi/a_B^2)^2$, and are suppressed.

At finite $\mathbf{q}$, the presence of the cavity forces the TM mode to develop a finite angle with the out-of-plane direction, that yields a deviation from the optical selection rules analogous to the results of Ref. [13], and a finite coupling of polarized photons to both valleys,

$$\Gamma_{\nu, \tau}^{2, \ell} = \gamma_0 \lambda_{tw}/a_B \left[ q_{\nu} \delta_{\nu, -\tau} \delta_{\nu, -\ell} - s_q e^{-2i\theta_q} \delta_{\nu, \tau} \delta_{\nu, \ell} \right] c_{2p}, \tag{11}$$

where $\gamma_0 = e v_F/(a_B \pi \omega_0 c_0 L_z)$ is the oscillator strength between cavity photons and $s$ excitons, and $c_{2p} = 8/(9\sqrt{6})$ is a form factor associated to the ratio between $2p$ and $s$ exciton Bohr radius. Using the parameters of Ref. [14], with an exciton Bohr radius in MoS$_2$ on order of $a_B \sim 0.277$ nm, realistically gives $\lambda_{tw}/a_B \sim 0.1$. On the other hand, for an effective exciton radius of $a_{ex} \sim 1$ nm, the coupling is reduced.

This result marks a breaking of the optical selection rules, as anticipated in Refs. [2] and [32], that owes to the $C_3$ symmetry of the crystal Bloch functions at the $K$ and $K^\prime$ points. Finite coupling to $p$ excitons can be understood by noticing that, upon neglecting the linear in $\mathbf{k}$ term, the Hamiltonian Eq. (2) is equivalent to gapped bilayer graphene, for which optical selection rules predict bright $p$ excitons and dark $s$ excitons. Thus, the $C_3$ crystal symmetry yields a mixing of even-odd parity selection rules.

### IV. RESOLVING THE $2p^\pm$ SPLITTING

If on the one hand the selection rule Eq. (11) allows coupling to exciton $2p$-states, it does not allow to resolve
the \( p^\pm \) splitting predicted by finite Berry curvature effects. This is due to the fact that out of the four \( 2p \) states, \( 2p^+ \) in valley \( K \) and \( 2p^- \) in valley \( K' \), that are related by time-reversal symmetry and are pair-wise degenerate, only two of them (\( 2p^+ \) in valley \( K \) and \( 2p^- \) in valley \( K' \)) become bright according to Eq. \( 11 \). We now show that the inclusion of a Rashba SOI or the presence of a Skyrmion on the substrate allow to couple the four exciton \( 2p \) states to the light field.

Before proceeding we adapt the notation to account for the spin degree of freedom. The spin \( s \) eigenstates of the electronic Hamiltonian \( H(k) = H_0(k) + H_{\text{SOI}} \) are denoted as \( |u_{k,\nu,\tau}^{\alpha,\tau}\rangle \). The presence of the strong SOI locks spin and valley, so that at valley \( \tau \) the lowest energy transition is between conduction and valence band states of spin \( s = \tau \), so that selection rules for coupling to light of spin-like excitons is generally written in terms of the matrix element \( \langle u_{k,v,\tau}^{\nu,\tau}\rangle \hat{P}_{\nu,\tau}(q) \langle u_{k,\nu,\tau}^{\nu,\tau}\rangle \). We now consider the modification of \( \Gamma_{\nu,\tau}^{\nu,\tau} \) due to the presence of Rashba SOI and the presence of a Skyrmion.

### A. Rashba spin-orbit interaction

Let us consider a Rashba SOI, that can be obtained by sandwiching the monolayer TMD between different materials, that generate a breaking of the \( z \rightarrow -z \) symmetry, and can be enhanced by application of an out-of-plane electric field. We further apply an in-plane magnetic field that couples to the electronic degrees of freedom via the Zeeman interaction, so that we add the following term \( H_1 = H_R + H_Z \),

\[
H_1 = \lambda_R (\tau s_x \sigma_y - s_y \sigma_x) + \frac{1}{2} g \mu_B B s_x,
\]

with \( g \) the TMD \( g \)-factor and \( \mu_B \) the Bohr magneton. We consider the Rashba and Zeeman terms as perturbations and calculate the electronic eigenstates at first order perturbation theory in \( H_1 \). This way, for instance in valley \( K (\tau = 1) \) we have

\[
\langle \psi_{k,\uparrow}^{\nu,K} \rangle (1) = \langle \psi_{k,\uparrow}^{\nu,K} \rangle + \frac{1}{\delta_\alpha} \langle \psi_{k,\downarrow}^{\nu,K} \rangle \langle \psi_{k,\downarrow}^{\nu,K} \rangle |H_1| \langle \psi_{k,\uparrow}^{\nu,K} \rangle.
\]

The matrix elements of \( H_1 \) between the unperturbed states are given, in a unified the notation, by

\[
\langle \psi_{k,-\tau}^{\nu,K} | H_1 | \psi_{k,\tau}^{\nu,K} \rangle = -i \lambda_R S_k e^{i \tau \phi_k} + V_Z,
\]

\[
\langle \psi_{k,-\tau}^{\nu,K} | H_1 | \psi_{k,\tau}^{\nu,K} \rangle = i \lambda_R S_k e^{i \tau \phi_k} + V_Z,
\]

with \( S_k = v_F k / \sqrt{(v_F k)^2 + \Delta^2} \), \( V_Z = g \mu_B B / 2 \), where a crucial winding \( e^{i \tau \phi_k} \) appears due to the Rashba field.

It then follows that the matrix element between conduction and valence band \( \langle u_{k,\nu,\tau}^{\nu,\tau}\rangle \hat{P}_{\nu,\tau}(q) \langle u_{k,\nu,\tau}^{\nu,\tau}\rangle \) can be expanded at second order in the perturbation \( H_1 \), by expanding the bra at first order in the Zeeman field and the ket at first order in the Rashba field, and viceversa. This way, a non-zero matrix element results between conduction and valence band, as schematically depicted in Fig. \( 2 \) that is at first order in the Zeeman field and in the Rashba field, the latter carrying a finite winding that can compensate the exciton angular momentum of the \( p \) states. The resulting new selection rules read

\[
\Gamma_{\nu,\tau}^{\nu,\tau} = -i \tau \Gamma_R (\delta_{\tau,\ell} + \delta_{\tau,-\ell}) \left[ c_q \delta_{\nu,\ell} - s_q e^{-2i\nu\theta_k} \delta_{\nu,-\ell} \right],
\]

where the coupling strength is

\[
\Gamma_R = \gamma_0 \lambda_R V_Z h v_F 4 \sqrt{2} \frac{\Delta}{\delta_{\nu,\ell} a_B \Delta} g \mu_B / 3.
\]

The two terms appearing in Eq. \( 16 \) proportional to \( \delta_{\tau,\pm\ell} \) are obtained by processes in which the conduction band eigenstate Eq. \( 13 \) is expanded at first order in the Rashba field and the valence band at first order in the Zeeman term, and viceversa, as schematically depicted in Fig. \( 2 \).

Clearly, a very strong Rashba SOI is required to overcome the transition through the valence band, that involves the spin-splitting \( \delta_{\nu,\ell} \) and have an appreciable coupling. Aiming at \( \Gamma_R / \gamma_0 \sim 0.01 \), for an applied in-plane field on order of 10 Tesla one needs a Rashba coupling constant stronger than 10 meV, that is out of reach by means of a simple gate.

### B. Skyrmions

In order to overcome the difficulty posed by the requirement of a strong Rashba coupling constant, we consider to employ spatially varying magnetic fields. It has been estimated that a Rashba coupling constant of up to 10 meV can be realized for an array of equally spaced nanomagnets with a periodicity of 100 nm. These numbers are exactly what we need in order to obtain a strong effective Rashba SOI and at the same time separate the length scales of the excition motion and the

![Schematics of the coupling between polarization \( \nu \) photons and spin-like \( p \) excitons in valley \( \tau \). A \( N = 1 \) Skyrmion or the Rashba field can simultaneously mediate a spin-flip transition and an angular momentum quantum necessary to couple to \( p \) excitons. The left and right schemes refer to the two possible transition to the two \( 2p^\pm \) states, in which the Zeeman and Rashba/Skyrmion term exchange their role.](image)
electronic motion. Unfortunately, the resulting Rashba
misses an important in-plane spin component and the
array of spatially periodic nanomagnet breaks the rotation
symmetry of the system, that is required to effectively
couple p-excitons to the valence-conduction band transi-
tion. We then resort to the use of a Skyrmion placed in
the substrate, that has been shown to effectively generate
a Rashba SOI on the carriers of a graphene flake placed
on top of a Skyrmion.[40]

The magnetization field of a Skyrmion is described by a
classical unit vector $\mathbf{n}(r)$ that represents a maps from the
one-point compactification of the plane ($\mathbb{R}^2 \cup \{\infty\} \simeq S^2$)
onto the two-sphere spanned by $\mathbf{n}$. The map $\mathbf{n} : S^2 \rightarrow S^2$ is
defined by the homotopy class $\pi_2(S^2) \in \mathbb{Z}$ that
defines the integer-valued $CP^1$ topological invariant
$$Q = \frac{1}{4\pi \ell} \int dxdy \mathbf{n} \cdot \partial_x \mathbf{n} \times \partial_y \mathbf{n}.$$ (18)
The index $Q$ counts the number of times the Skyrmion
magnetization $\mathbf{n}$ wraps around the sphere as it evolves
from the Skyrmion center to infinity. Parametrizing the
plane in polar coordinates $r = (r, \phi)$ and the unit sphere
by $(\Theta, \Phi)$, the unit vector $\mathbf{n}$ is written as
$$\mathbf{n}(r) = (\cos \Phi(\phi) \sin \Theta(r), \sin \Phi(\phi) \sin \Theta(r), \cos \Theta(r)),$$ (19)
and the mapping is specified by the function $\Phi(\phi)$ and
$\Theta(r)$, as long as the magnetization field becomes $\phi$
-independent far from the Skyrmion center[10]. Choosing
$$\Phi(\phi) = N\Phi + \gamma,$$ (20)
and $\Theta(r)$ a function ranging from $\pi$ at $r = 0$ to $0$ as
$r \rightarrow \infty$ we have that $Q = N$.

The Skyrmion in the substrate generates a spatially
varying Zeeman field described by the term $H_S = J \mathbf{n}(r) \cdot
\mathbf{s}$. Assuming the Skyrmion to vary on a spatial scale
much longer than the inverse intervalley separation, it
is a good approximation to neglect inter-valley scattering
generated by the Skyrmion. This way, the electronic
states at first order perturbation theory read
$$|u_{k,\tau}^{\alpha,\tau}(1)\rangle = |u_{k,\tau}^{\alpha,\tau}\rangle + \frac{1}{\delta_{v}} \sum_{k'} \langle u_{k',\tau}^{\alpha,\tau}|H_S|u_{k,\tau}^{\alpha,\tau}\rangle|u_{k',\tau}^{\alpha,\tau}\rangle,$$ (21)
where the spatially varying spin texture couples different
momentum states via the matrix element
$$\langle u_{k,\tau'}^{\alpha,\tau}|H_S|u_{k',\tau}^{\alpha,\tau}\rangle = J \langle u_{k,\tau'}^{\alpha,\tau}|\mathbf{n}(r)\cdot\mathbf{s}\rangle \times \int d\mathbf{r} e^{i(k-k')\cdot\mathbf{r}} e^{iN\tau\phi} \sin \Theta(r),$$ (22)
and the second term in the r.h.s. comes from the matrix
element of opposite spin states mediated by the Skyrmion
and contains the winding number $N$ multiplied by the
spin state quantum number $s = \tau$.

By further applying also an in-plane magnetic field in
the, say, z-direction, the matrix element between con-
duction and valence band $\langle u_{k,\tau}^{\alpha,\tau}|\mathbf{P}_{\nu,\tau}(q)|u_{k',\tau}^{\alpha,\tau}\rangle$ can be expanded at second order in the perturbation, analogously
to Sec. [IV A] by expanding the bra at first order in the
Zeeman field and the ket at first order in the Skyrmion
field, and viceversa.

The resulting selection rules are given by
$$\Gamma_{\nu,\tau,\ell} = i\tau \Gamma_{\nu,\tau\ell} (\delta_{N,\ell} - \delta_{N,\ell-}) \left[c_q \delta_{\nu,\tau} - s_q e^{-2i\nu\theta_s} \delta_{\nu,-}\right],$$ (29)
where the role of the winding number $N$ becomes mani-
fest. This way, for a unit winding $N = 1$ we can couple
to both $2p^+$ and $2p^-$ state in each valley. The strength of the coupling is
$$\Gamma_{S} = \frac{J V_{Z}}{\delta c_{\delta} c_{n}},$$ (24)
that is completely analog to Eq. (17) obtained for the
case of Rashba SOI (see Fig. 2), with the very difference
that the exchange $J$ can range from from few meV to 100
meV. The coefficient $c_n \lesssim 1$ depends on the precise form of the function $\Theta(r)$.

V. SPIN-UNLIKE EXCITONS

So far, along the entire analysis we assumed to deal
with spin-like excitons, that form between electronic
states with same spin. These are the relevant lowest energy
excitons in MoS$_2$ and MoSe$_2$ compounds, where the
sign of the splitting in the intrinsic spin-orbit interaction
Eq. (3) is positive. In the compounds formed with the
transition metal $W$, that are WS$_2$ and WSe$_2$ we have
$\delta_c < 0$, so that the lowest energy valence-conduction
band electronic transition is between opposite spin states.
For this reason it does not couple to light, that does not
flip the spin, and it is therefore dark. The spin-orbit
interaction in WS$_2$ and WSe$_2$ is stronger than in Mo-
based compounds, with typical values of $\delta_c = 180$ meV
and $|\delta_c| = 10$ meV, so that $s_z$ spin component is a good
quantum number and the spin-valley locking is guaran-
teed.

Due to the fact that dark excitons have opposite spin
locked to the out-of-plane direction, an in-plane magnetic
field has been proved effective in coupling $s$ excitons to
light[13][23]. Analogously, it is clear that a Skyrmion, that
contains both an in-plane magnetic field and a topological
charge that results in a winding of the Zeeman field, can
couple to $p$ excitons at first order perturbation theory.

The calculation goes along the line of the one previ-
ously explained for spin-like excitons. Denoting as $|u_{k,\tau}^{\alpha,\tau}\rangle$
the bare electronic band eigenstates, the coupling of photo-
tons with polarization $\nu$ to spin-unlike excitons with prin-
cipal quantum number $n$ and angular momentum $\ell$ is given by
$$\Gamma_{\text{Unlike}} = c_{A} A_q \sum_k \Phi_{k}^{n,\ell} \langle u_{k,\tau}^{\alpha,\tau}|\mathbf{P}_{\nu,\tau}(q)|u_{k,\tau}^{\alpha,\tau}\rangle.$$ (25)
The matrix element between valence and conduction
band is calculated by expanding the band eigenstates at
first order perturbation theory in the Skyrmion field as in Eq. (21) and the result is

$$\Gamma_{\text{Unlike}} = \delta_{\nu,\tau} \left( \frac{J}{\delta_c} + \delta_{\ell,-\tau N} \right) \Gamma^A_{C2p}. \quad (26)$$

The transition to opposite angular momentum $\ell$ states goes via different bands, resulting in a different oscillator strength. For a Skyrmion sufficiently close to the TMD sample, the amplitude $\Gamma_{\text{Unlike}}$ is a fraction of the amplitude for bright A excitons. In general, in a system containing several Skyrmions, all with the same winding $N$, the signal will be multiplied by the number of Skyrmions (every transition is independent and among them incoherent).

VI. CONCLUSIONS

In this work we study how to externally engineer the selection rules for exciton-photon coupling by playing with the fundamental topological properties of the electronic carriers. In particular, we address the selection rules for coupling of photons to dark excitons in transition metal dichalcogenides, with a particular attention to the possibility to probe $2p^6$ exciton states. In order to amplify the signal, we suggest to embed the monolayer TMD in an optical cavity. The resulting finite momentum selection rules also describe the matrix element at the origin of cavity-polaritonics.

We first review the origin of the optical selection rules from a massive Dirac Hamiltonian describing the low energy electronic degrees of freedom and the resulting coupling to light, showing how trigonal warping terms in the electronic model can mediate coupling to two out of the four $p$ states of interest. We then consider the presence of a Rashba spin-orbit interaction or the presence of a Skyrmion in the underlying substrate and show how the application of an in-plane magnetic field can switch on a coupling between photons and all four $2p$ exciton states. For the case of the Rashba field, the winding imparted to the spin degree of freedom by the spin-orbit coupling mediates a unit of angular momentum at a cost of a spin-flip process, that has to be compensated by the in-plane magnetic field. For the case of a Skyrmion, it is its topological charge that mediates the required unit of angular momentum. Thanks to their stronger exchange field, Skyrmions provide a much stronger matrix element and can be engineered in the substrate. An analogous mechanism applies to unlike-spin excitons, for which the spin-flip process accompanying the transfer of angular momentum does not need to be compensated and directly provides the correct selection rules.

We believe that the results presented can shed light on the role of topological invariants in the coupling of electronic systems to photonic degrees of freedom and open the way to the engineering and control of topological light-matter coupling in cavity systems and topological polaritonics.

VII. ACKNOWLEDGMENTS

I acknowledge very useful discussions with R. Frisenda and P. Perna and I am particularly grateful to E. Ercolessi, for the hospitality at the Department of Physics of the University of Bologna, and to F. Guinea, for financial support through funding from the Comunidad de Madrid through the grant MAD2D-CM, S2013/MIT-3007 and from the European Commission under the Graphene Flagship, contract CNECTICT-604391.
