(Dated: September 17, 2019)

We consider the angular momentum of a charge \( q \) rotating in a homogeneous magnetic field and study the role of the electromagnetic quantum vacuum. Its orbital angular momentum is caused by the recoil of energetic vacuum photons that grows as \( n^2 \), i.e. faster than the kinetic angular momentum \(-2n\hbar \) of a Landau level.

Keywords: Casimir effect and related phenomena, quantum electrodynamics

I. INTRODUCTION

The radiation of the electromagnetic (EM) quantum vacuum is perfectly isotropic and possesses an energy density \( \hbar \omega d\omega/\pi^2 c^3 \) in the frequency interval \( d\omega \). This statement is Lorentz-invariant [1]. The mystery of its UV-divergence is still one of the major challenges in physics, but poses in general no problems to calculate the Casimir force between dielectric or metallic objects [2]. Due to its perfect isotropy, energy current and momentum density of the quantum vacuum vanish.

This is no longer true when the vacuum interacts with matter. In a pioneering work [3] Feigel predicted "Casimir" momentum in bi-anisotropic materials. Although the Poynting vector of the quantum vacuum still vanishes [3], a momentum density emerges from a divergence at high energies. Relativistic photons were already known to be relevant for the Lamb shift [1], in contrast to Casimir-Polder forces [2], caused by low-energy vacuum photons. In a microscopic bi-anisotropic quantum model, the divergency of EM momentum is removed by mass renormalization [3], resulting in a Casimir momentum of the order of \( \alpha^2 \) times the classical Abrahams momentum [3]. It was also demonstrated for a chiral quantum particle in a magnetic field [3, 4].

EM angular momentum is of great recent interest [10] and in macroscopic media even controversial [11], since matter and radiation are hard to disentangle. In Ref. [12] Casimir-Polder torques were discussed to stir vortices in superfluids. How does "Casimir" angular momentum emerge on a microscopic scale? The simplest model for which this question can be answered is the well-known cyclotron problem of a non-relativistic charge \( q \) without spin rotating in a uniform magnetic field \( B_0 \), in quantum-mechanics better known as the Landau problem. In the Coulomb gauge and in Gaussian units, the vector potential reads,

\[
H = \frac{1}{2\mu} \left( \mathbf{p} - \frac{q}{c_0} \mathbf{A}_0(t) - \frac{q}{c_0} \mathbf{A}(r) \right)^2 + \sum_{k\Pi} \hbar \omega_{\mu\Pi} a_{k\Pi}^\dagger a_{k\Pi} \label{eq:hamiltonian}
\]

Here, \( \mathbf{p} \) the canonical momentum satisfying \( [r_i, p_j] = i\hbar \delta_{ij} \). It is customary to choose the \( z \)-axis along the direction of \( qB_0 \) and to introduce the cyclotron frequency \( \omega_c = qB_0/\mu c \). It is convenient to express the vector potential of the quantum vacuum in terms of the spherical vector harmonics \( \Phi_{\Pi}(\hat{k}) \) defined on the unit sphere in reciprocal space [13],

\[
\mathbf{A}(r) = \sqrt{\frac{2\pi\hbar c_0}{k^3}} \sum_{k\Pi} \frac{1}{k^{3/2}} \left( a_{k\Pi} \exp(-i r \cdot \hat{k}) \Phi_{\Pi}(\hat{k}) + a_{k\Pi}^\dagger \exp(i r \cdot \hat{k}) \Phi_{\Pi}(\hat{k}) \right) \tag{2}
\]

The continuum limit has been taken, \( \sum_{k} = \int d^3k/(2\pi)^3 \) and \( [a_{k\Pi}, a_{k'\Pi}^\dagger] = \delta_{k k'} \delta_{\Pi \Pi'} \). The vector index \( \Pi = \{J, M, p\} \) summarizes the 3 discrete quantum numbers of total EM angular momentum \( J \), its \( z \)-component \( M \) and two transverse polarizations \( p \), the longitudinal vector harmonic being excluded by the Coulomb gauge. Without the quantum vacuum, the kinetic momentum of the charge is \( \mathbf{p}^K = \mu d\mathbf{r}/dt = [\mu H_0, \mathbf{r}]/i\hbar = \mathbf{p} - q\mathbf{A}_0(t)/c_0 \). The canonical angular momentum \( l_z = (\mathbf{r} \times \mathbf{p})_z \) commutes with \( H_0 \) and has eigenvalues \( \langle m \rangle = m\hbar \). The Hamiltonian \( H_0 \) has the eigenstates \( | n, m, k_z \rangle \) of a 2D harmonic oscillator whose energy levels \( E_n = (n + \frac{1}{2})\hbar \omega_c + \frac{\hbar^2 k_z^2}{2\mu} \) are independent of \( m \) due to gauge invariance [14].

In general, total angular momentum \( L_z \) is conserved, equal to the sum of the canonical angular momentum \( l_z \) of the charge and the angular momentum of the transverse EM field \( J_z \). The angular kinetic momentum operator of the charge is not conserved and can be written as,

\[
l_z^K = L_z - J_z - \frac{q}{c_0} (\mathbf{r} \times \mathbf{A})_z \equiv l_z \tag{3}
\]

The "Lenz" term \( l_z^L = \mu \omega \mathbf{c}^2/2 \) is responsible for the electromotive force in classical electrodynamics, recently discussed quantum-mechanically [15] as well as key element in the EM momentum controversy [16]. Without the quantum vacuum, the kinetic angular momentum of a Landau state is given by \( \langle n, m|l_z^K|n, m\rangle = -(2n+1)\hbar \omega_c = -2E_n/(\omega_c) \), again independent on \( m \). When the quantum vacuum is included, \( \langle l_z^K \rangle \) will decay radiatively, but slow enough for \( \langle l_z^K \rangle \) to be well-defined and modified.

We will use time-dependent perturbation theory to calculate the different contributions of the quantum vac-
uum to \( l_z^K \) for an excited Landau state, and all proportional to \( q B_0(t) \) for slow adiabatic changes. We identify the interaction \( W = -(q/\mu c_0) p^K \cdot A(r) \) between rotating charge and quantum vacuum, and imagine to switch it on slowly like \( W(t) = W \exp(\epsilon t/\hbar) \) at \( t_0 \to -\infty \), when the total wave function is assumed to be in the pure state \( |N\rangle = |n,m,k_z = 0\rangle \otimes |0\rangle \) \[17\]. In this process \( \mathcal{L} \) is conserved and equal to its initial value \( \langle |m\rangle - n \rangle \hbar \). The index \( N' \) refers to all possible product states \( \{n,m,k_z \otimes \{n_{\mathcal{P}}\} \} \) of charge plus transverse photons. Explicit reference will be made to the highly degenerated levels \( n \), neither to the momentum \( k_z \) of the charge along the magnetic field. The degeneration of the \( m \)-levels is protected by gauge invariance, and the impact of photon recoil on the longitudinal displacement is negligible. Since \( W_{NN} = 0 \), the wave function at \( t \geq t_0 \) is perturbed as,

\[ \Psi_N(t) = \exp \left( -\frac{i}{\hbar} \int_{t_0}^{t} dt' [E_N + \Delta E_N(t')] \right) |N\rangle + \sum_{N'} |N'\rangle W_{NN'}(t) / E_N - E_{N'} + i\epsilon + \cdots \]

with \( \Delta E_N(t) = \sum_{N} W_{N,N'}(t) W_{N',N}(t) / (E_N - E_{N'} + i\epsilon) \) the second-order perturbation of the energy level \( E_N \), the sum \( \sum_{N} \) avoiding the initial level \( N \) \[13\]. For an excited state, \( \int_{t_0}^{t} dt' \Delta E_N(t') = \int_{t_0}^{t} dt' (E_{N'} + \hbar A / 2i) - (1/2) i\hbar N_n \) with \( N_n \) a time-independent normalization of the wave function. Lamb shift and spontaneous emission rate are

\[ E_L = \hbar \omega_c \frac{2\alpha}{3\pi} x \log \frac{2}{x}, \quad A_n = n \omega_c \frac{4\alpha}{3} \]

with \( x = \hbar \omega_c / \mu c_0^2 \) and \( \alpha = q^2 / \hbar c_0 \) the fine structure constant; \( E_L \) is equal for all Landau levels whereas radiative decay is proportional to rotational energy.

In reciprocal space, the transverse EM momentum \( J_z \) in Eq. \[3\] is expressed as \( (J_z)_{ij}(k) = -i \hbar \delta_{ij} / (\hbar k \times \nabla_k)_{ij} \) as a sum of orbital angular momentum and spin \[13\]. Neither one of them behaves as a genuine angular momentum \[19\] but this separation is physically useful. In Hilbert space \( J_z \) reads,

\[ J_z = \hbar \sum_{k} \alpha_i^k |j(k) \rangle \langle j(k) | \alpha_j(k) \]

with the photon annihilation operator \( \alpha_i^k(k) = k^{-1} \sum_{\mathcal{P}} \alpha_i^k \Phi_i^N(k) \), and its associated creation operator \( \alpha_j^k(k) \). The quantum expectation of \( J_z \) is obtained by inserting the linearly perturbed eigenfunction \[14\] on both sides of the matrix element \( \langle \Psi_N(t) | J_z | \Psi_N(t') \rangle \). This creates either a virtual or real photon with energy \( \hbar \omega_c \) and angular momentum \( \mathcal{P}^N \) out of the quantum vacuum at the cost of canonical angular momentum.

Working out the photon operators, we leave us with

\[ \langle J_z \rangle = \frac{2\pi \hbar q^2}{\mu c_0^2} \sum_{k} \frac{1}{k^{2}} \sum_{\mathcal{P} \mathcal{K}} \left( \delta_{\mathcal{K} \mathcal{K}} / (k')^{3/2} / (k^{3/2}) \right) \]

\[ \times \langle n | p^K \cdot \Phi_i^N(k) \rangle e^{i k r} \bar{E}_n - H_0 / \hbar \omega_c - i \epsilon / \hbar \omega_c \]

\[ \times \Phi_i^N(k) J_{ij} (k) \Phi_{ij}^N(k) \]

\[ \times \bar{E}_n / H_0 - \hbar \omega_c + i \epsilon / \hbar \omega_c \]

\[ \langle n | p^K / \Phi_i^N | n \rangle \]

From this expression the EM spin of the quantum vacuum can be identified as,

\[ \langle S_z \rangle = \frac{1}{3} \sum_{k} \frac{1}{k} \langle n | p^K / \Phi_i^N | \bar{E}_n - H_0 / -E(k) / + i \epsilon / \hbar \omega_c \rangle \times \]

\[ \times \]

\[ \frac{1}{\hbar} \epsilon_{zij} \times \frac{1}{\hbar} \epsilon_{zij} \times \]

\[ \frac{1}{\hbar} \epsilon_{zij} \times \frac{1}{\hbar} \epsilon_{zij} \times \]

\[ \frac{1}{\hbar} \epsilon_{zij} \times \frac{1}{\hbar} \epsilon_{zij} \]

We have performed the angular integral over \( k \) to eliminate \( \Delta(k) \), neglected the photon recoil \( p^K / \hbar k / \mu \) irrelevant for spin, and defined the energy \( E(k) = \hbar \omega_c + h^2 k^2 / 2m \). The orbital angular momentum is associated with a differential operator acting on \( \delta_{\mathcal{K} \mathcal{K}} \), and an integration by parts is imposed to perform the integral over \( k' \). Since this operator acts only on angles, we find for the orbital angular momentum,

\[ \langle L_z \rangle = 2\pi \hbar q^2 / \mu c_0 \sum_{k} \langle n | p^K / \bar{E}_n - H_0 / -E(k) / + i \epsilon / \hbar \omega_c \rangle \]

\[ \times \]

\[ \times \]

\[ \times \]

As \( k_z = 0 \) the kinetic operator \( p^K \) is located in the \( xy \) plane. It is customary to write \( p^K / + (-) p^K = (2 \mu \hbar \omega_c)^{1/2} c (t) \) in terms of the raising and lowering operators of the Landau levels, in terms of which \( H_0 = \hbar \omega_c (c^2 + 1/4) \). To evaluate the spin in Eq. \[6\] we use \( \epsilon_{zij} p_{ij} f (H_0) p^K = -i \mu \hbar \omega_c (c^2 f(E_{n-1}) c - c f(E_{n+1}) c) \).
The first term implies the release of a real photon with energy \( h \omega_c \). As \( \epsilon \downarrow 0 \), this part of \( \langle S_z \rangle \) is written as \( (h/2) \int_0^t dt' \exp(2i \epsilon t'/h) \delta(h \omega_c - h \omega_k) \), so that

\[
\frac{d}{dt} \langle S_z \rangle = -\frac{1}{2} A_n h
\]

with \( A_n \) defined in Eq. 1. The second term involves virtual photons and is finite as \( \epsilon \downarrow 0 \),

\[
\langle S_z \rangle = \langle n + 1 \rangle \frac{\alpha^2}{3 \mu c_0} \int_0^\infty \frac{kdk}{(h \omega_c + E(k))^2}\]

\[
= \alpha \frac{h}{3\pi} \langle n + 1 \rangle x \log \frac{2}{x}
\]

In expression 7 for \( \langle L_z \rangle \) the derivative \( \nabla_k \) acts on 3 factors inside brackets. Its action on the factor in the middle, caused by the photon recoil, is a factor \( x \) smaller than the rest. The action on the first factor gives \( \epsilon_{zst} \nabla_s \Delta \langle m \rangle \Delta \mu = -k^{-1} \epsilon_{zst} \nabla_k \Delta \mu \) and produces an angular momentum \( \langle L_z(3) \rangle = \langle S_z \rangle \). Finally, the action of \( \nabla_k \) on \( \exp(\mathbf{k} \cdot \mathbf{r}) \) leads to the expression

\[
\langle L_z(3) \rangle = \frac{2 \pi h^2 \alpha^2 t/\mu^2 c_0}{x} \times \]

\[
\sum_k \langle n | p^K_m \Delta \langle m \rangle (\mathbf{k}) | 1/n \rangle \frac{1}{H_n - i \epsilon} \langle \mathbf{r} \times \mathbf{k} \rangle : \frac{1}{H_{n+1} + i \epsilon} p^K|n\rangle
\]

where \( H_n = E_n - H_0 - E(k) + h |p^K \rangle \cdot \mathbf{k}/\mu \). This time, the photon recoil cannot be ignored and we must expand either one of the denominators which produces an integral \( dk/dk \) with integrand of the type

\[
\epsilon_{zst} \nabla_s \Delta \langle m \rangle \epsilon_{tst} \nabla_t \Delta \mu \rangle = -k^{-1} \epsilon_{zst} \nabla_k \Delta \mu \]
In particular, $n^2$ terms also cancel and

$$\langle \delta l^T \rangle = 2\langle S_z \rangle; \quad \frac{d}{dt} \langle \delta l^T \rangle = -\hbar A_n$$

By adding up the four contributions $\langle S_z \rangle$, $\langle J_z \rangle$, $\langle J_\parallel \rangle$ and $\langle \delta l^T \rangle$ we find for the total angular momentum of the quantum vacuum

$$\langle J_z^{QV} \rangle = \hbar \frac{4\alpha}{3\pi} (n + 2) x \log \frac{2}{x} - \hbar \frac{4\alpha}{15\pi} (n + 1)(n + 4)x$$

(13)

and $d\langle J_z^{QV} \rangle/dt = -2\hbar A_n$. We conclude that the quantum vacuum achieves an angular momentum that is, in units of $\hbar$, proportional to $\alpha \times x = \alpha \times \hbar \omega_e / \mu c_0^2 \approx 10^{-12}/\text{Tesla}$, which is time-dependent if $B_0$ is. In all momentum integrals the photon momentum $\hbar k$ takes values up to $\mu c$ yet is significant weight of non-relativistic momenta. A relativistic description of the rotating electron is thus relevant but should affect only numerical coefficients in Eq. [13].

Even in a relativistic picture, Eq. [3] for the kinetic angular momentum is valid, and $\langle J_z^K \rangle$ remains quantized to $-(2n + 1)\hbar$ [23]. In the ground state, the existence of Casimir angular momentum makes the kinetic angular momentum slightly more negative than $-\hbar$, in states with large $n$ it will be slightly less negative than $-(2n + 1)\hbar$, the correction growing like $n^2$. Note that the gauge-invariant magnetic moment $M_z = (q/2\mu)l^K$ of the rotating charge is subject to the same correction. Due to the quantum vacuum, the kinetic angular $-(2n + 1)\hbar$ decays to the Landau level $n - 1$ with rate $A_n$ so that $d\langle l^K \rangle/dt = +2\hbar A_n$ and $\langle l^K_z \rangle = \delta \frac{J_z^{QV}}{\hbar} \text{ is conserved in the decay.}$

The non-relativistic analysis imposes that $E_n \ll \mu c_0^2$, implying, for an electron in a field of 10 Tesla, that $n \ll 10^9$. Pushing our theory to the extreme synchrotron regime, the relativistic contribution of Casimir orbital angular momentum would be of order $10^{-4}$.

II. CONCLUSIONS

The main objective of this work is to establish the existence of angular momentum of the EM quantum vacuum, induced by the presence of a rotating charge in a magnetic field. It is instructive to look at the separate contributions of spin, orbital angular momentum and angular momentum directly associated with the gauge fields. All are oriented along the magnetic field and proportional to the product of fine structure constant and the small ratio of rotational energy to rest energy. Spin and orbital angular momentum decay in the same way, their coupling being large, yet the orbital angular momentum of the quantum vacuum, induced by photon recoil, dominates angular momentum for highly energetic Landau levels. Casimir angular momentum is governed by virtual photons with energies up to the rest mass of the charge and, despite the UV renormalizability of the theory, would merit a relativistic treatment. A future challenge would be to study EM angular momentum in the fully relativistic synchrotron problem, or to investigate it for Rydberg orbits.

[18] We ignored the perturbation $\langle \delta \Psi_N \rangle = \sum_{N'N''} \langle N' \rangle W_{N'N''} W_{N''N}/((E_{N''} + 2\epsilon)(E_{N''} + \epsilon))$. For one-photon processes, the matrix element $\langle n, \{0\}_{l^K} \delta \Psi_{n(a)} \rangle$ vanishes.

[20] The eigenfunctions are the same for the relativistic Hamiltonian without spin, and thus the Lenz momentum $\langle l^K \rangle$ remains unaltered, that in turn determines $\langle l^K_z \rangle$ [15].
