A density for the local time of the Brox diffusion *

Jonathan Gutierrez-Pavón † and Carlos G. Pacheco ‡

September 16, 2019

Abstract

We give explicitly the probability density of the local time of the Brox diffusion at first passage times. Such formula is used to find the moments and to related the minima and maxima of the environment to the most and least visited points of the diffusion.

2000 Mathematics Subject Classification:

Keywords: Brox diffusion, Local times, favorite points, Ray-Knight theorem.

1 Introduction

When studying processes with a random environment, it is natural to analyze de effect of the environment on the behaviour of the process. In fact, one is interested on determining, up to some confidence, the behaviour of the trajectories by knowing something of the environment. A very well known situation of this type arises with models such as the so-called Sinai’s random walk and the Brox diffusion, where information of the environment can say where is mainly localized the particle, see for instance [3, 1].

In this paper we focus on this kind of question for the Brox diffusion. It is known that the environment gives rise to a stochastic process, sometimes called the potential, and it is already known as well how the minimum values of such potential determines the places

where the particles accumulate more local time, see \[2\]. The places in the state space where the local time takes high values are said to be favorite points.

For these reasons we are interested in studying the local time and its probability densities. One has to remember that for the Brownian motion the local times can be related to specific stochastic processes such as the Bessel diffusion; this is the content of the so-called Ray-Knight theorems. What we do here is to calculate explicitly the probability density of the local time for the Brox diffusion under certain stopping times. It is interesting to see how the density is a mixture of an absolutely continuous density and a discrete one. A very straightforward application is finding moments of the local times where one can easily read the connection between minima of the potential and favorite points of the diffusion, see Remark \[5\].

\section{Preliminaries}

Intuitively speaking the Brox diffusion was originally described with the following stochastic differential equation

\begin{equation}
\begin{aligned}
dX_t &= -\frac{1}{2} W'(X_t) \, dt + dB_t,
\end{aligned}
\end{equation}

where $B := \{B_t : t \geq 0\}$ represents the standard Brownian motion, and $W := \{W(x) : x \in \mathbb{R}\}$ is a two-sided Brownian motion. The processes $B$ and $W$ are independent from each other. Here $W'$ denotes the derivative of $W$, and usually $W'$ is known as the white noise.

To give a rigorous meaning of the expression (1) we can use the associated generator of the Markov process. More precisely one can say that the process $X := \{X_t : t \geq 0\}$ is associated with the infinitesimal generator

\begin{equation}
Lf(x) := \frac{1}{2} e^{W(x)} \frac{d}{dx} \left( e^{-W(x)} \frac{df(x)}{dx} \right).
\end{equation}

In this case, the scale function is

\begin{equation}
s(x) := \int_0^x e^{W(y)} \, dy,
\end{equation}

and the speed measure is

\begin{equation}
m(A) := \int_A 2e^{-W(y)} \, dy, \quad \text{for Borel sets } A \subseteq \mathbb{R}.
\end{equation}

Therefore we can represent the operator $L$ in the following way

\begin{equation}
Lf = \frac{d}{dm} \frac{d}{ds} f.
\end{equation}
When leaving fixed a trajectory of $W$, the process $X$ associated with this operator is indeed a diffusion, thus, one can give an explicit formula of the process $X$ in the following way:

$$X_t = s^{-1}(B_{T_t^{-1}}),$$  \hspace{1cm} (4)

where

$$T_t := \int_0^t e^{-2W(s^{-1}(B_u))} \, du.$$  

Now, let us say some facts on local times.

Let $L_X(t, x)$ be the local time of the Brox diffusion at time $t$ at the site $x$. It is known that $L_X := \{L_X(t, x) : t \geq 0, x \in \mathbb{R}\}$ is jointly continuous stochastic process such that for any measurable function $f$ and for any $t \geq 0$:

$$\int_0^t f(X_s) \, ds = \int_{-\infty}^\infty f(x)L_X(t, x) \, dx.$$  \hspace{1cm} (5)

By substituting (4) in (5) it is easy see that

$$L_X(t, x) = e^{-W(x)}L_B(T^{-1}(t), s(x)),$$  \hspace{1cm} (6)

where $L_B$ represent the local time of the Brownian motion, see [5]. We use previous formula to give a explicit expression of local time of the Brox process.

Finally, we briefly mention the statement of the Ray-Knight theorem, see for instance [4]. It says that $\{L_B(\sigma(1), 1-a), a \in [0, 1]\}$ is the same in distribution as a two dimensional squared Bessel process $\{Z_a, 0 \leq a \leq 1\}$, where $\sigma(1) = \inf\{t : B_t = 1\}$. In general, it is also true that for fixed $a < b$, the local time $\{L_B(\sigma(b), a)\}$ has the same distribution as the random variable $Z_{b-a}$. In particular, for fixed $a < b$, the distribution of $L_B(\sigma(b), a)$ is an exponential random variable with mean 2.

### 3 Local time of Brox diffusion

Let us now define the random variable that we are going to analyze. Take the stopping time $\tau(b) := \inf\{t : X_t = b\}$. Our goal is to study the stochastic process $\{L_X(\tau(b), a), b > a\}$, for $a, b$ fixed.

**Proposition 1** For $0 < a < b$ fixed, the random variable $L_X(\tau(b), a)$ is exponential with parameter $\lambda := \frac{e^{W(a)}}{2(s(b) - s(a))}$. 

3
Proof. Using (6) we have that $L_X(\tau(b), a) = e^{-W(a)}L_B(T^{-1}(\tau(b)), s(a))$. One can see that $T^{-1}(\tau(b)) = \sigma(s(b))$.

Then, by the Ray-Knight theorem, if $Z$ represents a two dimensional squared Bessel process, then we have

$$P(L_X(\tau(b), a) \leq x) = P(e^{-W(a)}L_B(T^{-1}(\tau(b)), s(a)) \leq x) = P(e^{-W(a)}Z_{\sigma(s(b))} \leq x) = P(e^{-W(a)}Z_{\sigma(s(b))} \leq x) = P\left(Z_1 \leq \frac{e^{W(a)x}}{s(b) - s(a)}\right).$$

Using the fact that $Z_1$ is an exponential random variable with mean 2, we obtain the result. ■

Lemma 2 For any fixed environment $W$, and $a \in \mathbb{R}$ fixed, the process $\{L_X(\tau(t), a) : t \geq 0\}$ has independent increments.

Proof. Take times $t_1 < t_2 < t_3 < t_4$, and define increments $I_1$ and $I_2$ as,

$$I_1 := L_X(\tau(t_2), a) - L_X(\tau(t_1), a),$$

and similarly for $I_2$ using $t_3$ and $t_4$ in lieu of $t_1$ and $t_2$, respectively.

Using (6) we have that

$$I_1 = e^{-W(a)}(L_B(T^{-1}(\tau(t_2)), a) - L_B(T^{-1}(\tau(t_1)), a))$$

and the same for $I_2$.

If $T_i := T^{-1}(\tau(t_i))$ for $i = 1, 2, 3, 4$, notice that $T_1 \leq T_2 \leq T_3 \leq T_4$, and although they depend on $B$, they are stopping times. Thus, by the strong Markov property, the random variables $I_1$ and $I_2$ are independent because they are measurements on disjoint "time-windows". ■

We use previous results to find the distribution of the random variable

$$L_X(\tau(c), a) - L_X(\tau(b), a),$$

where $0 < a < b < c$. 4
Theorem 3

The probability density \( f \) of \( L_X(\tau(c),a) - L_X(\tau(b),a) \) is given by

\[
f(t) = \lambda(1 - \alpha)e^{-\lambda t} + \alpha \delta_0(t),
\]

where

\[
\lambda = \frac{e^W(a)}{2(s(c) - s(a))} > 0, \quad \text{and} \quad \alpha = \frac{s(b) - s(a)}{s(c) - s(a)}.
\]

Here \( \delta_0 \) represents the Dirac Delta function at the point 0.

Proof. Note first that

\[
E\left(e^{-tL_X(\tau(c),a)}\right) = E\left(e^{-t[L_X(\tau(c),a)-L_X(\tau(b),a)]}\right) \cdot E\left(e^{-tL_X(\tau(b),a)}\right).
\]

Thus,

\[
E\left(e^{-t[L_X(\tau(c),a)-L_X(\tau(b),a)]}\right) = \frac{E\left(e^{-tL_X(\tau(c),a)}\right)}{E\left(e^{-tL_X(\tau(b),a)}\right)}.
\]

On the other hand, using the fact that \( L_X(\tau(b),a) \) is exponential with parameter \( \lambda := \frac{e^W(a)}{2(s(b) - s(a))} \), then the moment-generating function of \( L_X(\tau(b),a) \) is the following:

\[
E\left(e^{-tL_X(\tau(b),a)}\right) = \frac{e^W(a)}{e^W(a) + 2t(s(b) - s(a))}.
\]

Substituting (10) in (8) we obtain the moment-generating function of \( L_X(\tau(c),a) - L_X(\tau(b),a) \)

\[
E\left(e^{-t[L_X(\tau(c),a)-L_X(\tau(b),a)]}\right) = \frac{e^W(a) + 2t(s(b) - s(a))}{e^W(a) + 2t(s(c) - s(a))}.
\]

The previous expression can be written as

\[
E\left(e^{-t[L_X(\tau(c),a)-L_X(\tau(b),a)]}\right) = \frac{1}{1 + \frac{2(s(c) - s(a))t}{e^W(a)}} + \frac{2(s(b) - s(a))}{e^W(a)} \cdot \frac{t}{1 + \frac{2(s(c) - s(a))t}{e^W(a)}}.
\]

We now consider the following formulae:

\[
\mathcal{L}^{-1}\left(\frac{1}{1 + \frac{2(s(c) - s(a))t}{e^W(a)}}\right) = \frac{e^W(a)}{2(s(c) - s(a))} e^{-\frac{e^W(a)t}{2(s(c) - s(a))}},
\]
From the formula (11), we can see that the moment-generating function of \( X \) satisfies
\[
\mathcal{L}^{-1} \left( \frac{t}{1 + \frac{2(s(c) - s(a))t}{e^{W(a)}}} \right) = \frac{e^{W(a)}}{2(s(c) - s(a))} \delta_0(t) - \frac{e^{2W(a)}}{4(s(c) - s(a))^2} e^{-\frac{s(c) - s(a)}{2}} \cdot \frac{-e^{W(a)t}}{t},
\]
where \( \mathcal{L}^{-1} \) is the inverse Laplace transform, and \( \delta_0 \) represent the Dirac Delta function.

Using the previous formulae, we can obtain the distribution of \( L_X(\tau(c), a) - L_X(\tau(b), a) \), for \( 0 < a < b < c \).

Indeed, if \( F \) represents such distribution function, then we have
\[
F(t) = \left[ 1 - \frac{s(b) - s(a)}{s(c) - s(a)} \right] \cdot \left[ 1 - e^{\frac{-s(c) - s(a)}{s(c) - s(a)}} \right] + \frac{s(b) - s(a)}{s(c) - s(a)} \cdot H_0(t),
\]
where \( H_0 \) represent the Heaviside function. Thus we obtain the density (13).

Now, we can use these formulae to calculate explicitly the moments of the random variable
\( L_X(\tau(c), a) - L_X(\tau(b), a) \).

**Corollary 4** It holds that
\[
E \left[ (L_X(\tau(c), a) - L_X(\tau(b), a))^n \right] = n! \left( \frac{2(s(c) - s(b))}{e^{W(a)}} \right) \left( \frac{2(s(c) - s(a))}{e^{W(a)}} \right)^{n-1},
\]
where \( a, b, c \) are three numbers such that \( 0 < a < b < c \).

**Proof.** First note that if \( f(t) = \frac{1+At}{1+Bt} \), where \( A \) and \( B \) are constants, then
\[
\frac{d^n f(t)}{dt^n} = n!(-1)^n(B - A)(1 + Bt)^{n-1} B^{n-1}.
\]
From the formula (13), we can see that the moment-generating function of \( L_X(\tau(c), a) - L_X(\tau(b), a) \) has the form \( f(t) = \frac{1+At}{1+Bt} \) with \( A = \frac{2(s(b) - s(a))}{e^{W(a)}} \) and \( B = \frac{2(s(c) - s(a))}{e^{W(a)}} \).

Now, using the formulae (13) and (14), as well as the fact that the random variable \( X \) satisfies
\[
\frac{d^n E(e^{-tX})}{dt^n} \bigg|_{t=0} = (-1)^n E(X^n),
\]
we have the explicit formula for the moments of \( L_X(\tau(c), a) - L_X(\tau(b), a) \).

Finally, let us mention the following important application. In the case where \( n = 1 \) we end up with
\[
E(L_X(\tau(c), a) - L_X(\tau(b), a)) = \frac{2(s(c) - s(b))}{e^{W(a)}}.
\]
Remark 5 We can see in the previous expression (15) that if $a$ satisfies $W(a) \leq W(t)$ for all $t \in [0, b]$, then the expected value of $L_X(\tau(c), a) - L_X(\tau(b), a)$ is the largest possible. That is, if $W(a)$ is a minimum of $W$ in the interval $[0, b]$, then it is expected that the random variable $L_X(\tau(c), a) - L_X(\tau(b), a)$ reaches its largest value.

Similarly, if $W(a)$ is a maximum of $W$ in the interval $[0, b]$, then it is expected that the random variable $L_X(\tau(c), a) - L_X(\tau(b), a)$ reaches its smallest value.

In short, the stochastic process $X$ spends more time at minima of the environment, and less time at maxima of the environment.
