(Dated: April 22, 2020)

We propose the effective simulation of light-matter ultrastrong-coupling phenomena with strong-coupling systems. Recent theory and experiments have shown that the quantum Rabi Hamiltonian can be simulated by a Jaynes–Cummings system with the addition of two classical drives. This allows to implement nonlinear processes that do not conserve the total number of excitations. However, parity is still a conserved quantity in the quantum Rabi Hamiltonian, which forbids a wide family of processes involving virtual transitions that break this conservation. Here, we show that these parity-non-conserving processes can be simulated, and that this can be done in an even simpler setup: a Jaynes-Cummings type system with the addition of a single classical drive. By shifting the paradigm from simulating a particular model to simulating a particular process, we are able to implement a much wider family of nonlinear coherent protocols than in previous simulation approaches, doing so with fewer resources and constraints. We focus our analysis on three particular examples: a single atom exciting two photons, frequency conversion, and a single photon exciting two atoms.

Introduction.—The ultrastrong coupling (USC) of light and matter is attracting increasing interest beyond the fields of cavity [1] and circuit [2, 3] quantum electrodynamics (QED) [4, 5]. This interest has been stimulated in the last decade by several experiments finally reaching USC in a variety of physical systems [4, 5]. The USC of light and matter (e.g., a cavity mode and a natural or artificial atom) occurs when their coupling strength $g$ becomes comparable to the atomic ($\omega_\sigma$) or cavity ($\omega_c$) frequencies. More precisely, according to the usual convention, the USC regime occurs when $\eta = \max(g/\omega_\sigma, g/\omega_c)$ is in the range [0.1, 1]. The regime $\eta \geq 1$ is often referred to as deep strong coupling (DSC) [6].

Compared to strong coupling (SC; $\eta < 0.1$, but $g$ larger than the loss rates in the system), USC opens new perspectives for efficiently simulating known effects and observing fundamentally new phenomena in quantum nonlinear optics [7–17], quantum field theory, supersymmetric (SUSY) field theories [18], cavity optomechanics [19–26], quantum plasmonics [21, 27–29], light-induced superconductivity [30, 31], quantum thermodynamics [32], photochemistry (chemistry QED) [33–36], as well as metamaterial and material sciences. Ultrastrong coupling also has applications in quantum metrology and spectroscopy [37], and quantum information processing [13, 38–43].

The basic model for USC of a single two-level atom to a single-mode cavity is the quantum Rabi model [44, 45] (QRM). Its multi-atom or multi-mode generalizations include the Dicke [46] and Hopfield [47] models. When $\eta < 0.1$, these models for USC can be reduced to the simpler Jaynes–Cummings model [48] (JCM) and its multi-mode or multi-atom generalizations (e.g. the Tavis–Cummings model [49]). Since SC is typically easier to realize in experiment than USC, the question arises whether the predicted USC phenomena can be observed or at least simulated also in the SC regime, e.g., by adding classical drives applied to atom(s) or cavity mode(s) in the SC models. We note that simulating the QRM could also enable simulating other closely related fundamental quantum models, which include the spin–boson [50, 51] and Kondo [50, 52, 53] renormalization-group models, the Rashba-Dresselhaus model [18], and the Jahn–Teller model [54–58] among others. Even vacuum-induced symmetry breaking [59], which is analogous to the Higgs mechanism, has been predicted in the USC regime. Quantum simulations of the atom-cavity dynamics in the USC and DSC regime in the Rabi and Dicke models have recently attracted much theoretical [60–72] and experimental [73–76] interest. The methods described in Refs. [61, 63] and implemented in
circuit-QED [74] and trapped-ion experiments [76] simulate the QRM in the USC regime with a light-matter system described by the JCM in the SC regime. These quantum simulations require two drives to be applied to a system with a single atom and a single-mode resonator.

In this Letter, we propose to shift the paradigm from simulating the full QRM to simulating particular processes characteristic of the USC regime, e.g., violating the conservation of number of particles. This approach allows to employ fewer resources and to go beyond the standard QRM and implement hallmark USC processes that are forbidden due to parity conservation [8, 10–13]. We illustrate this approach by analysing three different phenomena that require breaking parity conservation: a single two-level atom emitting two photons [8], frequency conversion of two photonic modes coupled to a two-level atom [12], and a single photon exciting two atoms [10]. We also give a protocol for an experimental implementation and show its feasibility in several, well-developed experimental systems.

**Hamiltonians for light-matter coupling.**—The QRM describes the interaction between a two-level atom (qubit) of frequency $\omega_a$ and a cavity mode of frequency $\omega_c$ by the Hamiltonian ($\hbar = 1$)

$$H_R = H_0 + \sigma_x X = H_0 + g(\sigma^+ |a + a^\dagger\rangle), \quad (1)$$

where $H_0 = (\omega_a/2)\sigma_z + \omega_c a^\dagger a$ is the free Hamiltonian, $a^\dagger$ is the annihilation (creation) operator of the cavity mode, $X = a + a^\dagger$ is the canonical position operator, $\sigma_x = \sigma^+ - \sigma^- = |a + a^\dagger\rangle - \langle a + a^\dagger|$, and $\sigma_z$ are Pauli operators, $\sigma^\dagger$ is the atomic lowering (raising) operator, and $g$ is the atom-field coupling constant. Under the rotating-wave approximation (RWA), which is valid if $\{\omega_c, \omega_a\} \gg \{g, |\omega_c - \omega_a|\}$, the counter-rotating terms, $\sigma^\dagger a^\dagger$ and $\sigma a$, in Eq. (1) can be ignored. This leads to the standard JCM described by the Hamiltonian $H_{JC} = H_0 + g(\sigma^\dagger a^\dagger + \sigma a^\dagger a)$.

The transition energy of the effective qubit is now given by the Hamiltonian

$$H = \Delta_1 a_1^\dagger a_1 + \Delta_2 a_2^\dagger a_2 + \Delta_\sigma \sigma^\dagger \sigma + \Omega(\sigma + \sigma^\dagger) + g(\sigma^\dagger a_1^\dagger + a_2^\dagger a_2^\dagger + \text{h.c.}). \quad (2)$$

with $\Delta_1, \Delta_2, \Delta_\sigma$ and $\Omega$ the frequency detunings between the cavities or qubit and the driving field $\Delta_\sigma = \omega_x - \omega_h$, $\Omega$ is the amplitude of the driving field, and $g$ is the coupling rate between the cavities and the qubit (considered to be equal for simplicity).

The part of Eq. (2) that only depends on $\sigma$ can be easily diagonalized. Denoting the ground and excited eigenstates of the driven qubit $|g\rangle$ and $|e\rangle$, respectively, the new eigenstates of the driving field correspond to a rotated spin basis i.e.,

$$|+\rangle = \cos \theta |g\rangle + \sin \theta |e\rangle = e^{i \sqrt{\xi} \sigma_2} |g\rangle, \quad (3)$$

$$|-\rangle = \sin \theta |g\rangle - \cos \theta |e\rangle = e^{-i \sqrt{\xi} \sigma_2} |e\rangle \quad (4)$$

with $\cos \theta \equiv 1/\sqrt{1 + \xi^2}, \sin \theta \equiv 1/\sqrt{1 + \xi^2}, \xi \in [0, \pi/2]$, and $\Omega \equiv \Omega/(\Delta_\sigma/2 + R)$, where $R$ is the Rabi frequency given by $R \equiv \sqrt{\Omega^2 + (\Delta_\sigma/2)^2}$.

Working in the eigenbasis $|\pm\rangle$, the original lowering operator $\sigma$ can be written in terms of the new operators $\hat{\sigma} \equiv |+\rangle \langle -| + |-\rangle \langle +|$, as $\sigma = s^2 \hat{\sigma} - c^2 \hat{\sigma}^\dagger + cs \hat{\sigma}_z$, with $s = \sin \theta$, $c = \cos \theta$, $\hat{\sigma}_z \equiv 2 \hat{\sigma} \hat{\sigma} - 1$. Therefore, the resulting Hamiltonian in the rotated spin basis reads

$$H = \Delta_1 a_1^\dagger a_1 + \Delta_2 a_2^\dagger a_2 + R \hat{\sigma}_z + g(\sigma^\dagger a_1^\dagger + a_2^\dagger a_2^\dagger + \text{h.c.}). \quad (5)$$

The transition energy of the effective qubit is now given by $R$, which can be made small enough that counter-rotating terms of the kind $\sigma^\dagger a^\dagger$ and $\sigma a$ play a relevant role in the dynamics. The presence of the latter type of coupling terms, involving $\hat{\sigma}_z$, makes $R$ reminiscent of the generalized QRM, where a coupling term proportional to $\sigma_z (a + a^\dagger)$ is added to the QRM in Eq. (1) [7, 8, 10, 11, 80, 81]. Crucially, the presence of the $\hat{\sigma}_z$ coupling term, which was absent in previous proposals of simulation of the QRM, breaks parity symmetry and enables processes that changes the number of excitations in the system by an odd number [4, 5, 11].

We will now see how, in the limit of $\alpha \equiv g/R \ll 1$, the counter-rotating terms in Eq. (5) lead to Rabi oscillations between pairs of eigenstates of the bare Hamiltonian that are not directly coupled by the interactions [11], with Rabi frequencies $\propto g$. In the effective USC regime when $\alpha \sim 0.1$, we find the optimal condition in which $g/R \ll 1$ remains valid, while the effective Rabi frequencies $\sim 0.1 g$ can be significantly larger than the dephasing rate. The normal USC condition $\eta \gtrsim 0.1$ for observing these phenomena is thus lifted.

One example of such a nonlinear process is the simultaneous excitation of one photon in each cavity by the single qubit.
By plotting the energy levels of Eq. (5) [Fig. 2(a)], and zooming in around $\Delta_1 + \Delta_2 \approx 2R$, we find an avoided-level crossing [Fig. 2(b)]. The interaction around this point is described by the effective Hamiltonian [82]:

$$H_{\text{eff}}^I = \Delta_1 a_1^\dagger a_1 + \Delta_2 a_2^\dagger a_2 + (R + \lambda)\hat{\sigma}_z + \left(\chi a_1^\dagger a_1 + \chi a_2^\dagger a_2\right)\hat{\sigma}_z + g_{\text{eff}}^I \left(a_1^\dagger a_2^\dagger + h.c.\right),$$

(6)

which couples the states $|+\rangle, |\pm\rangle \rightarrow |\pm\rangle$. This effective interaction requires both states to be quasi-resonant, which implies, ignoring for now small dispersive energy shifts, the two conditions:

$$\Delta_1 + \Delta_2 \approx 2R, \quad \Delta_1 \neq \Delta_2 \neq (\pm R, \pm 2R).$$

(7)

The second condition is imposed in order to be detuned from first-order processes (e.g., $\Delta a_1^\dagger + h.c.$ if $\Delta_1 = 2R$) and competing second-order processes (e.g., $\Delta a_1^\dagger + h.c.$ for $\Delta_1 = R$) exciting degenerate photon pairs within a single cavity [77–79]. The effective two-photon coupling rate in Eq. (6) is given by

$$g_{\text{eff}}^I = g^2 \sin^3 \left[Rf(1 - f)\right],$$

(8)

where we defined $\Delta_1 = 2fR$ and $\Delta_2 = (1 - f)2R$, $f \in (0, 1)$, so that Eq. (7) is automatically fulfilled. This effective interaction is mediated by the second-order processes shown in Fig. 2(c). The Lamb shift of the qubit is

$$\lambda = g^2 \left[c^4 (\Delta_{1,+}^{-1} + \Delta_{2,-}^{-1}) - s^4 (\Delta_{1,-}^{-1} + \Delta_{2,+}^{-1})\right]/2,$$

(9)

and the dispersive coupling rates are

$$\chi_i = g^2 (c^4/\Delta_{i,+} - s^4/\Delta_{i,-}),$$

(10)

with $\Delta_{i,\pm} \equiv \Delta_i \pm 2R$.

Equation (8) shows that the resonant-driving condition $\Delta_1 = 0$ ($\theta = \pi/4$) does not provide the maximum possible two-photon coupling rate. In particular, for a fixed $R$, we see that the optimal angle $\theta$ maximizing $g_{\text{eff}}^I$ is $\theta^* = \pi/3$. This angle yields the optimum value $g_{\text{eff}}^I(\theta^*) \approx 1.3g_{\text{eff}}^I(\theta = \pi/4)$. Alternatively, we can compute the optimal detuning $\Delta_\sigma$ for a fixed $\Omega$, which is experimentally more meaningful since varying $\Delta_\sigma$ for a fixed $\Omega$ is more straightforward than varying $\theta$ for a fixed $R$. By writing Eq. (8) explicitly in terms of $\Delta_\sigma$ and $\Omega$, we obtain the optimal detuning $\Delta_\sigma^*=\Omega/\sqrt{2}$. The corresponding value of $g_{\text{eff}}^I$ is then given by $g_{\text{eff}}^I(\Delta_\sigma^*) \approx 1.18g_{\text{eff}}^I(\Delta_\sigma = 0)$.

In order to obtain full two-photon Rabi oscillations between the states $|1\rangle = |+\rangle, |\pm\rangle$ and $|2\rangle = |\pm\rangle, |\mp\rangle$, the quasi-resonance condition Eq. (7) needs to be fine-tuned to account for the Lamb shift of the qubit and the dispersive qubit-cavity couplings in Eq. (6), given by $\lambda$ and $\chi_1, \chi_2$. In other words, $\Delta_1$ and $\Delta_2$ must be chosen such that $|1\rangle|H_{\text{eff}}|1\rangle = |2\rangle|H_{\text{eff}}|2\rangle$. Introducing a correction $\delta$ such that $\Delta_1 = 2Rf + \delta$, we solve this equation for the Hamiltonian in Eq. (6) and obtain

$$\delta = 2\lambda + \chi_1(2n + 1) + \chi_2(2m + 1).$$

(11)

**Experimental protocol.**—We now discuss an experimental protocol for implementing and measuring the non-linear process. This protocol is shown in Fig. 3. Starting with no photons in the cavities and the qubit in its ground state $|g\rangle$, the first step is to apply a rotation of $2\theta$ around the $y$-axis to bring the qubit into the eigenstate $|+\rangle$. This single-qubit rotation is a basic element of any quantum information toolbox. At this stage, the cavities and the qubit are detuned and no interaction takes place. Then, the driving field is switched on and the non-linear process becomes resonant. After the system has evolved for a time $t$, the drive is switched off (effectively decoupling the qubit and the cavity), and the state of the qubit in the $|\pm\rangle$ basis is transformed back into the $\{|g\rangle, |e\rangle\}$ basis (eigenstates...
where the frequency-conversion rate is given by

\[ H_{\text{eff}} = \Delta a^\dagger a + \sigma_1^+ \sigma_1^0 \sigma_2^0 + \Omega(\sigma_1 + \sigma_2 + \text{h.c.}) + g[g^I(\sigma_1^+ \sigma_1^0 + 1), (16) \]

with an effective coupling rate that emerges from third-order processes,

\[ g_{\text{eff}}^I = g^3 (c^3 s^3 + 3 c s^5) / (3 R^2). \]

As in the previous cases, the effective coupling can be maximized by driving the qubit slightly off resonance, using either the optimal angle \( \theta^* \) or the optimal detuning \( \Delta^* \), whose expressions we provide in [82].

**Experimental implementations.**—The results presented here are based on very fundamental models that describe the exchange of single excitations between a qubit and a harmonic oscillator, and can, therefore, be applied in many different systems. In Table I, we compare, under experimentally feasible assumptions, the effective coupling strengths \( g_{\text{eff}} \) and

**FIG. 3:** USC process I: Illustration of the experimental protocol, showing (a) the Bloch sphere picture of the qubit state, (b) the time evolution of the occupation probabilities for the most relevant states, and (c) a schematic diagram of the proposed pulse sequence. From time \( t_0 \) to \( t_1 \), the qubit is rotated to the correct initial state in the rotated spin basis. From time \( t_1 \) to \( t_2 \), the qubit is driven and the system evolves according to the Hamiltonian in Eq. (5), i.e., moving back and forth along the red trajectory depicted in the Bloch sphere. At time \( t_2 \), the drive is turned off and the qubit is rotated back to the original basis, where it is then measured at time \( t_3 \).
decoherence rates $\gamma$ that can be obtained in five experimental platforms. An experimental implementation is feasible when $g_{\text{eff}}/\gamma > 1$, i.e. when the effective coupling is strong. Table I shows that the second-order processes that we have proposed here should be ready for implementation in several systems, and the third-order process may be within reach for circuit-QED setups. However, we note that the nonlinear processes may also be exploited even in the dissipative regime where $g_{\text{eff}} < \gamma$, e.g. yielding multi-photon emission with non-classical properties [77–79, 88].

Conclusions.—We have shown how, rather than simulating the full QRM with a JCM, one can simulate specific nonlinear processes characteristic of the USC regime. This requires fewer resources and allows to implement processes that are forbidden in the standard QRM due to parity conservation. Our method is ready for its implementation on several existing experimental platforms and opens up new possibilities for exploring USC physics and its applications in technologies such as quantum information and quantum metrology.

Effective Hamiltonians

In this work, we use a matrix form of perturbation theory that allows one to obtain energy corrections to arbitrary orders with a single matrix inversion. Let us consider a Hilbert subspace \( \mathcal{A} \) consisting of \( N_A \) states \( \{|a_1\}, |a_2\}, \ldots \) whose effective dynamics we wish to describe. This subspace is coupled to another subspace \( \mathcal{B} \) consisting of \( N_B \) states \( \{|b_1\}, |b_2\}, \ldots \) that we want to adiabatically eliminate. We define the projectors onto the respective subspaces as \( P_A \) and \( P_B \). The total Hamiltonian of the combined system is given by

\[
H = \begin{pmatrix} h & V \\ V^\dagger & \tilde{H} \end{pmatrix},
\]  

(S1)

where \( h = P_A H P_A \) is an \( (N_A \times N_A) \) matrix acting only on \( \mathcal{A} \), \( \tilde{H} = P_B H P_B \) is an \( (N_B \times N_B) \) matrix acting only on \( \mathcal{B} \), and \( V = P_B H P_A \) is an \( (N_A \times N_B) \) matrix coupling both subspaces. Our objective is to obtain an effective Hamiltonian \( h_{\text{eff}} \) describing the dynamics within \( \mathcal{A} \). The underlying assumption is that the eigenvalues of \( h \) are close to the energy \( E \), while the eigenvalues of \( \tilde{H} \) are detuned from \( E \) by values much larger than the elements of \( V \), and therefore can be adiabatically eliminated. This is done by writing the eigenvalue problem:

\[
\begin{pmatrix} h & V \\ V^\dagger & \tilde{H} \end{pmatrix} \begin{pmatrix} \phi \\ \chi \end{pmatrix} = E \begin{pmatrix} \phi \\ \chi \end{pmatrix},
\]

(S2)

where \( \phi \) and \( \chi \) are column vectors of length \( N_A \) and \( N_B \), respectively. After matrix multiplication, we obtain the following system of two equations for \( \phi \) and \( \chi \):

\[
\begin{align*}
(E - h)\phi &= V \chi, \\
(E - \tilde{H})\chi &= V^\dagger \phi.
\end{align*}
\]

(S3a)

(S3b)

By solving Eq. (S3b) and substituting into Eq. (S3a), we obtain:

\[
(E - H_{\text{eff}})\phi = 0,
\]

(S4)

where \( H_{\text{eff}}(E) = h + \delta h \), and

\[
\delta h = V \frac{1}{E - \tilde{H}} V^\dagger.
\]

(S5)

\( H_{\text{eff}} \) corresponds to effective Hamiltonians that we have presented in the main text. Notably, this simple expression includes contributions from processes beyond second-order perturbation theory; the order of such processes is encoded in the size of the matrix. In the following sections we provide further details on how the effective Hamiltonian was obtained in the three cases studied in the main text.
We consider the following two subspaces, with \( N_A = 2 \) and \( N_B = 12 \):

- \( \mathcal{A} = \{|n, m, +\}, |n + 1, m + 1, -\| \} \)
- \( \mathcal{B} = \{|n + 1, m, \pm\}, |n, m, \pm\}, |n + 2, m + 1, \pm\}, |n + 1, m + 2, \pm\}, |n, m - 1, \pm\}, |n - 1, m, \pm\} \)

Note that states such as \( |n + 2, m + 1, \pm\) do not contribute to the effective coupling between the two states in \( \mathcal{A} \), but to the Lamb shifts and dispersive cavity-qubit couplings, through processes such as \( |n + 1, m + 1, -\rangle \rightarrow |n + 2, m + 1, \pm\rangle \rightarrow |n + 1, m + 1, -\rangle \). For simplicity, those processes are neither depicted in Fig. 2 of the main text nor in Fig. S1 and S2. Using \( \Delta_1 = \Delta_2 + \Delta_3 + \delta = 2R \sqrt{f_1} + \delta \)---where both states have the same energy in the absence of coupling \( E_0 = \Delta_2 + R = R(2f_1 - 1) \)---indicates the strength \( g_{\text{eff}} \) of the effective interaction between these two states. (c) The transitions in the second-order process that creates the effective coupling between \( |n, m, -\rangle \) and \( |n - 1, m + 1, +\rangle \). Blue solid arrows: transitions that conserve the number of excitations. Red dashed arrows: transitions that change the number of excitations by one. Blue dashed arrows: transitions that change the number of excitations by two.

**USC effect I: Details for two photons excited by a single atom**

**USC effect II: Details for frequency conversion**

We consider the following two subspaces, with \( N_A = 2 \) and \( N_B = 12 \):

- \( \mathcal{A} = \{|n + 1, m, -\}, |n, m + 1, +\| \} \)
- \( \mathcal{B} = \{|n + 1, m, \pm\}, |n, m, \pm\}, |n + 2, m, \pm\}, |n + 1, m + 2, \pm\}, |n, m - 1, \pm\}, |n - 1, m, \pm\} \)

Here, the correction that we obtain is

\[
\delta h^{\text{II}} = \left( -\frac{(n + 1)\chi_1 - m\chi_2 - \lambda + C}{g_{\text{eff}}^{\text{II}} \sqrt{(n + 1)(m + 1)}} \right) \left( \frac{g_{\text{eff}}^{\text{II}} \sqrt{(n + 1)(m + 1)}}{g_{\text{eff}}^{\text{II}} \sqrt{(n + 1)(m + 1)}} \right),
\]

which allows us to write the general form of the effective Hamiltonian \( H_{\text{eff}}^{\text{II}} \) in the general form

\[
H_{\text{eff}}^{\text{II}} = \Delta_1 a_1^\dagger a_1 + \Delta_2 a_2^\dagger a_2 + (R + \lambda)\sigma_z + \left( \chi_1 a_1^\dagger a_1 + \chi_2 a_2^\dagger a_2 \right)\sigma_z + g_{\text{eff}}^{\text{II}} \left( a_1 a_2^\dagger \sigma + \text{h.c.} \right).
\]
The expression for $g_{\text{eff}}^{\text{II}}$ is given in the main text. The dispersive coupling rates are in this case given by

$$\chi_i = g^2 \left( \frac{c^4}{2R + \Delta_i} + \frac{s^4}{2R - \Delta_i} \right), \quad (S8)$$

and the Lamb shift is

$$\lambda = \frac{g^2}{2} \left( \frac{c^4(4R + \Delta_1 + \Delta_2)}{(2R + \Delta - 1)(2R + \Delta_2)} + \frac{s^4(4R - \Delta_1 - \Delta_2)}{(2R - \Delta_1)(2R - \Delta_2)} \right). \quad (S9)$$

The dispersive couplings and the Lamb shift make the diagonal elements of $\delta h^{\text{II}}$ unequal. Since both elements need to be equal in order to achieve complete Rabi oscillations, one needs to introduce a small correction the resonance condition $\Delta_1 + \Delta_2 = 2R$. Introducing the correction $\delta$ such that $\Delta_1 = 2Rf + \delta$ into the final expression of $H_{\text{eff}}$ (which implies the approximation of ignoring $\delta$ during the derivation of $H_{\text{eff}}$), and imposing that the diagonal elements are equal, we are left with the expression for the correction to the general resonance condition:

$$\delta = (2n + 1)\chi_1 + (2m + 1)\chi_2 + 2\lambda. \quad (S10)$$

This expression in terms of $\chi_i$ and $\lambda$ coincides with the one obtained for the case of two photons excited by a single atom. Similarly, driving the qubit on resonance does not maximize $g_{\text{eff}}^{\text{II}}$ either. Optimizing the angle gives

$$\theta^*(f \leq \frac{1}{2}) = \arccos \left[ \frac{\sqrt{3 + 2f \pm \sqrt{9 - 4f + 4f^2}}}{2\sqrt{2}} \right]. \quad (S11)$$

The factor gained with respect to $\theta = \pi/4$ is also $f$-dependent and has the following expression:

$$\frac{g_{\text{eff}}^{\text{II}}(\theta^*)}{g_{\text{eff}}^{\text{II}}(\theta = \pi/4)} = -\frac{(-6f + f' + 3) \sqrt{-2f(2f + f' - 2) + f' + 3}}{8\sqrt{2}(2f - 1)} \quad (S12)$$

where $f' = \sqrt{4(f - 1)f + 9}$. For the particular case $f = 1/4$, we find

$$g_{\text{eff}}^{\text{II}}(\theta^*) \approx 1.76 g_{\text{eff}}^{\text{II}}(\theta = \pi/4). \quad (S13)$$

Alternatively, we can compute the optimal detuning $\Delta_\sigma$ for a fixed $\Omega$ (instead of fixed $R$), which is experimentally more meaningful given that varying $\Delta_\sigma$ for a fixed $\Omega$ is more straightforward than varying $\theta$ for a fixed $R$:

$$\Delta_\sigma^* = -\Omega \frac{1 - 2f}{|1 - 2f|} \sqrt{2 + \frac{1 - \sqrt{1 - f(1 - f)|1 - 2f|}}{f(1 - f)}}. \quad (S14)$$

For the particular case $f = 1/4$, $\Delta_\sigma^* \approx -0.96 \Omega$, which leads to

$$g_{\text{eff}}^{\text{II}}(\Delta_\sigma^*) \approx 1.52 g_{\text{eff}}^{\text{II}}(\Delta_\sigma = 0). \quad (S15)$$

**USC effect III: Details for two atoms excited by a single photon**

We consider the following two subspaces, with $N_A = 2$ and $N_B = 12$:

- $A = \{|+, +, n\}, |-, -, n + 1\}$,
- $B = \{|+, -, n + 1\}, |-, +, n + 1\}, |+, +, n + 1\}, |+, -, n\}, |-, +, n\}, |-, -, n\}, |-, -, n + 2\}, |-, +, n + 2\}, |-, -, n + 2\}, |-, -, n - 1\}, |+, +, n - 1\}.$

Here, the correction that we obtain is

$$\delta h^{\text{III}} = \begin{pmatrix} \frac{2n \chi + 2\lambda + C}{g_{\text{eff}}^{\text{III}} \sqrt{n + \Gamma}} & g_{\text{eff}}^{\text{III}} \sqrt{n + \Gamma} \\ g_{\text{eff}}^{\text{III}} \sqrt{n + \Gamma} & -2(n + 1)\chi - 2\lambda + C \end{pmatrix}. \quad (S16)$$
FIG. S2: USC effect III: Energy-level diagrams and transitions for the process of exciting two atoms with a single photon. (a) Energy levels $E_n$ for the Hamiltonian in Eq. (15) as a function of $\Delta_a$. Parameters: $\Omega = 20g$, $\Delta_\sigma = \Delta_\sigma^*$ [see Eq. (S21)], with $R = \sqrt{\Omega^2 + \Delta_a^2 / 4}$. The Hilbert space is truncated at 4 photons for simplicity. (b) Zoom-in on the anti-crossing between the energy levels corresponding to $|+, +, 0\rangle$ and $|-, -, 1\rangle$. The size of the level splitting at the resonance $\Delta_a = \Delta_\sigma^* = 4R + \delta$—where both states have the same energy in the absence of coupling $E_0 = 2R$—indicates the strength $g_{III}^{eff}$ of the effective interaction between these two states. (c) The transitions in the third-order process that creates the effective coupling between $|-, -, n + 1\rangle$ and $|+, +, n - 1\rangle$. Blue solid arrows: transitions that conserve the number of excitations. Red dashed arrows: transitions that change the number of excitations by one. Blue dashed arrows: transitions that change the number of excitations by two.

The dispersive coupling and the Lamb shift are given by second-order processes:

\[
\chi = g^2 \frac{(2R - \Delta_a)c^4 + (2R + \Delta_a)s^4}{4R^2 - \Delta_a^2}, \tag{S17}
\]

\[
\lambda = \frac{\chi}{2}. \tag{S18}
\]

Setting $\Delta_a = 4R + \delta$, the optimum resonance condition is given by

\[
\delta = (4n + 2)\chi + 4\lambda = 4(n + 1)\chi. \tag{S19}
\]

For a fixed $R$, we can see that the optimal angle $\theta$ maximizing $g_{\text{eff}}$ is $\theta^* = \arctan\left(\sqrt{\frac{1 + \sqrt{5}}{3 - \sqrt{5}}}\right) \approx 0.356\pi$, giving the following maximum value of $g_{\text{eff}}^{III}$:

\[
g_{\text{eff}}^{III}(\theta^*) = \sqrt{\frac{11 + 5\sqrt{5}}{8}} \frac{g^3}{6R^2} \approx 1.67g_{\text{eff}}^{III}(\theta = \pi/4). \tag{S20}
\]

That is, when choosing the optimal angle $\theta^*$ we obtain $1.67 \times$ enhancement with respect to the resonant case $\Delta_\sigma = 0$, which corresponds to $\theta = \pi/4$. In a similar way, we can express this in terms of the optimal detuning:

\[
\Delta_\sigma^* = \Omega \sqrt{\frac{14\Omega^2 - 122}{45}} \approx 0.73\Omega. \tag{S21}
\]

The corresponding value of $g_{\text{eff}}$ is then given by

\[
g_{\text{eff}}^{III}(\Delta_\sigma^*) \approx -1.3 \frac{g^4}{6\Omega^2} = 1.3g_{\text{eff}}^{III}(\Delta_\sigma = 0) \tag{S22}
\]

giving $1.3 \times$ enhancement with respect to the resonant case, for the same driving amplitude $\Omega$.

Validity of the perturbation theory

In this section, we address the question of the validity of the perturbation theory for the three studied USC effects for large values of the perturbation parameter $g/\Omega$. To do so, we study the energy-level splitting $\Delta E_k$ between the two eigenstates $|\varphi_k\rangle$
FIG. S3: Validity of the applied perturbation theory for the three examples. (a) Examples of the avoided crossings at two different values of the perturbation parameter $g/\Omega$. Smaller values of $\Omega$ imply larger splitting. (b-c) Splitting at the avoided crossing (solid) versus $\Omega/g$, compared to the effective rates computed from perturbation theory (dashed). The perturbation theory works when the two curves overlap. (e-f) The overlap between the two eigenstates at the avoided crossing and the two states involved in the nonlinear process; when the perturbation theory starts failing, the overlap is reduced, meaning that eigenstates contain contributions from other states.

and $|\varphi_{k,-1}\rangle$ at the avoided-level crossing that we associate to each nonlinear process, see Fig. S3 (a). The resulting splitting is compared to the effective coupling rates $g_{\text{eff}}^\text{I}$, $g_{\text{eff}}^\text{II}$, and $g_{\text{eff}}^\text{III}$ that we have computed from perturbation theory, as we show in Fig. S3 (b-c). In addition, we compute the overlap between the two eigenstates $|\varphi_{k,k-1}\rangle$ and the two states between which we expect the Rabi oscillations to occur in each of the three cases considered in the text, see Fig. S3 (e-g). As $\Omega/g$ is reduced, the effective coupling rates increase. The perturbation theory starts failing at $\Omega/g \lesssim 10$ for cases I and II, and $\Omega/g \lesssim 2$ for case III (which is a third-order process). Below these values of $\Omega/g$, $|\varphi_{k,k-1}\rangle$ stop being composed exclusively of the two isolated states that constitute the desired nonlinear process, and the effective coupling rate predicted from perturbation theory departs from the real half-splittings between these eigenstates.

Effect of decoherence

Here we provide further study of the effect of decoherence (beyond Table I in the main text) computing the dynamics of the nonlinear processes in the presence of cavity losses. This is done by using the standard Lindblad master equation for the
FIG. S4: Effect of decoherence induced by radiative decay in the cavity modes for the three nonlinear processes considered in this work. In each case, we monitor the population $n_a = \langle a^\dagger a \rangle$ of a cavity undergoing Rabi oscillations under the nonlinear processes with and without decay. Lossless dynamics are represented by straight, blue curves. Dissipative dynamics are shown in dashed curves, with lighter color representing higher decay rates. Decay rates used are $g_{\text{eff}} \times (0.25, 0.5, 1)$, $\Omega/g = 20$ (a), 20 (b) and 10 (c).

Dynamics of the density matrix:

$$\dot{\rho} = -i[H, \rho] + \frac{\gamma_a}{2} \sum_{i=1}^{N_{\text{cav}}} \left( 2a_i \rho a_i^\dagger - a_i^\dagger a_i \rho - \rho a_i^\dagger a_i \right).$$  \hspace{1cm} (S23)

where $\gamma_a$ is a cavity decay rate, and the sum runs over the total number of cavities (two in cases I and II, one in case III). In Fig. S4 we show that the effect of decoherence is the expected damping of the Rabi oscillations. The apparent higher robustness to losses of case III (two atoms excited by a single photon) can be explained by the fact that there is only one cavity, which is the only lossy subsystem, as compared to two cavities in cases I and II. We have assumed the cavity decay to be the main decoherence mechanism, therefore ignoring the decay or dephasing of the atoms to simplify the discussion.
