(Dated: 30 October 2019)

We present a general variational approach for computing the laser-induced rovibrational dynamics of molecules taking into account the hyperfine effects of the nuclear quadrupole coupling. The method combines the general variational approach TROVE, which provides accurate rovibrational hyperfine energies and wave functions for arbitrary molecules, with the variational method RichMol, designed for generalized simulations of the rovibrational dynamics in the presence of external electric fields. We investigate the effect of the nuclear quadrupole coupling on the short-pulse laser alignment of a prototypical molecule CFClBrI, which contains nuclei with large quadrupole constants. The influence of the nuclear quadrupole interactions on the post-pulse molecular dynamics is negligible at early times, first several revivals, however at later timescales the effect is entirely detrimental and strongly depends on the laser intensity. This effect can be explained by dephasing in the laser-excited rotational wavepacket due to irregular spacings between the hyperfine-split nuclear spin states across different rotational hyperfine bands.

Laser-induced rovibrational molecular dynamics is a subject of active research in physics and chemistry. In particular, the control of molecular spatial alignment and orientation is highly leveraged in many ultrafast imaging experiments and stereochemistry studies to increase the experimental resolution. The mechanism of the alignment and orientation is tied to the driven rotational dynamics of molecules in the ground vibrational state and described by two-photon or three-photon Raman excitation processes. The adiabatic alignment is induced by slowly increasing laser electric field, which creates a directional potential trapping molecules in pendular states. Adiabatic alignment combined with a dc electric field, produces the mixed-field orientation of molecules. In the impulsive alignment regime using short laser pulses, the created rotational wavepacket evolves with repeated alignment/orientation and antialignment revivals. In all of these schemes, the temporal evolution of the rotational wavepacket and the resulting revival structure is characteristic to the rotational-energy-level structure of the molecule. Typically, this temporal wavepacket evolution is accurately predicted using the rigid-rotor or semirigid rotor Hamiltonian models. Many heavy atoms, such as, for example, bromine, iodine, or platinum, have large nuclear quadrupoles. In molecules, these create large hyperfine splittings, comparable or even larger than the rotational-energy spacings. These strong hyperfine interactions arise from the coupling between the quadrupole moments of nuclei and the electric field gradients produced by the distribution of nuclei and electrons through the molecule. In such heavy-atom containing molecules the presence of the manifold of hyperfine-split nuclear-spin states makes the temporal evolution of the laser-excited rotational wavepacket, and thus the alignment revival structure, more complicated. Therefore, a detailed understanding of the effect of these nuclear-quadrupole interactions is an important ingredient for the control over the alignment of heavy-atom-containing molecules, with corresponding implications for molecular-frame imaging experiments. Heavy atoms are commonly utilized as strong scattering and absorption centers in x-ray imaging experiments. They are also exploited as good leaving groups in Coulomb-explosion velocity-map imaging of molecular dynamics.

Here, we present a general variational approach for computing the field-driven rovibrational dynamics of molecules including nuclear-quadrupole interactions. The present approach extends our previously reported variational method for computing the nuclear-quadrupole hyperfine spectra of small molecules. We developed a generalized methodology for computing the matrix representations of various electric-multipole-moment tensor operators in the basis of hyperfine wave functions. These tensor operators are used as building blocks of the molecule-field interaction potential in simulations of the field-driven rovibrational dynamics, as implemented in the computational approach RichMol. To our knowledge, this is the first attempt to generalized simulations of this kind. We demonstrate the effect by calculating the one-dimensional alignment dynamics of the asymmetric CF$_{35}$Cl$_{20}$Br$_{12}$I$_7$ molecule by a short laser pulse.

In brief, in RichMol the time-dependent wavepacket \( \Psi(t) \) is built from a superposition of the field-free rovibrational wave functions \( |J,m_J,l\rangle \),

\[
\Psi(t) = \sum_{J,m_J,l} c_{J,m_J,l}(t) |J,m_J,l\rangle,
\]

where \( J \) and \( m_J \) denote the quantum numbers, in units of \( \hbar \), of the total rotational angular momentum operator \( \mathbf{J} \) and its projection onto the laboratory-fixed \( Z \) axis,
respectively. \( t \) represents a set of additional rotational and vibrational quantum numbers. The time-dependent coefficients \( c_{J,m_J}(t) \) are determined by a numerical solution of the time-dependent Schrödinger equation using the time-evolution operator method. The total Hamiltonian consists of the sum of the molecular rovibrational Hamiltonian \( H_{\text{rv}} \), with the eigenfunctions \( |J, m_J, l\rangle \), and the molecule-field interaction potential \( V(t) \), expanded in terms of molecular electric multipole moment operators:

\[
H(t) = H_{\text{rv}} - \mu_A E_A(t) - \frac{1}{2} \alpha_{AB} E_A(t) E_B(t) + \ldots
\]  

(2)

\( A \) and \( B \) are Cartesian indices denoting the \( X, Y, \) and \( Z \) axes in the laboratory frame and the summation over all Cartesian indices is implicitly assumed. \( E_A(t) \) is the \( A \) Cartesian component of the electric field vector, and \( \mu_A \) and \( \alpha_{AB} \) are the electronic contributions to the molecular-frame electric-dipole-moment vector and polarizability tensor, respectively. The interaction terms of higher expansion order, such as the first and second hyperpolarizability tensors, can also in principle be included into the sum in (2).

The time-evolution operator for the time step \( \Delta t = t-t' \) is computed using the split-operator method as

\[
U(t,t') = e^{-i \frac{\Delta t}{\hbar} H_{\text{rv}}} \left( e^{i \frac{\Delta t}{2 \hbar} \mu_A E_A(\frac{t+t'}{2})} \right) \left( e^{-i \frac{\Delta t}{2 \hbar} \alpha_{AB} E_A(\frac{t-t'}{2})} \right) \ldots e^{-i \frac{\Delta t}{\hbar} H_{\text{rv}}}. 
\]  

(3)

\( H_{\text{rv}} \) is diagonal in the basis of its eigenfunctions \( |J, m_J, l\rangle \) and the diagonal elements are the molecular rovibrational energies. The exponentsials of the Cartesian tensor operators \( \mu_A, \alpha_{AB}, \ldots \) are evaluated using an iterative approximation based on the Krylov-subspace methods. The computational performance of the iterative methods depends crucially on how efficient the matrix-vector products can be computed between the operator exponential and the subspace vectors. In the following, we will use \( T_A^{(\Omega)} \) to denote any index-symmetric tensor operator of rank \( \Omega \) with \( A \) being a multi-index labeling Cartesian components in the upper simplex of the tensor in the laboratory frame. For example, for the dipole moment, \( \Omega = 1 \) and \( A = X, Y, \) or \( Z \), and for the polarizability tensor, \( \Omega = 2 \) and \( A = XX, XY, XZ, YY, YZ, \) or \( ZZ \).

The computations of the matrix-vector products can be significantly sped up by expressing the matrix representation of Cartesian tensor operators \( T_A^{(\Omega)} \) in a contracted tensor form:

\[
\langle J', m_J', l'| T_A^{(\Omega)} | J, m_J, l \rangle = \sum_{\omega=0}^{\Omega} \mathcal{M}_{A,\omega}^{(J',m_J',J,m_J)} K_{\omega}^{(J',l',J,l)}.
\]  

(4)

The explicit expressions for the \( \mathcal{M}_{A,\omega} \) and \( K_{\omega} \) matrices depend on the form of the field-free wave functions \( |J, m_J, l\rangle \). We use the general-molecule variational approach TROV\textsuperscript{30-32} to compute the field-free energies and wave functions \( |J, m_J, l\rangle \), which are represented by linear combinations of products of vibrational wave functions \( |v\rangle \) and symmetric-top rotational functions \( |J, m_J, k\rangle \)

\[
|J, m_J, l\rangle = \sum_{v,k} c_{v,k}^{(J,l)} |v\rangle |J, m_J, k\rangle.
\]  

(5)

\( v \) denotes the composite vibrational quantum number and \( k \) denotes the quantum number of the molecular-frame \( z \)-projection of the rotational angular momentum operator in units of \( \hbar \). Using the wave functions from (5), the expressions for \( \mathcal{M}_{A,\omega} \) and \( K_{\omega} \) can be derived as

\[
\mathcal{M}_{A,\omega}^{(J',m_J',J,m_J)} = (-1)^{m_J'} \sqrt{(2J'+1)(2J+1)}
\times \sum_{\sigma=-\omega}^{\omega} |U^{(\Omega)}|_{A,\omega,\sigma}^{(-1)} \left( \begin{array}{ccc} J & \omega & J' \\ m_J & \sigma & -m_J' \end{array} \right),
\]  

(6)

and

\[
K_{\omega}^{(J',l',J,l)} = \sum_{k',v'} \left( \begin{array}{c} J' \\ k' \end{array} \right) \left( \begin{array}{c} J \\ k \end{array} \right) \left( \begin{array}{c} l' \\ k' \end{array} \right) \left( \begin{array}{c} l \\ k \end{array} \right) \frac{1}{U^{(\Omega)}_{\omega,\sigma,a}} \left( \begin{array}{c} v' \end{array} \right) |T_a^{(\Omega)}| \left( \begin{array}{c} v \end{array} \right).
\]  

(7)

\( T_a^{(\Omega)} \) denotes Cartesian tensor operator in the molecular frame, with \( a \) being a Cartesian multi-index (similar to \( A \)), and the matrix \( U^{(\Omega)} \) defines the transformation of tensor from Cartesian to spherical-tensor form.\textsuperscript{33}

This approach is general and can be interfaced with any rovibrational computer code that provides the tensor-matrix elements in the form of (6). The approach also permits the use of more complex field-free wave functions than those defined in (5). As multipole-moment operators commute with the nuclear-spin angular momenta, the operators’ matrix elements in the basis of hyperfine states can also be cast into the form of (6). In the following, we derive the explicit expressions for the \( \mathcal{M}_{A,\omega} \) and \( K_{\omega} \) matrix elements in the basis of the nuclear-spin hyperfine-structure wave functions.

The general variational implementation of the nuclear-spin hyperfine effects at the level of the nuclear-quadrupole interaction was recently implemented\textsuperscript{33} and used for the generation of a quadrupole-resolved line list of the ammonia molecule.\textsuperscript{34} The nuclear-quadrupole interaction in a molecule containing \( n = 1 \ldots N \) quadrupolar nuclei is described by the coupling of the electric field gradient tensor (EFG) at each \( n \)-th nucleus \( V(n) \) with its quadrupole moment tensor \( \mathcal{Q}(n) \). The total spin-rovibrational Hamiltonian takes the form

\[
H_{\text{svr}} = H_{\text{rv}} + \sum_{n} V(n) \cdot \mathcal{Q}(n).
\]  

(8)
The overall rotational, $J$, and the nuclear spin, $I_n$, and total, $\mathbf{F}$, angular momentum operators for $n = 1 \ldots N$ quadrupolar nuclei are coupled as $I_{1,2} = I_1 + I_2$, $I_{1,3} = I_1 + I_3$, ..., $I_{1,N-1} = I_1 + I_{N-1}$, $I \equiv I_{1,N} = I_{1,N-1} + I_N$, and $\mathbf{F} = J + I$. The nuclear-spin functions $|I, m_I, \mathcal{I}\rangle$ depend on the quantum numbers $I$ and $m_I$ of the collective nuclear spin angular momentum operator $\mathbf{I}$ and its projection onto the laboratory $Z$ axis, respectively. The set of auxiliary spin quantum numbers $\mathcal{I} = \{I_1, I_{1,2}, \ldots, I_{1,N-1}\}$ of the intermediate spin angular momentum operators provide a unique assignment of each nuclear-spin state. The total spin-rovibrational wave functions $|F, m_F, u\rangle$ are built as symmetry-adapted linear combinations of the products of the rovibrational wave functions $|J, m_J, l\rangle$ in $[3]$ and the nuclear-spin functions $|I, m_I, \mathcal{I}\rangle$:

$$
|F, m_F, u\rangle = \sum_{\mathcal{I}, J, I, l} c_{\mathcal{I}, I, J, l}^{(F, u)} \left( \sum_{m_J, m_I} (-1)^{F + m_F} \right) |I, m_I, \mathcal{I}\rangle |J, m_J, l\rangle \times \sqrt{\frac{2F + 1}{2J + 1}} \left( -m_F, m_I \right) |J, m_J, l\rangle,
$$

(9)

$c_{\mathcal{I}, I, J, l}^{(F, u)}$ are the eigenvector coefficients of the spin-rovibrational Hamiltonian $[3]$. $F$ and $m_F$ are the quantum numbers of $\mathbf{F}$ and its projection onto the laboratory-fixed $Z$-axis, and $u$ denotes the hyperfine-state running index.

The explicit expressions for the matrix elements of the spin-rovibrational Hamiltonian $[3]$ for an arbitrary number of quadrupolar nuclei and details of the variational solution can be found in reference $[34]$. Here, we derived explicit expressions for the matrix elements of the general electric multipole Cartesian tensor operator $\left\langle F', m'_F, u' \left| T^{(\Omega)}_A \right| F, m_F, u \right\rangle$, which in the contracted-tensor form of $[4]$ are

$$
\mathcal{M}^{(F', m'_F, F, m_F)}_{\omega} = (-1)^{m'_F} \sqrt{(2F' + 1)(2F + 1)} \times \sum_{\sigma = -\omega}^{\omega} \left[ U^{(\Omega)}_{\omega} \right]^{-1}_{\omega, \sigma} \left( -m'_F, \sigma \right) \left( m_F \right) \left( F' \right)
$$

(10)

and

$$
\mathcal{K}^{(F', \omega', F, \omega)}_{\omega} = \sum_{I', \Omega, J', u', I, \Omega, J, u} \left[ (F', \omega', u') c^{(F, u)}_{\omega} (I, \Omega, J, u) \right] \left[ (F' \omega', J', \Omega) \delta_{I', J, \Omega} \right] \left( 2J' + 1 \right) \left( 2J + 1 \right) \left( F' \right) \left( F \right)
$$

(11)

$\mathcal{K}^{(J', \omega', I', \Omega, I, \Omega, J, u, \omega)}_{\omega}$, defined in $[7]$, contains the rovibrational matrix elements of $T^{(\Omega)}_A$ in the basis $|J, m_J, l\rangle$. Using the expressions $[10]$ and $[11]$ in $[4]$, RichMol could directly be employed to simulate the coupled nuclear-spin-rovibrational molecular dynamics in external fields. In $[5]$, the diagonal representation of $H_{\nu v}$ in the rovibrational energies was replaced by the diagonal representation of $H_{\nu v}$ in the hyperfine energies $[5]$. This new approach was used to investigate the effect of nuclear-quadrupole coupling on the impulsive alignment of bromochlorofluorodiodomethane CF$_{35}$ClBr$_{112}$I$_{127}$. A short non-resonant laser pulse is linearly polarized along the laboratory $Z$ axis. Its intensity is given by the Gaussian function $I(t) = I_0 \exp\left( -4\ln 2 \frac{t^2}{\sigma^2} \right)$ with $\sigma = 1$ ps and $I_0 = 6 \times 10^{11}$ W/cm$^2$ or $1 \times 10^{12}$ W/cm$^2$.

The excitation by a non-resonant laser field is described by the electric polarizability term in the interaction potential $[2]$. The explicit expressions for the elements of the matrix $U^{(2)}_{\omega, \sigma}$ for the polarizability are listed in the Table I of reference $[35]$. The degree of molecular alignment is characterized by the expectation value $\langle \cos^2 \theta \rangle = \langle \Psi(t) | \cos^2 \theta | \Psi(t) \rangle$, with the angle $\theta$ between the molecular-frame $z$ and the laboratory-frame $Z$ axis. The matrix elements of the $\cos^2 \theta$ operator can be easily computed using the general expressions $[10]$, $[11]$, and $[7]$ by noting the relationship $\cos^2 \theta = (2d_{00} + 1)/3$, where $d$ is the Wigner $d$ matrix. The vibrational matrix elements of $d_{00}$ in $[7]$ are $\langle u'|d_{00}|u\rangle = \delta_{u'}u$ and $U^{(2)}_{\omega, \sigma} = \delta_{u', \sigma} \delta_{0, \sigma}$: here the index $\alpha$ in $[7]$ is redundant.

For simplicity we neglected the vibrational motion of the molecule and approximated the full rovibrational wave functions in $[5]$ by rigid-rotor solutions. The equilibrium geometry and polarizability of CFClBrI were calculated using density functional theory (DFT) with the B3LYP functional and the def2-TZVP basis set $[11, 22]$ in conjunction with the relativistic effective core potential def2-ECP on the iodine atom $[23]$. Calculations of the electric field gradient tensors, needed for the nuclear-quadrupole coupling Hamiltonian in $[5]$, were carried out at the DFT/B3LYP level of theory using the all-electron scalar relativistic Douglas-Kroll-Hess Hamiltonian $[24]$ with the DKH-def2-TZVP basis set $[20, 24]$. All electronic structure calculations employed the quantum chemistry package ORCA $[25]$. The quadrupole moments for the $^{35}\text{Cl}$, $^{79}\text{Br}$, and $^{127}\text{I}$ nuclei are $Q = -81.65$ mb, $313$ mb, and $-696$ mb, respectively.

The calculations of the molecule-field-dynamics in the basis of the nuclear-spin hyperfine states were performed in a three-step procedure: First we solved the field-free problem using the rigid-rotor Hamiltonian and obtained the rotational energies and the rotational matrix elements of the EFG and the polarizability tensors, as well as of the $\cos^2 \theta$ operator, $[10]$ and $[7]$. Then we used the rotational energies and the matrix elements of the EFG tensors together with the nuclear-quadrupole constants to build and diagonalize the nuclear-spin quadrupole-coupling Hamiltonian $[26, 27]$. We obtained the spin-rotational eigenfunctions in $[7]$ and transformed the rotational matrix elements of the polarizability tensor and $\cos^2 \theta$ operator into the spin-rotational eigen-basis using $[10]$ and $[7]$. Finally, we used the spin-rotational energies and the matrix elements of the polarizability to build the molecule-field
interaction Hamiltonian and solve the time-dependent problem. The wavepacket $\Psi(t)$ in (1) was built from a linear combination of spin-rotational wave functions with time-dependent coefficients. The expectation value $\langle \cos^2 \theta \rangle$ is calculated from the spin-rotational matrix elements of $\cos^2 \theta$ computed at the previous step.

Here, we used a rotational basis that included all spin-rotational states of CFClBrI with $F \leq 41/2$, corresponding to $J \leq 26$. We assumed that CFClBrI is initially in the ground rotational state $J = 0$, which has 96 different nuclear-spin state components, including the $m_F$ degeneracy. Therefore, we performed a series of simulations starting from the different nuclear-spin components and averaged the results assuming equal normalized populations of different spin components. For comparison, we also performed calculations neglecting the hyperfine effects, i.e., using rigid-rotor wavefunctions as the field-free basis.

The temporal evolution of the alignment calculated for two different laser intensities is shown in Fig. 1. For both laser intensities, the alignment without nuclear-quadrupole interaction shows complex revival patterns originating from the dephasing and rephasing of the rotational wavepacket. Since CFClBrI is an asymmetric-top molecule (asymmetry parameter $\kappa = -0.75$), the revival patterns lack the typical periodicity of the $J$-type or $C$-type revivals observed for near-symmetric-top molecules. Noticeably, the broader wave packet, produced by the higher-intensity pulse, shows higher-frequency oscillations and generally reduced peak alignment. This is ascribed to mismatches of the phases of the populated rotational states after the laser pulse and successive dephasing due to the molecule's asymmetry, preventing the simultaneous rephasing of more than a few rotational states with significant populations.

The nuclear-quadrupole interaction increases complexity of the revival dynamics and depletion of the peak alignment compared to the rigid-rotor results. Nevertheless, during the first 300 ps after the laser pulse the degree of alignment is almost identical to the rigid-rotor result. We also observed a dependence of the nuclear-quadrupole effect on the laser-field intensity. For the lower intensity, the impact is seen about 200 ps earlier than for the higher intensity.

The non-periodic recurrences in the alignment dynamics of the asymmetric-top molecules originate from large asymmetry splittings of the rotational energy levels. The influence of the nuclear-quadrupole interaction can be understood in a similar manner, as dephasing effect resulting from the incommensurate hyperfine splittings for different rotational states. The dephasing is stronger for the wavepacket dominated by the low-energy rotational states, where the hyperfine splittings are most irregular. For large $J$, the hyperfine splittings become increasingly uniform.
and the contribution to the dephasing is minimized. This explains why the effect of the nuclear-quadrupole interaction is less striking for the higher-intensity laser field, which populates higher-energy rotational states. For both intensities, however, the small-$J$ states have relatively large populations and the nuclear-quadrupole interaction has a strong influence on the field-free alignment.

In conclusion, we have presented the first general implementation of nuclear-quadrupole hyperfine effects in the rovibrational dynamics of molecules driven by external electric fields. Our approach combines TROVE, which provides hyperfine energies and wave functions for arbitrary molecule, with RichMol, designed for generalized simulations of external-field effects. In principle, the presented approach can be applied to simulate the fully-coupled spin-rovibrational dynamics of any molecule with no inherent limitations on the number of quadrupolar nuclei. The external field effects are not limited by the polarizability interaction: other multipole moment operators, including the permanent dipole moment or the first and second hyperpolarizabilities, can be considered without additional implementation efforts.

We studied the influence of the nuclear-quadrupole coupling on the laser impulsive alignment of a prototypical heavy-atom molecule CFCIBrI. While the effect is small for the first few revivals, it turns out to be entirely detrimental for the revivals at later times. The laser field plays an important role, with lower intensities prompting larger effect of the nuclear-quadrupole coupling. This can be explained by dephasing of the rotational wavepacket due to the incommensurate structure of the hyperfine-split levels for different rotational states. This effect is stronger for small-$J$ rotational states and practically disappears for states with high angular momenta. Given that small-$J$ states in the wavepacket will be the source of the largest dephasing effects, we expect that stronger laser intensities and higher initial rotational temperatures should further diminish the effect of the nuclear-quadrupole coupling. More rigorous studies of these effects for different alignment scenarios and molecular systems are ongoing. We envisage future applications of the presented approach to inform and interpret diverse laser-field experiments on molecules containing nuclei with large quadrupole constant.

This work has been supported by the Deutsche Forschungsgemeinschaft (DFG) through the priority program “Quantum Dynamics in Tailored Intense Fields” (QUTIF, SPP1840, KU 1527/3, YA 610/1) and the cluster of excellence “Center for Ultrafast Imaging” (CUI, EXC 2056, ID 390715994).
