(Dated: February 19, 2024)

We propose an architecture for a high-fidelity deterministic controlled-phase gate between two photonic qubits using bulk optical nonlinearities in near-term feasible photonic integrated circuits. The gate is enabled by converting travelling continuous-mode photons into stationary cavity modes using strong classical control fields that dynamically change the cavity-waveguide coupling rate. This process limits the fidelity degrading noise pointed out by Shapiro [J. Shapiro, Phys. Rev. A, 73, 2006] and Gea-Banacloche [J. Gea-Banacloche, Phys. Rev. A, 81, 2010]. We show that high-fidelity gates can be achieved with self-phase modulation in $\chi^{(3)}$ materials as well as second-harmonic generation in $\chi^{(2)}$ materials. The gate fidelity asymptotically approaches unity with increasing storage time for a fixed duration of the incident photon wave packet. Further, dynamically coupled cavities enable a trade-off between errors due to loss and wave packet distortions since loss does not affect the ability to emit wave packets with the same shape as the incoming photons. Our numerical results show that gates with 99% fidelity are feasible with near-term improvements in cavity loss using LiNbO₃ or GaAs.

The quest for deterministic photon-photon logic gates has generally been hindered by the absence of sufficiently strong nonlinearities at optical frequencies. One possible solution is to use detection as an effective nonlinearity [1], but two-qubit gates realized this way are probabilistic and require large resource overheads [2]. Even with large Kerr nonlinearities, Shapiro showed in 2006 that two-photon gates between traveling wave packets cannot achieve high fidelity [3]; this fundamental limit was further elucidated in more recent work [4–7]. Newer theoretical proposals have re-opened the discussion by showing that arbitrarily high fidelity is possible in certain limits [8–10], but their implementation appears to be very complex.

Here, we introduce an approach relying on dynamically coupled cavities to provide a means for absorbing, storing, and re-emitting photons from a multimode nonlinear optical cavity. Classical control fields couple two cavity modes via nonlinear wave mixing with a time-dependent coupling rate determined by the amplitude and phase of the controls. As illustrated in Fig. 1a, incident wave packets couple to cavity mode a (green mode) and are transferred to mode b (blue mode) via their controlled coupling. Destructive interference between the directly reflected component of the incident wave packet and light leaking out from mode a causes complete absorption by adjusting the controlled coupling to transfer population from mode a to b at the right rate. Photons are then stored in mode b, which is decoupled from the waveguide, and subsequent control fields release them through mode a. A similar cavity configuration was recently proposed to separate temporal modes of propagating pulses [11].

While stored in the decoupled cavity mode, photons

FIG. 1. (a) Absorption, storage, and emission process. Mode *a* (green) is waveguide-coupled and mode *b* (blue) is decoupled. (b) Cavity mode-spectra showing the strongly waveguide-coupled mode with a correspondingly broad resonance (green) and decoupled modes (blue and purple) with narrow resonances. Photon-photon interactions for $\chi^{(3)}$ and $\chi^{(2)}$ materials are also illustrated. XPM: Cross-phase modulation. SPM: Self-phase modulation. SHG: second-harmonic generation. (c) Photonic integrated circuit (PIC) that implements a controlled-phase gate on dual-rail encoded photonic qubits.

are single-mode in the limit of zero intrinsic cavity loss. The fidelity limitations pointed out in Ref. [3] therefore do not apply to their interaction during this time. However, the control field that optimally absorbs and emits wave packets depends on the photon number when nonlinear interactions are present during the absorption and emission process. Since the same control field must be applied to any input state, it unavoidably introduces a finite amount of error consistent with Refs. [3–7]. Our numerical analysis reveals that this error scales favorably with the ratio between the storage time, T, and the duration of the input wave packet. The result is a scheme for high-fidelity photon-photon gates using bulk nonlinearities that should be feasible with near-term improvements in technology.

For an input state with two dual-rail encoded photonic qubits (see Fig. 1c), we denote the action of the gate by e.g. $|0\rangle_t |1\rangle_c \rightarrow |\bar{0}\rangle_t |\bar{1}\rangle_c$. Single-photon input states like $|1\rangle = \int dt \xi_{in}(t) \hat{w}^{\dagger}(t) |\emptyset\rangle$ are fully characterized by their wave packets, $\xi_{in}(t)$, where normalization requires $\int |\xi_{in}(t)|^2 dt = 1$ and $\hat{w}(t)$ is the continuoustime annihilation operator of the waveguide. Output wave packets are defined through $|\bar{1}\rangle = \int dt \xi_{out}(t) \hat{w}^{\dagger}(t) |\emptyset\rangle$ or $|\bar{11}\rangle = \int \int dt_m dt_n \xi_{out}(t_m, t_n) \hat{w}^{\dagger}(t_m) \hat{w}^{\dagger}(t_n) |\emptyset\rangle$ corresponding to the input $|1\rangle_t |1\rangle_c \equiv |11\rangle$. The controlledphase operation corresponds to the phase requirement, $\arg(\langle 0|\bar{0}\rangle) = \arg(\langle 1|\bar{1}\rangle) = (\arg(\langle 11|\bar{11}\rangle) + \pi)/2$, and we define the one- and two-photon state fidelities as

$$F_1 = |\langle 1|\bar{1}\rangle|^2 = |\int \xi_{\rm out}(t)^* \xi_{\rm in}(t-T)dt|^2$$
(1a)

$$F_{11} = \left| \iint \xi_{\text{out}}(t_m, t_n)^* \xi_{\text{in}}(t_n - T) \xi_{\text{in}}(t_m - T) dt_n dt_m \right|^2$$
(1b)

We consider loss by including a loss rate, γ_L , for all cavity modes. The output is therefore in a mixed state but we only calculate the dynamics of the zero-loss subspace where the output states above are not normalized and the fidelity in Eq. (1) is a lower bound [12].

To calculate the output wave packets, we use a Schrödinger-picture version of the established time-bin formalism [13–15], which allows us to derive explicit equations of motion for the cavity states and inputoutput relations in terms of the cavity Fock basis. In the time-bin formulation the waveguide field is divided into N time-bins of duration Δt , and the cavity interacts with the time bins one after the other. We refer to Ref. [12] for detailed derivations of all the equations of motion and input-output relations used here.

We choose to calculate the controls so single-photon inputs are absorbed optimally into cavity mode b. We therefore only need to consider the linear part of the Hamiltonian without photon-photon interaction terms. For the n^{th} time-step, in which the cavity interacts with time-bin n, this Hamiltonian in a rotating frame is

$$\hat{H}_n = i\hbar\sqrt{\frac{\gamma}{\Delta t}} \Big(\hat{a}^{\dagger}\hat{w}_n - \hat{a}\hat{w}_n^{\dagger} \Big) + \hbar \Big(\Lambda_n^* \hat{a}^{\dagger}\hat{b} + \Lambda_n \hat{b}^{\dagger}\hat{a} \Big), \quad (2)$$

where \hat{a} and \hat{b} are annihilation operators for photons in cavity modes a and b. The discrete-time annihilation operator of the waveguide in bin n is \hat{w}_n . Its relation to the continuous-time operator is $\hat{w}(t_n) \equiv \hat{w}_n/\Delta t$ with $t_n = n\Delta t$ and $n \in [0, N]$. γ is the cavity-waveguide coupling rate of mode a and Λ_n is the coupling rate between modes a and b, which is completely determined by the control fields. For $\chi^{(3)}$ materials, Λ_n arises from four wave mixing between two control fields and modes a and b. To achieve energy-matching, the carrier frequencies obey the relation $\omega_2 - \omega_1 = \omega_a - \omega_b$, where ω_1 and ω_2 are the carrier frequencies of the control fields. For $\chi^{(2)}$ materials, Λ_n arises from three wave mixing between one control field and modes a and b. In this case, their frequencies obey $\omega_p = \omega_a - \omega_b$, where ω_p is the carrier frequency of the control field.

In Ref. [12] we derived solutions for $\Lambda_n^{(k)}$ that enable complete absorption of a single photon with an arbitrary wave packet or emission of an arbitrary output, where krefers to a $\chi^{(k)}$ material. The solutions differ due to crossphase modulation imparted on cavity modes a and b by the control fields only in $\chi^{(3)}$ materials. Fig. 2a shows an example of the absorption process with ξ_{in} being a Gaussian centered at T_{in} with temporal full-width-athalf-maximum $\tau_{\mathcal{G}}$ and spectral width $\Omega_{\mathcal{G}}$. The occupa-

FIG. 2. (a) Absorption of a Gaussian wave packet including the solution of $\Lambda^{(k)}$ for both $\chi^{(2)}$ and $\chi^{(3)}$ materials. (b) Fourier transformations of $\Lambda^{(k)}(t)$ from (a). The shaded areas plot Lorentzian resonances of mode *a* with linewidths $\gamma/\Omega_{\mathcal{G}} = 6$ for a $\chi^{(2)}$ material (blue) and $\gamma/\Omega_{\mathcal{G}} = 30$ for a $\chi^{(3)}$ material (red).

tion probability of mode b is $P_{01}^{(k)}$, where k again refers to the order of the nonlinearity. $\Lambda^{(3)}$ has a time-dependent phase to compensate for the cross-phase modulation it induces on modes a and b. This broadens and shifts its Fourier spectrum as seen in Fig. 2b. The absence of crossphase modulation in $\chi^{(2)}$ materials also enables a similar absorption probability with a five times smaller coupling rate, γ , compared to $\chi^{(3)}$ materials.

The probability of absorbing an incoming wave packet only depends on the ratio between mode *a*'s linewidth, γ , and the spectral width of the wave packet, Ω_{g} . Fig. 3 plots the error in the one-photon state fidelity, $1-F_1$, for a Gaussian wave packet with a storage time of $T/\tau_g = 14.4$. The different curves correspond to different loss rates, γ_L , which is assumed equal for all cavity modes. It shows how the error decreases much faster with increasing γ/Ω_{g} for $\chi^{(2)}$ materials than $\chi^{(3)}$ materials due to the absence of cross-phase modulation. The curves flatten

FIG. 3. Error in one-photon state fidelity, $1-F_1$, as a function of the linewidth of mode *a* for different loss rates (solid lines). Gray corresponds to $\gamma_L/\Omega_G = 0$ while it increases from 10^{-7} (blue) to 10^{-2} (red) in steps of 10 dB. Dashed lines plot the corresponding error in the conditional one-photon state fidelity, $1-\overline{F_1}$.

where the error becomes dominated by loss. Fig. 3 also plots the error in the conditional one-photon state fidelity defined by $\overline{F}_1 \equiv F_1/\langle \overline{1}|\overline{1}\rangle$. \overline{F}_1 may be understood as the probability of the input and output states being identical *given* there was no loss because it corresponds to the fidelity calculated using the re-normalized state $|\bar{1}\rangle/\sqrt{\langle \bar{1}|\bar{1}\rangle}$ [12]. The ideal scenario for lossy cavities is that the output wave packet is a scaled version of the input, $\xi_{\text{out}}(t) = \sqrt{\eta} \xi_{\text{in}}(t-T)$. For a given loss rate, γ_L , there is a corresponding value of η from which $\Lambda_n^{(k)}$ is calculated to achieve $\xi_{out}(t) \approx \sqrt{\eta} \xi_{in}(t-T)$, see Ref. [12] for details. Since the conditional fidelity by definition is independent of the scaling factor η , we expect it to be negligibly dependent on loss so that $\overline{F}_1 \approx F_1(\gamma_L = 0)$, which is confirmed in Fig. 3. Thus, the photons will exhibit very high visibility quantum interference with other photons in Gaussian wave packets if they are not lost. For increasing loss, it is always possible to achieve such high visibility at the cost of a corresponding decrease in n.

The gate fidelity is defined as the minimum state fidelity for all input states [16, 17]. We can ensure that $F_1 \approx 1$ if $\gamma/\Omega_{\mathcal{G}}$ is large enough, which means that the gate fidelity is given by F_{11} . Below, we choose $\gamma/\Omega_{\mathcal{G}} = 6$ for $\chi^{(2)}$ materials and $\gamma/\Omega_{\mathcal{G}} = 30$ for $\chi^{(3)}$ materials, which is seen to fulfill this requirement from Fig. 3. The Hamiltonian in Eq. (2) describes only the linear dynamics responsible for absorption and emission from the cavity. The nonlinear interactions responsible for the conditional phase shift are described by the Hamiltonians

$$\hat{H}^{(2)} = \hbar \chi_2 \left(\hat{c} \hat{b}^{\dagger} \hat{b}^{\dagger} + \hat{c}^{\dagger} \hat{b} \hat{b} \right)$$
(3a)

$$\hat{H}^{(3)} = \hbar \chi_3 \Big(\hat{a}^{\dagger} \hat{a} \hat{b}^{\dagger} \hat{b} + \frac{(\hat{a}^{\dagger} \hat{a} - 1) \hat{a}^{\dagger} \hat{a} + (\hat{b}^{\dagger} \hat{b} - 1) \hat{b}^{\dagger} \hat{b}}{4} \Big), \quad (3b)$$

where \hat{c} is the annihilation operator for photons in mode

c, see Fig. 1b. The nonlinear coupling rates are $\left[18,\,19\right]$

$$\chi_2 = \sqrt{\frac{\hbar\omega_b}{\epsilon_0}} \frac{\omega_b}{n^3} \frac{\chi^{(2)}}{\sqrt{V_m^{(2)}}} \quad \text{and} \quad \chi_3 = \frac{3}{2} \frac{\hbar\overline{\omega}^2}{\overline{n^4}\epsilon_0} \frac{\chi^{(3)}}{V_m^{(3)}}, \quad (4)$$

where $\overline{\omega}^2 = \sqrt{\omega_a \omega_b \omega_1 \omega_2}$, $\overline{n}^2 = \sqrt{n(\omega_a)n(\omega_b)n(\omega_1)n(\omega_2)}$, ϵ_0 is the vacuum permittivity, $\chi^{(k)}$ is the k^{th} -order nonlinear susceptibility, and $V_m^{(k)}$ is the mode volume for k^{th} -order interactions. In $\chi^{(3)}$ materials the conditional phase shift arises due to the self-phase modulation experienced by two photons while stored in mode *b*. In $\chi^{(2)}$ materials a π phase shift occurs when two photons undergo one Rabi oscillation between mode *b* and *c*, see Fig. 1b. The storage time is adjusted to ensure that the phase requirement is fulfilled in both cases.

Fig. 4a shows the error, $1-F_{11}$, for a $\chi^{(3)}$ material as a function of storage time for different values of the cavity loss rate, γ_L . Note that for each storage time, the

FIG. 4. (a) Plot of $1-F_{11}$ for a $\chi^{(3)}$ material as a function of storage time, T, for different loss rates. Gray corresponds to $\gamma_L/\Omega_{\mathcal{G}}=0$ and it increases from 4×10^{-7} (blue) to 10^{-3} (red). Dashed lines with the same color plot the corresponding values of the error in conditional fidelity, $1-\overline{F}_{11}$. (b) Plot of $1-F_{11}$ as a function of the intrinsic quality factor, Q_L , corresponding to the vertical cross-sections in (a). The legend shows the limiting values of the conditional fidelity, $1-\overline{F}_{11}$. Parameters: $\gamma/\Omega_{\mathcal{G}}=30, \, \chi^{(3)}=1.8\times10^{-19}\,\mathrm{m}^2/\mathrm{V}^2$ [20], $\lambda=1550\,\mathrm{nm},\,\overline{n}=3.4,\, V_m^{(3)}=10^{-3}\,(\lambda/\overline{n})^3.$

nonlinear coupling rate, χ_3 , was chosen to achieve the phase requirement mentioned above. Without loss, the error scales as $1 - F_{11} \propto 1/T^{2.0}$ and 99% fidelity is possible with $T/\tau_{\rm g} < 30$. The dashed colored lines in Fig. 4a plot the conditional fidelity, $\overline{F}_{11} \equiv F_{11}/\langle \overline{11}|\overline{11}\rangle$. Note that $\overline{F}_{11} \approx F_{11}(\gamma_L = 0)$ as in Fig. 3, which means that $1 - \overline{F}_{11}$ may be understood as the error resulting from wave packet distortion alone, while $1 - F_{11}$ additionally includes error from loss. Increasing the storage time (beyond the optimum indicated by circles in Fig. 4a) allows for reduced wave packet distortions at the cost of increased loss, resulting in a trade-off between the two error mechanisms.

Eq. (4) may be used to convert the normalized loss rate, $\tilde{\gamma}_L = \gamma_L / \Omega_g$, into an intrinsic quality factor, $Q_L = \omega / \gamma_L$. We do this using the parameters listed in the caption of Fig. 4 for a silicon cavity with an ultra-small mode volume [21–23]. Fig. 4b plots the error, $1 - F_{11}$, as a function of Q_L for the three vertical cross-sections in Fig. 4a corresponding to three limiting values of the conditional fidelity. The error is dominated by loss where the curves are linear and becomes dominated by wave packet distortion where the curves saturate.

Fig. 5a shows the error, $1-F_{11}$, for a $\chi^{(2)}$ material as a function of storage time for different values of the cavity loss rate. Here, the nonlinear coupling rate, χ_2 , is adjusted for each T to ensure that it corresponds to one Rabi oscillation of the SHG process. The error-scaling

FIG. 5. (a) Plot of $1 - F_{11}$ for second-order nonlinearity as a function of storage time. Gray corresponds to $\gamma_L/\Omega_G = 0$ and it increases from 10^{-5} (blue) to 2×10^{-3} (red). Dashed lines with the same color plot the corresponding values of the error in conditional fidelity, $1 - \overline{F_{11}}$. (b) Plot of the minimum error as a function of χ_k/γ_L corresponding to the circles in Fig. 4a (k = 3, red) and Fig. 5a (k = 2, blue). Dashed lines plot the corresponding values of the conditional fidelity. The slope of all curves are -1, demonstrating the relationship $1 - F_{11} = C^{(k)}\gamma_L/\chi_k$, where $C^{(2)} = 5.5$ and $C^{(3)} = 18.7$. Note that (a) and (b) share the y-axis.

is $1-F_{11} \propto 1/T^{4.1}$, which is better than in Fig. 4a since the photons only interact when they are both in mode b, while they interact during the entire absorption and emission process through both cross- and self-phase modulation for $\chi^{(3)}$ materials. For the optimum choice of T(indicated by circles in Figs. 4a and 5a), the error grows in proportion to the ratio between the loss rate and the nonlinear coupling, $1-F_{11} = C^{(k)}\gamma_L/\chi_k$, where k again denotes the order of the nonlinear interaction. Fig. 5b plots this relationship for both $\chi^{(2)}$ (blue) and $\chi^{(3)}$ materials (red). It also shows that the conditional error, $1-\overline{F}_{11}$, follows the same relation but is 5.1 and 3.0 times smaller (dashed lines) for $\chi^{(2)}$ and $\chi^{(3)}$ materials, respectively. The error may then be related to the quality factor and mode volume by

$$1 - F_{11}^{(2)} = \mathcal{C}^{(2)} \frac{\sqrt{\widetilde{V}_m^{(2)}}}{Q_L} \quad \text{and} \quad 1 - F_{11}^{(3)} = \mathcal{C}^{(3)} \frac{\widetilde{V}_m^{(3)}}{Q_L}, \quad (5)$$

where $V_m^{(k)} = \tilde{V}_m^{(k)} (\lambda/n)^3$ and $\mathcal{C}^{(k)} \propto C^{(k)} / \chi^{(k)}$. Table I lists the values of $\mathcal{C}^{(k)}$ for the two most promising

 $\chi^{(2)}$ materials and the most common $\chi^{(3)}$ material, silicon. The table also lists the required intrinsic quality factor to achieve a conditional fidelity of 99% for an ultra-small mode volume, $\tilde{V}_m^{(k)} = 10^{-3}$ [21–23], and a standard size for one-dimensional photonic crystal cavities, $\tilde{V}_m^{(k)} = 0.5$. The numbers seem prohibitively

	$\rm LiNbO_3$		GaAs		Si	
$\mathcal{C}^{(k)}$	$5.0\!\times\!10^6$		$8.6\!\times\!10^6$		$5.9\!\times\!10^{10}$	
$\widetilde{V}_m^{(k)}$	10^{-3}	0.5	10^{-3}	0.5	10^{-3}	0.5
Q_L	3×10^{6}	7×10^7	5×10^{6}	10^{8}	2×10^9	10^{12}

TABLE I. Required values of the intrinsic quality factor to achieve a conditional fidelity of 99% for three relevant materials. The corresponding values of Q_L for a fidelity of 99% are 5.1 times larger for $\chi^{(2)}$ materials and 3.0 times larger for $\chi^{(3)}$ materials. Parameters: LiNbO₃: $\chi^{(2)} = 54 \text{ pm/V}$ [24], $\lambda = 1550 \text{ nm}, n = 2.1$. GaAs: $\chi^{(2)} = 270 \text{ pm/V}$ [25], $\lambda = 3100 \text{ nm}, n = 3.5$. Si: $\chi^{(3)} = 1.8 \times 10^{-19} \text{ m}^2/\text{V}^2$ [20], $\lambda = 1550 \text{ nm}, n = 3.4$.

large for $\chi^{(3)}$ materials, but for $\chi^{(2)}$ they are close to state-of-the-art Qs in LiNbO₃, for which 10⁷ has been demonstrated in ring resonators both at telecom [26] and visible wavelengths [27] and 10⁶ in photonic crystal cavities [28, 29]. The large difference between $C^{(2)}$ and $C^{(3)}$ is primarily due to the difference in nonlinear coupling rates in Eq. (4), but there is also a contribution from the difference between $C^{(2)}$ and $C^{(3)}$ in Fig. 5b.

Our results show that dynamically coupled cavities offer a very promising approach to realize deterministic two-qubit gates between photons in a dual-rail encoding. With recent progress in nanofabrication of LiNbO₃ PICs [26, 28, 29] and development of ultra-confined photonic crystal cavities [21–23] it appears that experimental demonstrations are within reach. Recent theoretical work also promises the required spectral properties of $\chi^{(2)}$ cavities [30]. Noise sources not included in our analysis must also be investigated, including thermal noisephotons or photons generated by the control fields as well as higher-order nonlinear effects - in particular $\chi^{(3)}$ -effects in $\chi^{(2)}$ materials.

We acknowledge that experimental implementations remain very challenging, but hope it will stimulate the necessary near-term experimental advances to enable deterministic, high-fidelity photonic logic gates as well as extensions such as encoded logical qubits for quantum computing and one-way quantum repeaters.
