(Dated: September 17, 2019)

We consider the spin echo decay of a nitrogen-vacancy center spin qubit, based on \(m = 0\) and \(m = 1\) levels of the \(S = 1\) ground state spin manifold of the center, in presence of finite dynamic nuclear polarization of the nuclear environment. We show that the signal acquires a nontrivially time-dependent phase shift in presence of such polarization. In Gaussian approximation to calculation of dephasing this phase shift is absent when the NV center is prepared in a superposition of \(m = 1\) and \(m = −1\) states, i.e. when the qubit couples to the spin environment in a way analogous to that of spin-1/2. For nuclear environment devoid of spins strongly coupled to the qubit, the phase shift can be quite well described in Gaussian approximation, which makes it clear that it is related to a linear response function of the environment affected by an evolving qubit. Consequently, its observation signifies the presence of back-action of the qubit on the environment, and it thus excludes the possibility of physically well-motivated treatment of environment as a source of external classical noise affecting the qubit. Furthermore, when exact coherence dynamics is well described by weak coupling approximation, for qubit based on \(m = 0\) and \(m = 1\) levels observation of dependence of modulus of echo signal on nuclear polarization signifies non-Gaussian character of environmental influence. The same conclusion follows from observation of nonzero phase shift of spin echo signal of a qubit based on \(m = ±1\) levels.

I. INTRODUCTION

When a qubit undergoes pure dephasing due to interaction with its environment, measurement of coherence of the qubit subjected to an appropriately chosen control sequence can give a lot of information about dynamics of this environment [1,2]. The extraction of quantitative information about the environmental fluctuations is particularly straightforward when dephasing can be described in Gaussian approximation [1,4], in which the environmental fluctuations that affect the qubit’s phase are fully characterized by power spectral density (PSD), which is the Fourier transform of the relevant autocorrelation function of environmental variables. Such reconstruction protocols, connecting the observed time-dependence of coherence to putative spectrum of noise that affects the qubit, \(\rho\), is given in Gaussian approximation [1,2], if one is used.

A fact that makes qubit-based characterization of a Gaussian environment so straightforward is that the above \(\chi(t)\) is given by an integral of a product of \(S(\omega)\), the power spectral density of noise, and a frequency-dependent filter function determined by the sequence of operations applied to the qubit. For a sequence of \(\pi\) rotations that has a well-defined period, the filter has a band-pass character, making the qubit coherence decay dependent only on values of \(S(\omega)\) in narrow frequency ranges [1,2,5,7]. An observation important for this paper is that the structure of expression for \(\chi(t)\) is the same if \(\hat{V}\) operator is replaced by a classical stochastic process \(\xi(t)\), and tracing over environment is replaced by averaging over realizations of this process [2]. One can only tell the difference between dephasing due to quantum and classical noise, if it is feasible to compare qubit decoherence at significantly different temperatures of the environment. In the case in which the quantum description of the environment is necessary, the temperature dependence of \(\chi(t)\) should be visible.

The results presented here are based on recent Ref. [3], in which qubit dephasing due to interaction with an environment described as a collection of noninteracting bosons, was considered. It was observed there that when the qubit-environment coupling is of the form \(\frac{1}{2}(1 - \hat{\sigma}_z) \otimes \hat{V} = |−\rangle⟨−| \otimes \hat{V}\), the coherence differs from...
Eq. (1) by an additional phase factor,

$$\rho_{+-}(t) = \rho_{+-}(0) e^{-\lambda^2 x(t)} e^{-i\lambda^2 \Phi(t)}.$$  \hspace{1cm} (2)

The additional phase shift $\Phi(t)$ has a non-trivial time-dependence determined by dynamical properties of the environment [5], and which is nonzero when the environment is not in a high-temperature state close to a maximally mixed one. This happens when the inverse temperature of the environment in thermal equilibrium, $\beta$, is finite, or when the environment had been intentionally driven away from a maximally mixed state. The latter is especially relevant for this paper, as we will focus here on the case of Dynamic Nuclear Polarization (DNP) of nuclear spin environment interacting with an electron spin qubit.

While the existence of such a nontrivial time-dependent phase factor $\Phi(t)$ for a bosonic environment coupled in the above “biased” way (for which only one of the levels of the qubit is in fact coupled to the environment) had been known for a freely evolving qubit [21, 31], its presence for qubits subjected to dynamical decoupling has only been appreciated recently [8].

The phase $\Phi(t)$ is absent if we replace $\hat{V}$ by a classical random signal $\xi(t)$, as in this case both $\frac{1}{2} \hat{\sigma}_z \xi(t)$ and $\frac{1}{2} (1 - \hat{\sigma}_z) \xi(t)$ couplings, lead to the same result for qubit dephasing. This is simply because a time-dependent shifting of the energy scale has no influence on energy splitting between the qubit levels, and thus on coherence. The observation of nonzero $\Phi(t)$ under dynamical decoupling in Gaussian dephasing regime - when the environment can be treated as Gaussian, or time $t$ is short enough for calculations in $\lambda^2$ order to approximate the exact result - signifies that the influence of the environment cannot be treated as an external classical noise $\xi(t)$.

The “biased” coupling discussed above arises in natural way for a qubit that is based on $m = 0$ and 1 levels of spin $S = 1$, or for a qubit for which only one of its states is endowed with dipole moment allowing for coupling to external field. The first case applies to a widely investigated spin qubit based on nitrogen-vacancy center in diamond [11, 12] coupled to a spin environment, while the second hold for an excitonic qubit and its coupling to phonons [5, 10, 13, 14] for a singlet-triplet qubit in a double quantum dot [15, 16] that is affected by charge noise. The environments consisting of spins [17, 19] and charge fluctuators [2, 13] are not necessarily Gaussian, but there are regimes of environment sizes, timescales and qubit-environment couplings in which they can be treated as such to a good approximation [2, 20, 21].

In this paper we consider spin echo dynamics of a coherence signal of an NV center spin qubit coupled to an environment of $^{13}$C nuclear spins. We consider the presence of finite dynamic nuclear polarization (DNP) of the nuclei. Creation of such a polarization has been successfully pursued in experiments [22, 30]. Crucially, creation of DNP is the most viable way of driving the nuclear environment away from a completely mixed state, equivalent to $\beta \to 0$ (infinite temperature) equilibrium state, that describes it in typical experimental conditions. Consequently, it leads to a possibility of observing $\Phi(t)$ when spin echo, or other dynamical decoupling sequences, are applied to the qubit. We analyze the conditions under which the spin echo decay of an NV center spin qubit interacting with its nuclear environment can be well described within Gaussian approximation, and calculate the phase shift $\Phi(t)$ that affects the echo signal in presence of finite DNP. We show that this shift should be easily observable in experiments, and its presence has to be taken into account when analyzing the spin echo signal of an NV center interacting with partially polarized nuclear bath. Let us stress that while the Gaussian approximation quantitatively describes the NV center decoherence when there are no nuclear spins in $\approx 1$ nm radius from the qubit, the most relevant for us here qualitative feature of the Gaussian prediction - the appearance of phase $\Phi(t)$ in spin echo experiment - applies to all the presented calculations, in which the Gaussian approximation is not made, and which are essentially exact on timescales of interest.

The paper is organized in the following way. In Section II we revisit the general theory of pure dephasing and derive a physically transparent expression for the phase $\Phi(t)$ that arises for qubit-environment couplings distinct from $\hat{\sigma}_z \otimes \hat{V}$, and we briefly remind the qualitative conditions that allow for using Gaussian approximation [2] when dealing with an environment that can be naturally decomposed into weakly interacting subsystems (e.g. a spin bath with weak intra-bath interactions). In Section III we revisit the most practical approach to calculation of electron spin qubit decoherence caused by a nuclear environment, the Cluster-Correlation Expansion (CCE) [21, 31, 33], and discuss its generalization to the case of finite DNP. Then, in Section IV we give numerical results for spin echo decay for the qubit at low magnetic fields ($B = 156$ G), for which the most relevant environmental dynamical processes leading to the decay are single-spin precession. We compare there the results of the full CCE calculations with Gaussian approximation results, and show that the latter approximation is applicable for environments that do not contain spins that are very close to the qubit, and thus very strongly coupled to it. The phase shift $\Phi(t)$ of the echo signal is shown there to appear whenever there is finite DNP. Comparison between decoherence of the qubit based on $m = 0$ and $m = 1$ levels of the ground-state spin $S = 1$ manifold of the NV center, with the qubit based on $m = \pm 1$ levels is also given there. We discuss how by comparing the coherence signal obtained for these two kinds of NV-based qubit one can detect the non-Gaussian features of environmental fluctuations leading to qubit decoherence. In the concluding Section V we discuss the relevance of the presented results for experiments on spin qubits interacting with dynamically polarized spin baths, and for distinguishing between Gaussian vs non-Gaussian and classical vs quantum character of environmental influence on the
II. PURE DEPHASING OF A QUBIT IN GAUSSIAN APPROXIMATION

A. Calculation of attenuation function and phase shift in Gaussian approximation

We consider the qubit-environment interaction given by

\[ \hat{H}_{\text{int}} = \frac{\lambda}{2} (\eta + \hat{\sigma}_z) \otimes \hat{V}, \]  

where \( \eta \) is a parameter that controls the degree of “bias” of the coupling: for \( \eta = 0 \) we have an unbiased \( \hat{\sigma}_V \) interaction, while for \( \eta = \pm 1 \) only one of the states of the qubit couples to the environment. Since such a pure dephasing coupling \( \hat{H}_{\text{int}} \) commutes with the free Hamiltonian of the qubit \( \hat{H}_Q \propto \hat{\sigma}_z \), only the off-diagonal elements of qubit's density matrix undergo evolution,

\[ \hat{\rho}_Q(t) = \begin{pmatrix} \rho_{++}(0) & \rho_{+-}(t) \\ \rho_{-+}(0) & \rho_{--}(0) \end{pmatrix}, \]  

where the so-called decoherence function \( W(t) = \text{Tr}(\hat{\sigma}_- \hat{\rho}_Q(\hat{t})/\rho_{++}(0)) \) encapsulates all the changes in qubit’s state induced by the interaction with the environment.

In addition, we shall assume that during its evolution, the qubit can be influenced by an application of external control fields. The control scheme we focus on in particular is of the dynamical decoupling type: the qubit is subjected to sequence of specifically timed pulses of transverse field that cause an effectively instantaneous \( \pi \)-rotations of its Bloch vector (spin flips). For example, the spin echo (which is the main focus of this paper) is a special case of such sequence, where a single pulse is applied at the midpoint of the evolution. It should be stressed that the application of the echo protocol (or any other sequence of pulses that decouples the qubit from low frequency noise [2]) removes the trivial phase \( \Delta \) (due to \( \Delta E \) energy splitting of the qubit) from coherence signal. In general, the effects of dynamical decoupling control defined by the sequence of pulse application timings, \( \{\tau_0 = 0, \tau_1, \tau_2, \ldots, \tau_n-1, \tau_n = t\} \) (here, \( t \) is the total evolution duration), can be conveniently parametrized with the so-called time-domain filter function \( f(\tau) \):

\[ W(t) = \text{Tr}\left( \hat{\sigma}_- U(t) \hat{\rho}_Q(\hat{t}) \hat{U}^\dagger(t) f(\tau) \right), \]  

with the unitary evolution operator conditioned by the choice of pulse sequence given by

\[ \hat{U}(t|f) = T e^{-\frac{i}{2} \int_0^t d\tau (\eta + \hat{\sigma}_z f(\tau)) \hat{V}(\tau)}, \]  

where \( \hat{V}(\tau) = \exp(i\tau \hat{H}_E) \exp(-i\tau \hat{H}_E) \) is the interaction picture of the environmental operator that couples to the qubit. See Appendix A for detailed derivation of this result and the explicit definition of filter \( f(\tau) \).

Defining the symbol \( \langle \bullet \rangle = \text{Tr}_E(\bullet \hat{\rho}_E) \) to denote the partial trace over environmental degrees of freedom, the coherence function can written is a standard form of averaged ordered exponential, that can in turn be expressed in terms of cumulant series [2],

\[ W(t) = \text{Tr}\langle \hat{\sigma}_- U(t) \hat{\rho}_Q(t) \hat{U}^\dagger(t) \rangle = \exp\left( \sum_{k=0}^{\infty} \lambda^k \kappa_k(t|f) \right), \]  

where \( \kappa_k(t|f) \) is a \( k \)th order cumulant. Using the above relation one can calculate the explicit form of cumulants by expanding both sides of the equation and comparing the terms of respective orders in coupling strength \( \lambda \). We shall begin by expanding the evolution operators,

\[ W(t) = \left( 1 + \frac{i\lambda}{2} \int_0^t d\tau_1 \eta + f(\tau_1) \right) \hat{V}(\tau_1) \\
- \frac{\lambda^2}{4} \int_0^t d\tau_1 \int_0^{\tau_1} d\tau_2 \eta + f(\tau_1) \hat{V}(\tau_1)(\eta + f(\tau_2)) \hat{V}(\tau_2) \\
\times \left( 1 - \frac{i\lambda}{2} \int_0^t d\tau_2 \eta - f(\tau_2) \right) \hat{V}(\tau_2) \\
- \frac{\lambda^2}{4} \int_0^t d\tau_1 \int_0^{\tau_1} d\tau_2 \eta - f(\tau_2) \hat{V}(\tau_2)(\eta - f(\tau_1)) \hat{V}(\tau_1) \right) + O(\lambda^3), \]  

and we skip writing down the terms of order higher than \( \lambda^2 \). Assuming \( \langle \hat{V}(\tau) \rangle = 0 \), we express the double, equal-time integrals as the time-ordered ones,

\[ \int_0^t d\tau_1 \int_0^{\tau_1} d\tau_2 = \int_0^t d\tau_1 \int_0^{\tau_1} d\tau_2 + \int_0^t d\tau_1 \int_0^{\tau_1} d\tau_2 \]  

which allows us to rewrite the above expression in terms of averaged commutator and anticommutator of coupling operators,

\[ W(t) = 1 - \frac{\lambda^2}{2} \int_0^t d\tau_1 \int_0^{\tau_1} d\tau_2 f(\tau_1)f(\tau_2) \text{Re}(\langle \hat{V}(\tau_1), \hat{V}(\tau_2) \rangle) \\
- i\frac{\lambda^2}{2} \int_0^t d\tau_1 \int_0^{\tau_1} d\tau_2 f(\tau_2) \text{Im}(\langle \hat{V}(\tau_1), \hat{V}(\tau_2) \rangle) + O(\lambda^3) \]  

where we utilized the symmetries of commutator, \( \langle [\hat{V}(\tau_1), \hat{V}(\tau_2)] \rangle^* = -\langle [\hat{V}(\tau_1), \hat{V}(\tau_2)] \rangle \), and anti-commutator, \( \langle [\hat{V}(\tau_1), \hat{V}(\tau_2)] \rangle^* = \langle \hat{V}(\tau_1), \hat{V}(\tau_2) \rangle \).

On the other hand, the Gaussian environment can be defined as one for which the cumulant series terminates on second order,

\[ W(t) = e^{-\lambda^2 \kappa_2(t|f)} = e^{-\lambda^2 \chi(t) - i\lambda^2 \Phi(t)} \]  

\[ = 1 - \lambda^2 \chi(t) - i\lambda^2 \Phi(t) + O(\lambda^3). \]  

Comparing Eqs. (9) and (10) we identify the real and imaginary parts of (9) with the attenuation function and
the phase shift, respectively
\[
\chi(t) = \frac{1}{2} \int_0^t \int_0^{\tau_1} d\tau_1 d\tau_2 f(\tau_1) f(\tau_2) \text{Re}\langle [\dot{V}(\tau_1), \dot{V}(\tau_2)] \rangle,
\]
\[
\Phi(t) = \frac{\eta}{2} \int_0^t \int_0^{\tau_1} d\tau_1 d\tau_2 f(\tau_2) \text{Im}\langle [\dot{V}(\tau_1), \dot{V}(\tau_2)] \rangle.
\]
(12)

(13)

These equations simply restate the result of Ref. [8] in a more general context of environment that can be treated in Gaussian approximation when qubit decoherence is concerned, while not necessarily being equivalent to a system of noninteracting bosons. Note that the non-zero phase shift can exist only because of operator nature of the coupling \(\dot{V}(\tau)\) and its noncommutativity at distinct times \(\tau_1 \neq \tau_2\). On the other hand, the attenuation function is generated by the anti-commutator, and the noncommutativity is not necessary for the result to be nonzero. In fact, for coupling to classical stationary Gaussian noise, for which \(\dot{V} \) is replaced by a stochastic function \(\xi(t)\) and tracing over \(E\) is replaced by averaging over realizations of \(\xi(t)\), the attenuation function is still given by Eq. (12), with \(\xi(\tau_1)\xi(\tau_2)\) replacing \(\frac{1}{2} \text{Re}\langle [\dot{V}(\tau_1), \dot{V}(\tau_2)] \rangle\) (we assume \(\xi = 0\) for simplicity), while the phase term \(\Phi(t)\) is zero. Thus, at least when decoherence is well described within the Gaussian approximation, Eq. (10), the appearance of nonzero \(\Phi(t)\) means that the environmental influence on the qubit cannot be treated as an external classical noise affecting its phase.

If we rewrite the integrand defining \(\Phi(t)\) as
\[
\Phi(t) = i\eta \int_0^t d\tau_1 \int_0^{\tau_1} d\tau_2 f(\tau_2) \times \left( \frac{i}{2} \Theta(\tau_1 - \tau_2) \text{Im}\langle [\dot{V}(\tau_1), \dot{V}(\tau_2)] \rangle \right)
\]
\[
= i\eta \int_0^t d\tau_1 \int_0^{\tau_1} d\tau_2 f(\tau_2) K(\tau_1 - \tau_2),
\]
(14)

where we recognize in \(K(\tau)\) the Green-Kubo susceptibility. This quantity defines the linear response of environmental observable \(\dot{V}\) to external stimulus that probes the system by coupling to the same observable. Therefore, the following physical interpretation can be given for the origin of the phase shift. The qubit influences the environment by coupling through variable \(\dot{V}\). In turn, this disturbance modifies the 'noise' generated by the environment, which drives the decoherence of the qubit. In a sense, the phase shift can be understood as a self-interaction of the qubit mediated by the environment.

Similarly, the anti-commutator in attenuation function can be also be expressed in terms of another fundamental physical quantity,
\[
\chi(t) = \frac{1}{2} \int_0^t d\tau_1 d\tau_2 f(\tau_1) f(\tau_2) \left( \frac{1}{2} \text{Re}\langle [\dot{V}(\tau_1), \dot{V}(\tau_2)] \rangle \right)
\]
\[
= \frac{1}{2} \int_0^t d\tau_1 d\tau_2 f(\tau_1) f(\tau_2) C(\tau_1 - \tau_2),
\]
(15)

where \(C(\tau)\) is the correlation function that describes the natural temporal fluctuations of environmental observable \(\dot{V}\). The two quantities are deeply related; specifically, for system that exhibits detailed balance—such as environment in thermal equilibrium state \(\hat{\rho}_E = e^{-\beta H_E}/\text{Tr}(e^{-\beta H_E})\)—the Fourier transforms of correlation function (the spectral density),
\[
S(\omega) = \frac{1}{2} \int_{-\infty}^{\infty} e^{-i\omega \tau} \text{Re}\langle [\dot{V}(\tau), \dot{V}(0)] \rangle d\tau
\]
and of susceptibility,
\[
K(\omega) = \frac{1}{2} \int_{-\infty}^{\infty} e^{-i\omega \tau} \text{Im}\langle [\dot{V}(\tau), \dot{V}(0)] \rangle d\tau
\]
(16)

(17)

satisfy the fluctuation-dissipation theorem,
\[
S(\omega) = \text{coth}\left( \frac{\beta \omega}{2} \right) \text{Im} K(\omega).
\]
(18)

It is straightforward to express the attenuation function and the phase as integrals over frequencies:
\[
\chi(t) = \int_{-\infty}^{\infty} S(\omega) |\tilde{f}(\omega)|^2 \frac{d\omega}{2\pi},
\]
\[
\Phi(t) = i\eta \int_{-\infty}^{\infty} K(\omega) \frac{2}{\omega} e^{-i\omega t/2} \sin \frac{\omega t}{2} \tilde{f}(\omega) \frac{d\omega}{2\pi},
\]
(19)

where \(\tilde{f}(\omega)\) is the Fourier transform of \(f(t)\). We see thus that a measurement of qubit decoherence, when either the second-order expansion result applies, or, more generally, when Gaussian approach to environmental influence is justified (i.e. when the environment consists of noninteracting bosons, as in [8], or when we can use a central limit theorem-like reasoning, as we do in subsequent Section), is fully determined by appropriate frequency integrals over sequence-induced filters and power spectrum/susceptibility.

B. Weak coupling and Gaussian approximations for dephasing

Let us consider a situation in which the environment can be treated (exactly or approximately, e.g. on timescale of interest) as consisting of many uncorrelated and non-interacting entities. As we will see later, this is a good approximation for treatment of nuclear bath interacting with an electron spin qubit.

The Hamiltonian of the environment is then given by \(\sum_{k=1}^{N} \hat{H}_k\), and the qubit-environment coupling is given by \(\hat{V} = \sum_{k=1}^{N} \hat{V}_k\), where \(k = 1 \ldots N\) labels the environmental sub-systems. The initial density matrix of the environment is given by \(\hat{\rho}_E(0) = \prod_{k=1}^{N} \hat{\rho}_E^{(k)}(0)\). The resulting decoherence of the qubit factorizes into product of contributions from environmental subsystems:
\[
W(t) = \prod_{k=1}^{N} W^{(k)}(t) = \prod_{k=1}^{N} [1 - \delta W^{(k)}(t)],
\]
(20)
where we have defined $\delta W^{(k)}(t)$.

Let us now consider the case in which $|W^{(k)}| \ll 1$ for every $k$. We have then

$$W(t) \approx \exp \left[ -\sum_k \delta W^{(k)}(t) + O\left(\sum_k (\delta W^{(k)})^2\right) \right], \quad (21)$$

and we will refer to this as a weak coupling result. The only thing that is required for it to approximate the exact result is that every environmental subsystem only weakly perturbs the qubit, i.e. $|W_k(t)| \approx 1$ for each $k$.

Let us now bring back again the dimensionless qubit-environment coupling parameter $\lambda$ that multiplies $\hat{V}$. One can expect, that when $|\delta W_k(t)| \ll 1$, approximating $\delta W_k$ by an expression obtained in $\lambda^2$ order should be adequate. This, however, holds only on a certain timescale. Let us illustrate this with a simple example: an environment consisting of noninteracting spins, with $\hat{H}_E = \omega I_k^z$ and qubit-environment coupling given by $\lambda \sum_s \sigma_z A_l I_k^z$. If we consider a freely evolving qubit (with no $\pi$ pulses between its initialization and coherence measurement), we obtain for a completely mixed states of the environment

$$\delta W^{(k)}(t) = \lambda^2 \frac{A^2}{\omega^2 + \lambda^2 A^2} \sin^2 \sqrt{\omega^2 + \lambda^2 A^2} t^2. \quad (22)$$

This should be compared with a result of calculation in Gaussian approximation, using Eq. (12), that leads to

$$\delta W_G^{(k)}(t) = \lambda^2 A^2 \frac{\omega_t^2}{2}, \quad (23)$$

which agrees with Eq. (22) not only when $\lambda \ll \omega/A$ (which is necessary to enter the weak coupling regime, i.e. guarantee that $\delta W_k(t) \ll 1$), but also under the additional condition $t \ll t_c$, where $t_c = 4\omega / \lambda^2 A^2 \gg 4/\omega$. If the latter condition is broken, then the Gaussian approximation to $W^{(k)}(t)$ has the same amplitude as the exact result, but its oscillations will not follow those of the exact result. When both of them are fulfilled, the decoherence caused by $N$ weakly coupled environmental subsystems is given by a Gaussian formula, Eq. (11), with

$$\chi(t) + i\Phi(t) \approx \sum_{k=1}^N \delta W_G^{(k)}(t). \quad (24)$$

### III. DEPHASING OF AN NV CENTER INTERACTING WITH A POLARIZED BATH

#### A. The Hamiltonian of the NV center and the nuclear environment

The Hamiltonian of an NV center interacting with a bath of spin-1/2 nuclei is given by:

$$\hat{H} = \Omega \hat{S}_z + \Delta \hat{S}_z^2 + \hat{H}_E + \hat{S}_z \hat{V}, \quad (25)$$

where $\Omega$ is the Zeeman splitting of the qubit, $\Delta$ is the zero-field splitting term (present, because NV center in diamond has spin $S=1$), $\hat{H}_E$ is the Hamiltonian of the environment and $\hat{V}$ is the environmental operator coupling to the qubit. The Zeeman splitting is given by $\Omega = -\gamma_e B_z$ with $\gamma_e = 28.02 \text{ GHz/T}$ and $B_z$ is the magnetic field value (in Tesla). Zero-field splitting is given by $\Delta = 2.87 \text{ GHz}$. We have assumed that the magnetic field is parallel to the $z$ axis determined by a vector connecting the nitrogen and the vacancy, i.e. to the quantization axis associated with the zero-field splitting term.

The eigenvalues of $\hat{S}_z$ for spin-1 are $m = -1, 0, 1$. We can define an NV center spin qubit as based either on $m = 0, +1$ levels, or $m = +1, -1$ levels. As in this paper we are most interested in the “asymmetric” coupling of environment with the qubit, we will focus mostly on the former choice of energy levels. Nevertheless, for additional testing of validity of Gaussian approximation to decoherence we will also perform some calculation for qubit bases on $m_z = \pm 1$ levels.

The Hamiltonian of the environment consists of two terms:

$$\hat{H}_E = \hat{H}_Z^{\text{nuc}} + \hat{H}_Z^{\text{dip}}, \quad (26)$$

where the first term describes the Zeeman splitting due to external magnetic field:

$$\hat{H}_Z^{\text{nuc}} = \omega \sum_k \hat{I}_k^z, \quad (27)$$

with $\omega = \gamma_{13C} B_z$ and $\gamma_{13C} = 10.71 \text{ MHz/T}$ being the gyromagnetic ratio for $^{13}\text{C}$, while the second describes the dipolar interactions between the nuclei. For magnetic fields considered here, they can be treated in secular approximation, leading to:

$$\hat{H}_Z^{\text{dip}} \approx \sum_{k<l} B_{k,l} (\hat{I}_k^+ \hat{I}_l^- + \hat{I}_k^- \hat{I}_l^+ - 4 \hat{I}_k^z \hat{I}_l^z), \quad (28)$$

where

$$B_{k,l} = \frac{\mu_0 \gamma_{13C}^2}{4\pi r_{k,l}} (1 - 3 \cos^2 \theta_{k,l}), \quad (29)$$

in which $\mu_0$ is the magnetic permeability of vacuum, $r_{k,l}$ is internuclear distance and $\theta_{k,l}$ is the angle between the $z$ direction of magnetic field and a vector connecting nuclei that interact.

The $\hat{S}^z \hat{V}$ term in Eq. (25) is the hyperfine interaction between the electronic spin $S = 1$ and the nuclear spins. Due to large zero-field splitting $\Delta$ (note that Zeeman splittings $\Omega$ considered here are much smaller than $\Delta$), the transverse terms (i.e. those containing $\hat{S}_{x,y}$ operators) can be omitted, as they have negligible influence on qubit decoherence. We have then the qubit-nuclei coupling of pure dephasing form:

$$\hat{S}_z \hat{V} = \sum_k \sum_{j=x,y,z} \hat{S}_z \hat{A}_k^{j,z} \hat{I}_j^k, \quad (30)$$
We shall consider only the dipolar part of this interaction, because the deep defect nature of the NV center corresponds to its short-ranged electronic wavefunction (Fermi contact corrections are significant at \( d < 0.5 \) nm from the center). The dipolar interaction vector can be expressed as follows:

\[
\hat{A}_{k}^{z,j} = \frac{\mu_0 c \gamma_1 \gamma_j C}{4\pi R_k^3} \left[ -3r_{k}^{j} \hat{r}_{k}^{j} \left( 1 - 3r_{k}^{j} \hat{r}_{k}^{j} \right) \right],
\]

(31)

where \( R_k \) is the distance between NV center and the \( k \)-th nucleus, and \( r_{k}^{j} \) is the \( j \)-th component of normalized displacement vector between the qubit and \( k \)-th nucleus.

### B. Evolution

We assume here that the procedure that creates dynamic nuclear polarization is performed before the considered spin-echo experiment. The qubit and the environment are initially in a product state: \( \hat{\rho}(0) = \{|+\rangle \langle +| \otimes \hat{\rho}_{E} \rangle \rangle \) is the superposition state of the qubit. The initial state of the polarized nuclear environment is

\[
\hat{\rho}_{E}(0) = \left( \prod_{k=1}^{N} \frac{1}{\sqrt{2}} (|1\rangle \langle 1| + 2p_{k} \hat{I}_k^z) \right),
\]

(32)

where \( N \) is the number of nuclei that we take into consideration, i.e. spins located up to a certain distance from the qubit (with the more remote spins giving negligible corrections to the results on the timescale of interest).

Since we are dealing here with a pure dephasing evolution, only the off-diagonal elements of qubit’s reduced density matrix are changing due to interactions with the nuclear environment. We consider the spin echo experiment, in which the \( \pi \) pulse that exchanges the amplitudes of \(|m_1\rangle \) and \(|m_2\rangle \) states is applied to the qubit in the middle of the evolution time. The coherence of the qubit (for convenience normalized, so that its maximum value is 1) can then be written as

\[
W_{m_2,m_1}(t) \equiv \frac{\rho_{m_2,m_1}(t)}{\rho_{m_1,m_2}(0)} = \text{tr}_{E} \left( \hat{U}_{m_2} \hat{U}_{m_1} \hat{\rho}_{E}(0) \hat{U}_{m_2}^{\dagger} \hat{U}_{m_1}^{\dagger} \right),
\]

(33)

where

\[
\hat{U}_{m} = \exp \left( -i \hat{H}_{m} \frac{T}{2} \right),
\]

(34)

and \( \hat{H}_{m} = m \hat{V} + \hat{H}_{E} \).

For calculation of the above spin echo signal we use a Cluster-Correlation Expansion (CCE) method \([21,31–33]\), which allows for systematic inclusion of inter-nuclear interaction effects. The results that we show below are, however, obtained for magnetic fields (\( B \leq 1000 \) Gauss) and timescales (\( t \leq 50 \) \( \mu s \)) at which inter-nuclear dipolar interactions are expected to be irrelevant, as our calculations confirmed. We can then focus on the so-called CCC-1 approximation, in which the decoherence signal is approximated by a product of contributions to dephasing from single nuclear spins. This corresponds to the situation considered in Sec. II B with single nuclei forming the mutually uncorrelated subsystems of the environment. The coherence \( W(t) \) is then given by Eq. (20), with \( W_k(t) \) being the contribution to dephasing due to \( k \)-th nucleus, evaluated using Eq. (33) in which only the terms involving the \( k \)-th nucleus are kept in \( \hat{H}_{m} \), and \( \hat{\rho}_{E}(0) \) is replaced by \( \hat{\rho}_{E}(k)(0) = \frac{1}{2} ( |1\rangle \langle 1| + 2p_{k} \hat{I}_k^z ) \). Such a single-spin contribution can be easily calculated, giving

\[
W^{(k)}_{m_2,m_1}(t) = 1 - \frac{2A_k^2 (m_1 - m_2)^2}{\omega_1^2 \omega_2^2} \sin^2 \left( \frac{\omega_1 t}{2} \right) \sin^2 \left( \frac{\omega_2 t}{2} \right) + \frac{i}{\omega_k} \frac{A_k^2}{\omega_1^2 \omega_2^2} \sin \left( \frac{\omega_1 t}{2} \right) \sin \left( \frac{\omega_2 t}{2} \right) \times \left[ m_1 \omega_2 \cos \left( \frac{\omega_2 t}{2} \right) \sin \left( \frac{\omega_1 t}{2} \right) + m_2 \omega_1 \cos \left( \frac{\omega_1 t}{2} \right) \sin \left( \frac{\omega_2 t}{2} \right) \right],
\]

(35)

where

\[
A_{\perp} = \sqrt{\left( \frac{A_{\perp}^x}{2} \right)^2 + \left( \frac{A_{\perp}^x}{2} \right)^2},
\]

(36)

\[
\omega_i = \sqrt{\left( A_{\perp} \right)^2 \omega_1^2 + \left( m_1 A_{\perp} + \omega \right)^2},
\]

(37)

and \( p_k \) is the degree of polarization of the \( k \)-th nuclear spin, which can take values from \([-1,1]\).

We can see that presence of polarization leads to an appearance of additional term in \( W^{(k)} \) that is purely imaginary. Let us now show how imaginary parts of \( W^{(k)} \) due to single nuclei affect the phase of \( W(t) = \prod_{k=1}^{N} W_k(t) \) when N environmental spins are considered.

### C. Weak coupling and Gaussian approximations

Let us now consider the part of nuclear bath that is weakly coupled to the qubit. For \( \delta W^{(k)} = 1 - W^{(k)}(t) \) and \( W^{(k)}(t) \) given by Eq. (35), the weak coupling condition that makes \( |\delta W^{(k)}(t)| \ll 1 \) is given by

\[
\epsilon \equiv \frac{A_{\perp} \omega}{\omega_1} \ll 1.
\]

When this is fulfilled, then according to discussion in Sec. II B we can approximate the coherence signal by

\[
W(t) \approx \exp \left[ - \sum_k \delta W^{(k)}(t) \right] = \exp \left[ - \sum_k \text{Re} \delta W^{(k)}(t) \right] \exp \left[ -i \sum_k \text{Im} \delta W^{(k)}(t) \right].
\]

(38)

Let us write this result as \( |W(t)| e^{-\phi(t)} \). A specific feature of weak-coupling approximation is that the
polarization-induced phase $\Phi(t)$ is determined only by imaginary parts of $\delta W^{(k)}$, and moreover it is simply linearly proportional to the polarization $p$. At the same time $|W(t)|$ is independent of these parts, and consequently it is independent of $p$. This is not true if we also consider strongly coupled nuclei, for which we have to use the exact formula $W = \prod_k (1 - \delta W_k)$. If we write $W_k = |W_k|e^{-i\phi_k}$ we still have $\Phi = \sum_k \phi_k$, but $\phi_k$ for strongly coupled nuclei is not simply $\approx \text{Im} \delta W_k$ as it is for weak coupling, but it depends on both real and imaginary parts of $\delta W_k$.

When we also assume that $t \ll \frac{2\mu}{\Delta^2}$ we obtain the Gaussian approximation result:

$$
\delta W^{(k)}_G(t) = 2\epsilon^2 \sin^4 \left( \frac{t}{2\omega} \right) + 
- p\epsilon \xi_1 (m_1 - m_2)(m_1 + m_2) \sin^3 \left( \frac{\omega t}{2} \right) \cos \left( \frac{\omega t}{2} \right). \quad (39)
$$

This expression can also be, of course, obtained using Eq. (9) applied to a single-spin environment. In agreement with that formula, “asymmetric” coupling of the qubit to the environment is needed for appearance of the nontrivial phase in the echo signal: the imaginary part of $\delta W^{(k)}_G$ in (39) is exactly zero for $m_1 = -m_2$. It is important to note that this disappearance of imaginary contribution (and consequently the phase $\Phi(t)$ of $W(t)$) holds only at the Gaussian approximation level.

IV. RESULTS FOR ECHO SIGNAL OF AN NV CENTER

We consider diamond with natural concentration of spinful nuclei, i.e. 1.1% of $^{13}$C isotope. Magnetic field is set to $B = 156$ G, a value of the order of magnitude often used in experiments on qubit-based characterization of nuclear environment [34–37]. In such a field, spin echo signal exhibits prominent oscillations caused by precession of nuclear spins [32–38] that occur with a period of $\sim 10$ $\mu$s. We focus on echo delay times of the order of few tens of microseconds. We have checked that including inter-nuclear dipolar interactions does not influence the results on this timescale, and below we show calculations done within CCE-1 approximation, i.e. contributions of uncorrelated nuclei to dephasing. The results converge when we take into account nuclei located up to $R_{\text{conv}} \approx 10$ nm radius from the NV center. Initially, we assume that all the nuclei within this radius are polarized, and have the same polarization.

In Fig. 1 we show exact echo signal $W(t)$, weak-coupling approximation to it, given by Eq. (38) with exact $\delta W^{(k)}(t)$ taken from Eq. (35), and Gaussian approximation, in which we plug $\delta W^{(5)}(t)$ from Eq. (39) to
Eq. (38). Having limited our attention to weakly coupled bath, we see that moduli of coherence for each realization agree fairly well with curves for both of discussed approximations. Slight difference between weak and Gaussian approximation, can be seen, whenever the coherence drops to 0, which can be attributed to difference of amplitude of decoherence factors for both approximations. When we still find a few spins, whose coupling to the qubit is close to Zeeman splitting value, then the amplitude of contribution to Gaussian-approximated decoherence is roughly twice the amplitude of the weak coupling result. Value of the phase of decoherence function, when modulus is close to null, is very high, but after the revival, the exact phase is approaching 0 and the approximations are more accurate. Nevertheless, when one would try to measure the position of the dip of coherence, by measuring $S_\tau$ for the qubit, the phase accumulated due to DNP is definitely non-negligible. However, when the coherence is calculated for a bath in which only weakly coupled nuclei are present (in the simulation, we artificially remove the ball of radius $R_{cut} = 1.0$ nm around the qubit), the approximations hold very well, but still, the Gaussian approximation is slightly less accurate, especially at longer times, than the weak coupling approximation.

In Fig. 2 we focus on the spatial realization of the environment, for which the weak coupling approximation is in good agreement with the exact result for both the modulus and the phase of decoherence function, i.e. realization II. We plot there the echo coherence signal $W_{1-1}$ of a qubit initialized in a superposition on $m_s = \pm 1$ states, i.e. we consider initialization of so-called double transition coherence of the qubit based on $S = 1$ spin, as it was done theoretically in [39] and experimentally in [40]. When the influence of the environment on the qubit can be described in Gaussian approximation, the modulus of this coherence signal should be equal to the 4th power of the $|W_{01}|$ signal observed for initial superposition of $m_s = 0$ and 1 states [21, 39], and there should be no additional phase $\Phi_{1-1}(t)$ present in $W_{1-1}(t)$. We see that these expectation are very well confirmed by results shown in this Figure. Note that both the nonzero difference between $W_{1-1}$ and $|W_{01}|^4$ and the nonzero value of $\Phi_{1-1}(t)$ are signatures of non-Gaussian character of the environment, and both are absent in Gaussian approximation. Let us stress that the latter is a more convenient witness of non-Gaussianity: it requires measurement of only one coherence, not comparison of two coherences, and it requires only an observation of a non-zero phase shift.

In Fig. 3 we show the influence of magnitude of nuclear polarization $p$ on the spin echo results for the same realization as in Fig. 2. When we consider coupling to all the nuclei in this spatial realization of the environment (panel(a)), modulus of coherence shows slight dependence on the polarization degree. When modulus is dropping to zero, there is a non-trivial distinction between results for $\Phi(t)$ corresponding to different polarizations. The accumulated phase, of course, increases with the polarization degree. This behavior is observed for each total evolution time in Gaussian approximation, which is presented in panel b of the Figure. In this approximation, the modulus of coherence shows no fluctuations with respect to the level of DNP for the whole bath. Consequently, observation of any dependence of $|W_{01}|$ on polarization is another witness of non-Gaussian contributions to qubit’s decoherence.

Finally, in Fig. 4 we show how a more experimentally realistic spatial profile of dynamic nuclear polarization affects phase $\Phi(t)$. Specifically, we consider all the nuclei within a radius $R_{pol}$ from the center having finite $p$, and all the nuclei outside of the ball of this radius unpolarized. We focus on the case of spatial arrangement of environmental spins that leads to decoherence well-described in Gaussian approximation (the results in the presence of strongly coupled nuclei would mostly show how changing the polarization of one of the strongly coupled spins visibly affects the signal). In fact, for the considered realization (II), we do not observe any fluctuations of coherence modulus, which already tells us that the polarized nuclei are not coupled strongly enough, to affect the curvature of the function. Phase changes are observed when we polarize nuclei between 1.5 nm and 2.0 nm. Polarizing more environmental spins does not change the value of the phase. Note that in all of presented results we can observe that the Gaussian approximation is less accurate for longer coherence times, as the assumption of $t \ll \frac{2\omega}{A_\perp}$ no longer holds then.
Let us first point out the main experimental implication of our calculations for measurements of spin echo signal of such a qubit, one typically measures one component of qubit’s Bloch vector, say $\langle \hat{\sigma}_x(t) \rangle$. If the nuclear environment is in a completely mixed state (which is the case if the nuclei had not been subjected to a procedure leading to their nonzero dynamic nuclear polarization), the measured signal is simply given by $\exp[-\chi(t)]$. Note that for simplicity we assume here that the Gaussian approximation holds. One could also define for the time being $\chi(t) \equiv \ln W(t)$ with the decoherence function $W(t)$ given by Eq. (5) and not focus on the environmental influence being of Gaussian or non-Gaussian character - as we have shown here, the coherence signal is purely real if the state of the nuclei is completely mixed, even if the Gaussian approximation fails quantitatively.

However, in the presence of finite DNP, the measured signal is rather given by

$$\langle \hat{\sigma}_x(t) \rangle = e^{-\chi(t)} \cos \Phi(t) . \quad (40)$$

Consequently, the phase $\Phi(t)$ modifies the echo signal: in presence of DNP, the qubit initialized along the $x$ axis will rephase at echo time along a different direction, e.g. along the $y$ axis if $\Phi(t) = \pi/2$. Furthermore, the time-dependence of $\Phi(t)$ is not simply a linear one: the dynamics of the polarized environment evolving in the presence of the qubit is imprinted on qubit’s echoed state in a nontrivial manner. The possibility of such effects when measuring spin echo of a qubit interacting with intentionally (or non-intentionally) polarized nuclei has to be recognized before the experiment is designed, and it has to be taken into account when analyzing the measurements. It is also worth noting that while $\chi(t)$ is rather weakly dependent on nuclear polarization $p$ (with no dependence at all in the Gaussian limit), $\Phi(t)$ depends linearly on $p$, and consequently its measurement could be used for quantifying the polarization of nuclear
spins in the vicinity of the NV center. The fact that $\Phi$ is determined mostly by the spins closest to the qubit, as shown in Fig. 3, underlines the fact that the qubit acts as a local probe, sensitive most strongly to its immediate vicinity, i.e. nuclei that are up to a few nanometers away from it (assuming natural concentration of $^{13}$C nuclei, for smaller concentration the coherence times would be longer, and also the size of the part of environment that has visible impact on evolution of qubit’s coherence would be larger).

The above qualitative difference - zero or nonzero $\Phi(t)$ - between dephasing due to completely mixed and dynamically polarized bath, held exactly, without making any approximation to the calculation of environmental influence on the qubit (apart from making a very well-controlled at considered magnetic fields and timescales approximation of treating nuclear spins as noninteracting). We have however discussed in context of an analytical result from [8], recounted in Section II A, according to which for an environment that can be treated in Gaussian approximation, the nonzero phase $\Phi(t)$ appears in dynamical decoupling signal only for the “biased” coupling, e.g. for NV center qubit based on $m = 0, 1$ levels, and it is zero for the “ unbiased” coupling, e.g. for NV center qubit based on $m = \pm 1$ levels. For the nuclear spin environment discussed here this holds even without making the Gaussian approximation, but it is interesting to ask a question, to what extent the Gaussian approximation to $\Phi(t)$ account for the exact phase that appears for NV center subjected to spin echo. We have focused here on NV centers that do not have nuclear spins in their immediate vicinity, specifically within a radius of 0.5 nm from the qubit. For natural concentration of $^{13}$C nuclei, about 50% of NV centers fulfill this condition. The ones that do have such very strongly coupled nearest neighbors, are more suited to be used as optically active parts of a multi-qubit register consisting NV center, nuclear spin of nitrogen, and nuclear spins of the most strongly coupled $^{13}$C. Since here our focus is not on physics of a “microscopic” system of a few spins, but on qubit decoherence caused by a “mesoscopic bath”, i.e. a system that is treated as finite, but is too large to be considered to be precisely controllable, we have focused on environments with most strongly coupled spins removed.

However, even after such a rejection of environments containing a few entities very strongly coupled to the qubit, the presence of which leads to strongly non-Gaussian decoherence, a careful analysis of real and imaginary part of decoherence functions $W_0(t)$ and $W_{-1}(t)$ allows for checking to what extent the decoherence is Gaussian. As mentioned above, the polarization-dependence of $|W_{01}|$ is a sign of non-Gaussian character of environmental influence. In our calculations, this effect is not particularly strong due to exclusion of environments with most strongly coupled spins, for which this effect would be much more visible. Nevertheless, when the qubit is initialized between $m = \pm 1$ energy levels, the non-Gaussian signatures are of qualitative character. As it can be seen from Eq. (39), in this case, for Gaussian environment $\Phi(t)=0$. In other words, presence of phase in spin echo for such an “unbiased” coupling of the qubit proves the non-Gaussian character of the environment.

Finally, let us stress the relevance of observation of nonzero phase $\Phi(t)$ in echo signal for the question of classical vs quantum nature of the environmental influence. The presence of nonzero $\Phi(t)$ in a spin echo (or other balanced dynamical decoupling sequence) signal signifies that it is in general incorrect to replace the environmental influence by an external classical stochastic process $\xi(t)$ coupling to qubit’s $1 + \hat{\sigma}_z$. It is possible that such a replacement is possible in certain circumstances, i.e. when the coupling is unbiased (i.e. the “classical vs quantum” nature of environmental noise is relative to the form of the qubit-environment coupling), but we leave a careful examination of this issue for further work. Let us also note that another witness of nonclassical character of environmental influence was recently described in [44], and its effectiveness for NV center qubit interacting with partially polarized nuclear environment was investigated.

ACKNOWLEDGEMENTS

We thank Fattah Sakuldee and Jan Krzywda for discussions. This work is supported by funds of Polish National Science Center (NCN), Grant no. 2015/19/B/ST3/03152.

Appendix A: Dynamical decoupling control sequence

The density matrix of the composite qubit+environment system at time $t$ is given by

$$\rho_{QE}(t) = \hat{U}(t)\rho_{Q}(0)\hat{U}^\dagger(0),$$

(A1)

where the unitary evolution operator is given by standard time-order exponential,

$$\hat{U}(t) = T e^{-i \int_0^t d\tau (\hat{H}_Q + \hat{H}_E + \hat{H}_{\text{int}} + \hat{H}_{\text{ctr}}(\tau))}$$

(A2)

with the total Hamiltonian of $Q + E$, system composed of free environment Hamiltonian $\hat{H}_E$, free qubit Hamiltonian $\hat{H}_Q \propto \hat{\sigma}_z$, the interaction $H_{\text{int}} = (\eta + \hat{\sigma}_z)\hat{V}/2$, and the time dependent control Hamiltonian $\hat{H}_{\text{ctr}}$ that is responsible for the application $\pi$ pulses in a sequence defined by the set of timings pulse timings $\{\tau_0 = 0, \tau_1, \tau_2, \ldots, \tau_n = t\}$ ($\tau_0 < \tau_1 < \ldots < \tau_n$). Assuming that the pulses are perfectly accrued and effectively instantaneous we can approximate the action of the evolution operator as

$$\hat{U}(t) \approx \hat{U}_{\text{ctr}}\hat{U}_0(t, \tau_n-1)\ldots\hat{U}_{\text{ctr}}\hat{U}_0(\tau_2, \tau_1)\hat{U}_{\text{ctr}}\hat{U}_0(\tau_1, 0)$$
\[ (-i)^n \hat{\sigma}_z \hat{U}_0(t, \tau_{n-1}) \ldots \hat{\sigma}_z \hat{U}_0(\tau_2, \tau_1) \hat{\sigma}_z \hat{U}_0(\tau_1, 0) \]  
\[ \text{(A3)} \]

where \( \hat{U}_{\text{ctr}} = \exp(i(\pi/2)\hat{\sigma}_y/2) = -i\hat{\sigma}_y \), and \( \hat{U}_0(t, t_f) = \exp\{-i(\tau_f - \tau_0)[\hat{H}_E + \hat{H}_Q + \hat{H}_{\text{int}}]\} \).

For any function \( F \) of Pauli \( z \) operator \( \hat{\sigma}_z \) we have the following relation

\[ \hat{\sigma}_z F(\hat{\sigma}_z) \hat{\sigma}_z = F(-\hat{\sigma}_z) \quad \text{(A4)} \]

from which we get that

\[ \hat{U}(t) = e^{-i(t-\tau_{n-1})(-\hat{H}_Q + \hat{H}_E + \frac{1}{2}(\eta - \hat{\sigma}_z)\hat{V})} \ldots \times e^{-i(\tau_2 - \tau_1)(-\hat{H}_Q + \hat{H}_E + \frac{1}{2}(\eta - \hat{\sigma}_z)\hat{V})_E - i\tau_1(\hat{H}_Q + \hat{H}_E + \frac{1}{2}(\eta + \hat{\sigma}_z)\hat{V})} \]

\[ = \exp \left[ -i \int_0^t d\tau \left( \hat{H}_E + f(\tau) \hat{H}_S + \frac{1}{2}(\eta + f(\tau)\hat{\sigma}_z)\hat{V} \right) \right] \quad \text{(A5)} \]

where we encounter the time-domain filter function \( f(\tau) \) given by

\[ f(\tau) = \sum_{k=0}^{n-1} (-1)^k \Theta(\tau_{k+1} - \tau) \Theta(\tau - \tau_k) \quad \text{(A6)} \]

We assume that the dynamical decoupling sequence is balanced, i.e. \( \int_0^t d\tau f(\tau) = 0 \), so that its application removes from coherence signal the trivial phase due to static energy splitting of the qubit.

After switching to interaction picture, in which

\[ \hat{V}(\tau) = \exp(i\tau \hat{H}_E) \hat{V} \exp(-i\tau \hat{H}_E) \]

we arrive at the final result:

\[ \hat{U}(t) = e^{-it\hat{H}_E} T e^{-i \int_0^t d\tau \frac{1}{2}(\eta + f(\tau)\hat{\sigma}_z)\hat{V}(\tau)} \quad \text{(A7)} \]
