(Dated: October 31, 2019)

Quantum processes, such as quantum circuits, quantum memories, and quantum channels, are essential ingredients in almost all quantum information processing tasks. However, the characterization of these processes remains as a daunting task due to the exponentially increasing amount of resources required by traditional methods. Here, by first proposing the concept of quantum process verification, we establish two efficient and practical protocols for verifying quantum processes which can provide an exponential improvement over the standard quantum process tomography and a quadratic improvement over the method of direct fidelity estimation. The efficacy of our protocols is illustrated with the verification of various quantum gates as well as the processes of well-known quantum circuits. Moreover, our protocols are readily applicable with current experimental techniques since only local measurements are required. In addition, we show that our protocols for verifying quantum processes can be easily adapted to verify quantum measurements.

Introduction.—Quantum processes, such as quantum circuits, quantum memories, and quantum channels, are a broad class of transformations that a quantum mechanical system can undergo. Naturally, the characterization and identification of these quantum processes become an indispensable task in many fields of quantum information processing, including quantum communication [1], quantum computation [2], quantum metrology [3, 4], and more. Take quantum gates, or more generally quantum circuits, as an example. Efficient and reliable characterization of quantum circuits plays a vital role to guarantee the correctness of the computation results of quantum devices. Recently, several commercial institutions have claimed a great progress in the development of quantum computers with tens of qubits being built in practice. However, the standard quantum process tomography (QPT) method [5, 6] which requires measurements in the order of \(O(4^n)\) for an \(n\)-qubit system has already become powerless for these intermediate-size quantum devices.

Hence, a lot of effort has been devoted to searching for alternative nontomographic methods. Along this research line there are for instance, compressed sensing QPT [7–9], direct fidelity estimation (DFE) [10, 11], as well as randomized benchmarking (RB) [12–16]. However, all these approaches are either still requiring large amount of resources, or not generally applicable in many scenarios of practical interest.

Similar problems are also existing for the characterization of quantum states, where many efficient methods are proposed to overcome the resource-inefficiency problem with tomography. Among them, quantum state verification (QSV) [17] has drawn much interest due to its various nice properties including high efficiency and the requirement of local measurements only. In short, QSV is a procedure for gaining confidence that the output of some quantum device is a particular state by employing local measurements. Many different kinds of bipartite or multipartite quantum states [17–32] can be verified efficiently or even optimally by QSV. In general, a QSV protocol \(\Omega\) for verifying the target state \(|\phi\rangle\) has the form

\[
\Omega = \sum_i p_i \Omega_i,
\]

where \(\{\Omega_i, 1 - \Omega_i\}\) are random “pass” or “fail” tests, which are implementable with local measurements and satisfy that \(\text{Tr}(\Omega_i|\phi\rangle\langle\phi|) = 1\) for all \(i\). In the case that all \(N\) states pass the test, we achieve the confidence level \(1 - \delta\) with

\[
\delta \leq [1 - \nu(\Omega)]^N,
\]

where \(\nu(\Omega) := 1 - \lambda_2(\Omega)\) denotes the spectral gap between the largest and the second largest eigenvalues of \(\Omega\) [17, 30]. Hence, the QSV protocol \(\Omega\) can verify the target state to fidelity \(1 - \epsilon\) and confidence level \(1 - \delta\) with the number of copies of the quantum states satisfying

\[
N \geq \frac{\ln \delta^{-1}}{\ln \left(\frac{1}{1 - \nu(\Omega)\epsilon^{-1}}\right)} \approx \frac{1}{\nu(\Omega)\epsilon^{-1} \ln \delta^{-1}}.
\]

In this work, we propose the concept of quantum process verification (QPV). Specifically, with a similar spirit as that for QSV, two efficient and practical protocols are established for QPV. Thanks to the Choi-Jamiolkowski isomorphism [33, 34], we are able to relate QPV with QSV, and derive the ancilla-assisted protocol for QPV. Then, we show that the ancilla-assisted protocol can also be transformed to the prepare-and-measure protocol, which requires no ancilla systems. Specifically, we demonstrate the efficacy of our protocols with the verification of various quantum gates as well as the processes of some well-known quantum circuits. By this, we demonstrate that our protocols can provide an exponential improvement over QPT and a quadratic improvement over...
DFE. Moreover, these protocols are readily applicable with current experimental techniques as only local measurements are required. Last but not least, we show that our protocols for verifying quantum processes can be easily adapted to the verification of quantum measurements.

Choi-Jamiołkowski isomorphism.—Consider the (un-normalized) maximally entangled bipartite state $|\psi\rangle = \sum_{k=1}^{d} |k\rangle_A |k\rangle_S$ between a quantum system $S$ and an ancilla system $A$, where $\{ |k\rangle \}_{k=1}^{d}$ represents an orthonormal basis. For a quantum process $\mathcal{E}$ acting only on the system $S$ of $|\psi\rangle$, the output state is given by

$$
\mathcal{Y}_\mathcal{E} = (\mathcal{I} \otimes \mathcal{E})(|\psi\rangle\langle\psi|) = \sum_{k,l=1}^{d} |k\rangle\langle l| \otimes \mathcal{E}(|k\rangle\langle l|),
$$

which is also called the Choi matrix of the process $\mathcal{E}$. Given the Choi matrix $\mathcal{Y}_\mathcal{E}$, the process $\mathcal{E}$ can be obtained as

$$
\mathcal{E}(\rho) = \text{Tr}_A[(\rho^T \otimes \mathbb{I}) \mathcal{Y}_\mathcal{E}].
$$

The relations in Eqs. (4) and (5) are known as the Choi-Jamiołkowski isomorphism [33, 34], an isomorphism between the Choi matrix $\mathcal{Y}_\mathcal{E} \in \mathcal{B}(\mathcal{H}) \otimes \mathcal{B}(\mathcal{H})$, and the linear map $\mathcal{E}: \mathcal{B}(\mathcal{H}) \rightarrow \mathcal{B}(\mathcal{H})$. The Choi-Jamiołkowski isomorphism also implies that $\mathcal{E}$ is a completely positive map if and only if the Choi matrix $\mathcal{Y}_\mathcal{E}$ is positive semidefinite. Note that here we do not require $\mathcal{E}$ to be trace-preserving. The benefit of relaxing this restriction is that we can deal with the situation when post-selection or particle losses are allowed; see Appendix A for more details.

Tomographically, Eq. (5) implies that once the Choi matrix $\mathcal{Y}_\mathcal{E}$ is determined, all the information of the process $\mathcal{E}$ is also obtained. This inspired the so-called ancilla-assisted QPT [35], which requires additional ancilla systems, but only fixed entangled input states.

Ancilla-assisted quantum process verification.—Similar to the case of QPT, by making use of the Choi-Jamiołkowski isomorphism, one can verify the quantum process $\mathcal{K}$ indirectly by verifying the corresponding Choi state $\rho_{\mathcal{K}} := \mathcal{Y}_{\mathcal{K}} / \text{Tr}(\mathcal{Y}_{\mathcal{K}})$ instead. Especially, when $\rho_{\mathcal{K}}$ is pure, we can apply the QSV protocols for verifying $\mathcal{K}$. For simplicity, we first consider the case when $\mathcal{K}$ is a unitary gate $U$, i.e., the verification of quantum gates or quantum circuits. Furthermore, we employ the entanglement gate fidelity

$$
F_e(\mathcal{E},U) := F(\rho_{\mathcal{E}},\rho_U) = \text{Tr}(\rho_{\mathcal{E}}\rho_U)
$$

as a benchmark, which is also directly related to the more widely-used notion, the average gate fidelity by the following relation [36],

$$
\bar{F}(\mathcal{E},U) = \frac{dF_e(\mathcal{E},U) + 1}{d + 1}.
$$

Now, we are ready to formally define the QPV problem for quantum gates. Suppose we have a quantum process $\mathcal{E}$ which is promised to be a gate $U$. We want to use the hypothesis testing method to verify this claim with high confidence $1 - \delta$. In the ideal case, we want to distinguish two cases, $F_e(\mathcal{E},U) = 1$ or $F_e(\mathcal{E},U) \leq 1 - \epsilon$. The figure of merit is the sample complexity, i.e., how many copies of input states are required with respect to the infidelity $\epsilon$ and the confidence level $1 - \delta$.

Due to the Choi-Jamiołkowski isomorphism, we can transform the verification of $U$ to the verification of the pure Choi state $\rho_U$. Furthermore, it can be easily shown that $\rho_U$ is maximally entangled. Hence, with either non-adaptive or adaptive QSV strategies $\mathcal{Y}$ [20, 23, 24, 26], we can achieve the spectral gap given by $\nu(\mathcal{Y}) = (d - 1)/d$. In practice, we may have more restrictions to the allowed measurements, e.g., for the multi-qubit gates. However, according to the result in QSV [17], we can show that the worst-case failure probability in each run is always bounded by

$$
\max_{F(\rho_\mathcal{E},\rho_U) \leq 1 - \epsilon} \text{Tr}(\mathcal{Y}_{\mathcal{E}}) \leq 1 - \epsilon \nu(\mathcal{Y}).
$$

This implies the following proposition for the efficiency of this ancilla-assisted protocol.

Proposition 1. For any quantum gate $U$, we can verify it to the entanglement gate fidelity $1 - \epsilon$ and confidence level $1 - \delta$ with $N \approx \frac{1}{\delta \epsilon^2} \ln \frac{1}{\epsilon}$ input states by verifying the corresponding Choi state $\rho_U$ with the QSV protocol $\mathcal{Y}$.

We note that the inequality (instead of equality) in Eq. (8) results from the important difference between general QSV and the QSV of Choi states that when $\mathcal{E}$ is restricted to trace-preserving processes, $\rho_{\mathcal{E}}$ also has an extra restriction that Tr$_S(\rho_{\mathcal{E}}) = 1/d$. This restriction makes it possible to further improve the efficiency. However, if we relax the restriction of trace-preserving, the inequality is always attained; more details are shown in Appendix A. In fact, the above discussion provides a general method to verify all the quantum processes whose corresponding Choi state is pure. We call this approach that verifies the quantum processes indirectly by QSV of the corresponding Choi states as ancilla-assisted quantum process verification (AAPV).

Prepare-and-measure quantum process verification.—The above AAPV approach is easy to understand and straightforward to use with the help of QSV. However, the double requirements of additional ancilla systems and the maximally entangled input states are sometimes difficult to achieve in experiments. This difficulty can be avoided by considering the prepare-and-measure (P&M) protocol. More precisely, we show that one can always convert a one-way adaptive QSV protocol (with nonadaptive QSV as a special case) to a P&M QPV (PMPV) protocol without any efficiency loss.

In a PMPV protocol, we randomly choose an input state $\rho_i$ with probability $p_i$ and test the output state
depends on the measurement outcome of $N_i$. If the measurement outcome is $N_i$, then we say the channel $\mathcal{E}$ passes the test; otherwise we say $\mathcal{E}$ fails the test. The same as in QSV, we require that the target gate $U$ always passes the test, i.e.,
\[
\text{Tr}(U \rho_i U^\dagger N_i) = 1.
\]
For convenience, we denote the PMPV protocol as
\[
\Xi = \sum_i p_i \rho_i^T \otimes N_i.
\]
Then in each run the worst-case failure probability is given by
\[
\max_{F_e(\mathcal{E},U) \leq 1-\epsilon} \sum_i p_i \text{Tr}[\mathcal{E}(\rho_i)N_i] = \max_{F_e(\mathcal{E},U) \leq 1-\epsilon} \text{Tr}(\Xi \mathcal{E}).
\]
Given that $N_i \leq 1$, Eq. (9) is equivalent to
\[
\text{Tr}(\Xi \mathcal{U}) = 1.
\]
For the normalized Choi state $\rho_U = \frac{1}{d} \mathcal{U}$, the one-way adaptive QSV protocol (classical communication from A to S, with no communication, i.e., nonadaptive QSV as a special case) takes on the general form [23]
\[
\Omega = \sum_i M_i \otimes N_i,
\]
such that $\{M_i\}$ is a POVM (positive operator-valued measure) on the ancilla system A, i.e., $\sum_i M_i = 1$ and $\{N_i, 1 - N_i\}$ is a pass or fail test on the system S which depends on the measurement outcome of $\{M_i\}$. To ensure that the target state always passes the test, $\Omega$ needs to satisfy
\[
\text{Tr}(\Omega \rho_U) = \frac{1}{d} \text{Tr}(\Omega \mathcal{U}) = 1.
\]
Now, we can convert any one-way adaptive QSV protocol for $\rho_U$ in Eq. (13) to a PMPV protocol of the form Eq. (10) by letting
\[
p_i = \frac{\text{Tr}(M_i)}{d}, \quad \rho_i = \frac{M_i^T}{\text{Tr}(M_i)},
\]
where the $p_1 = 1$ follows from $\sum_i M_i = 1$. Further, one can easily verify that
\[
\Xi = \frac{1}{d} \Omega, \quad \text{Tr}(\Xi \mathcal{U}) = 1
\]
by considering Eqs. (14) and (15). Then the following proposition characterizes the resources required in the derived PMPV protocol.

**Proposition 2.** For any quantum gate $U$, the one-way ($A \rightarrow S$) adaptive AAPV protocol $\Omega$ can always be converted to a PMPV protocol $\Xi$ with the worst-case failure probability satisfying
\[
\max_{F_e(\mathcal{E},U) \leq 1-\epsilon} \text{Tr}(\Xi \mathcal{E}) = \max_{F_e(\rho_U;\mathcal{E}) \leq 1-\epsilon} \text{Tr}(\Omega \rho_U) \leq 1 - \nu(\Omega).
\]

Hence, for verifying the quantum gate $U$, the efficiency of the deduced PMPV protocol $\Xi$ is equal to the efficiency of the AAPV protocol $\Omega$.

A few remarks on the difference between $\Xi$ and $\Omega$ are in order. First, although the AAPV $\Omega$ requires an ancilla system, it has the benefit that only one single kind of (despite entangled) input states are needed. On the contrary, in PMPV $\Xi$, no ancilla system is required, but different kinds of input states are needed. Second, the AAPV protocol $\Omega = \sum_i M_i \otimes N_i$, the POVM $\{M_i\}$ is usually preferred to be written as a convex combination of projective measurements which are more experiment-friendly: this is however not necessary for PMPV as $\rho_i = M_i^T / \text{Tr}(M_i)$ are just different kinds of input states. For example, when no extra restrictions are imposed, instead of using mutually unbiased bases as the input states, one can use the general spherical $2$-designs which are easier to be constructed for a general $d$-dimensional space [26].

**Applications.** Quantum gates are basic yet essential components in various quantum information processing tasks. Here we demonstrate that our schemes can verify various quantum gates and quantum circuits efficiently and practically. For demonstration, we take the verification of the CNOT gate and the Clifford circuits as examples; more applications can be found in Appendix B.

The CNOT gate operates on two qubits which flips the second qubit if and only if the first qubit is $|1\rangle$. To verify it, we use the four-qubit entangled state
\[
|\psi\rangle = |0000\rangle + |0101\rangle + |1010\rangle + |1111\rangle
\]
as inputs in the AAPV protocol. Then the corresponding Choi state is given by
\[
\mathcal{Y}_{\text{CNOT}} = (I \otimes \mathcal{CNOT})(|\psi\rangle\langle\psi|) = |\phi\rangle\langle\phi|,
\]
where $\mathcal{CNOT}$ denotes the corresponding operation of the CNOT gate and
\[
|\phi\rangle = |0000\rangle + |0101\rangle + |1110\rangle + |1011\rangle.
\]
One notices that $|\phi\rangle$ is a stabilizer state, which can be verified efficiently by
\[
\Omega_{\text{CNOT}} = \frac{1}{4} (P_{2XXZ}^+ + P_{1ZZZ}^+ + P_{ZZZ}^+ + P_{XXZ}^+),
\]
where $X$ and $Z$ are Pauli operators, and the superscript $+$ indicates the projector onto the eigenspace with eigenvalue $1$. The spectral gap is given by $\nu(\Omega_{\text{CNOT}}) = 1/4$. Accordingly, we can construct the PMPV protocol by employing the relation in Eq. (16).

The efficiency of verifying the CNOT gate can be further improved by employing more measurement settings. In fact, together with the Hadamard gate and the phase gate, the CNOT gate generates the so-called Clifford circuits which are key components in many schemes for
quantum error correction and become universal for quantum computation when augmented with certain state preparations. Here, we show that our schemes are able to verify arbitrary Clifford circuit efficiently; see below the proposition.

**Proposition 3.** For any $n$-qubit Clifford circuit, we can construct the AAPV and PMPV protocols for verifying it to the entanglement fidelity $1 - \epsilon$ and the confidence level $1 - \delta$ with the number of input states satisfying

$$N \approx \frac{2^{2n} - 1}{2^{2n-1}} \epsilon^{-1} \ln \delta^{-1} \leq 2\epsilon^{-1} \ln \delta^{-1}. \quad (22)$$

Furthermore, all the measurements required are local Pauli measurements.

**Proof.** For the Clifford circuit $C$, the ancilla-assisted $I \otimes C$ remains as a Clifford circuit. Then the output Choi state is a 2$n$-qubit stabilizer state since the input maximally entangled $|\psi\rangle = (|00\rangle + |11\rangle)^{\otimes n}$ is a 2$n$-qubit stabilizer state [2]. The verification of all stabilizer states [17] can be constructed systematically by using the full set of stabilizers with $\nu(\Omega) = 2^{2n-1}/(2^{2n} - 1)$, thus

$$N \approx \frac{2^{2n} - 1}{2^{2n-1}} \epsilon^{-1} \ln \delta^{-1} \leq 2\epsilon^{-1} \ln \delta^{-1}. \quad \Box$$

We note that the best known method so far for the verification of Clifford circuits is DFE which, however, requires $O(\epsilon^{-2} \log \delta^{-1})$ input states with infidelity $\epsilon$ and confidence level $1 - \delta$, so that our QPV protocols over DFE with respect to the infidelity $\epsilon$ is universal. In fact, from Propositions 1 and 2, the quadratic improvement of our QPV protocols over DFE is exponential faster. In fact, although the physical settings of RB are rather different, our QPV protocols are still quadratically more efficient according to the statistical analysis in Refs. [16, 37] if sample complexity is considered.

Besides the Clifford gates, our protocols can also be used for the efficient verification of other important classes of quantum gates. For example, by taking advantage of the verification method for hypergraph states [21], we can verify $n$-qubit $C^{(n-1)}X$ and $C^{(n-1)}Z$ gates including the Toffoli (ccnot) gate, with $N \approx (n+1)\epsilon^{-1}\ln \delta^{-1}$ input states; see Appendix B for more details. Furthermore, our method is also applicable to the verification of the processes of some well-known quantum algorithms. In Appendix C, we take the Deutsch-Jozsa algorithm [38] as an example to illustrate this point.

**Verification of quantum measurement.**—At last, we also briefly show that our protocols for process verification can also be easily adapted to verify quantum measurements. The verification of quantum measurement is similar to the verification of quantum process with post-selection. However, they are also different in the sense that we cannot assume the availability of reliable quantum measurements anymore for measurement verification.

Suppose that we want to verify the projective measurement $\mathcal{P} = \{|i\rangle\langle i|\}_{i=1}^d$. For an arbitrary measurement $\mathcal{M} = \{M_i\}_{i=1}^d$, we characterize the fidelity between $\mathcal{P}$ and $\mathcal{M}$ with

$$F(\mathcal{M}, \mathcal{P}) = \frac{1}{d} \sum_{i=1}^d \langle i|M_i|i \rangle. \quad (23)$$

If we want to distinguish the two cases, $F(\mathcal{M}, \mathcal{P}) = 1$ or $F(\mathcal{M}, \mathcal{P}) \leq 1 - \epsilon$, we just need to prepare the input state $|i\rangle$ with probability $1/d$ and measure it with the measurement $\mathcal{M}$. If the measurement outcome is $i$, then we say that $\mathcal{M}$ passes the test, otherwise we say that $\mathcal{M}$ fails the test. Thus, the failure probability of the protocol in each run is given by

$$\max_{F(\mathcal{M}, \mathcal{P}) \leq 1 - \epsilon} \sum_{i=1}^d \langle i|M_i|i \rangle = 1 - \epsilon, \quad (24)$$

which follows directly from the definition in Eq. (23). This implies that we can verify the projective measurement $\mathcal{P}$ with $N \approx \epsilon^{-1} \ln \delta^{-1}$ copies of input states.

For entangled measurements in multi-partite systems, we have two choices. First, if we can generate entangled input states, we can simply use the previous protocol for verifying the measurements. Second, in the case that we can trust the reliability of single-partite measurements, then the verification of entangled measurements (or more precisely, quantum instruments) can be treated as verifying quantum process with post-selection; for more details, see Appendix A.

**Summary.—**The efficient characterization and identification of quantum processes play a crucial role in almost all tasks of quantum information processing, such as quantum computation, quantum communication, quantum metrology, and more. In this work, by proposing the concept of QPV, we have established two efficient and practical protocols for verifying quantum processes based on the similar spirit as that for QSV. Compared to the known methods, our protocols can provide an exponential improvement over QPT and a quadratic improvement over DFE. Specifically, we demonstrated the efficacy of our verification protocols with many applications, including the verification of various quantum gates, quantum circuits, as well as processes of quantum algorithms.

As an extension, we proved that quantum measurements can also be efficiently verified by using a similar idea as that for quantum processes. Moreover, the protocols proposed in this work are well within the reach of current experimental techniques as only local measurements are needed. As an outlook, it is meaningful to consider how our protocols should be modified in the presence of state preparation and measurement errors.

Appendix A: Quantum process verification

In real experiments, the quantum process $E$ is often not trace-preserving due to post-selection or particle losses. In this appendix, we show that our QPV protocols still work in such a scenario.

We consider the AAPV protocol first and define the Choi matrix as

$$\Upsilon_E = (I \otimes E) (|\psi\rangle\langle\psi|) = \sum_{k,l=1}^d |k\rangle\langle l| \otimes E(|k\rangle\langle l|),$$

(25)

where $|\psi\rangle = \sum_{k=1}^d |k\rangle_A |k\rangle_S$, and the Choi-Jamiolkowski isomorphism

$$\mathcal{E}(\rho) = \text{Tr}_A \left( (\rho^T \otimes 1) \Upsilon_E \right)$$

(26)

still holds. Further, we define the corresponding Choi state as

$$\rho_E := \Upsilon_E / \text{Tr}(\Upsilon_E).$$

(27)
When $\mathcal{E}$ is trace-preserving, $\rho_\mathcal{E}$ can be interpreted as the output of the process $I \otimes \mathcal{E}$ for the (normalized) input state $|\psi\rangle$. When $\mathcal{E}$ is not trace-preserving (more precisely, trace-decreasing), $\rho_\mathcal{E}$ can be viewed as the output state after post-selection. That is, an output is not guaranteed to be obtained for every input. Hence, we also call $\rho_\mathcal{E}$ the post-selected Choi state. We can apply the QSV protocol for verifying $\mathcal{K}$ when $\rho_\mathcal{K}$ is a pure state. For a quantum process $\mathcal{K}$, $\rho_\mathcal{K}$ is a pure state if and only if

$$\mathcal{K}(\rho) = K\rho K^\dagger,$$

(28)

Without loss of generality, we assume that $K$ is of full rank, then the corresponding operation with post-selection can be written as

$$\tilde{\mathcal{K}}(\rho) = \frac{K\rho K^\dagger}{\text{Tr}(K\rho K^\dagger)}.$$  
(29)

Note that under post-selection, $K$ can be verified only up to a constant factor $c$, i.e., $\tilde{\mathcal{K}}$ is invariant when $K \rightarrow cK$. Hence, instead of choosing the number of copies of the input states as the figure of merit, we choose the number of copies of the post-selected output states, which is invariant under $K \rightarrow cK$. Still, we rely on the entanglement fidelity defined as

$$F_e(\mathcal{E}, \mathcal{K}) := F(\rho_\mathcal{E}, \rho_\mathcal{K}).$$  
(30)

Furthermore, one can easily see that when we relax the trace-preserving condition, $\rho_\mathcal{E}$ can be any quantum state according to the Choi-Jamiołkowski isomorphism. Then, the following proposition follows directly from the corresponding result in QSV.

**Proposition 4.** For any quantum process with post-selection $\tilde{\mathcal{K}}(\rho) = \frac{K\rho K^\dagger}{\text{Tr}(K\rho K^\dagger)}$, we can verify $\tilde{\mathcal{K}}$ to the entanglement fidelity $1 - \epsilon$ and confidence level $1 - \delta$ with $N \approx \frac{1}{\epsilon} \ln \frac{1}{\delta}$ post-selected output states by verifying the post-selected Choi state $\rho_\mathcal{K}$ with the QSV protocol $\Omega$.

As in the case of verification for quantum gates, we can show that a one-way ($A \rightarrow S$) adaptive AAPV protocol can be converted to a PMPV protocol without any efficiency loss. Still, we denote a PMPV protocol as

$$\Xi = \sum_i p_i \rho_i \otimes N_i,$$

(31)

with the requirement that $\text{Tr}[\mathcal{K}(\rho_i)N_i] = 1$, i.e.,

$$\text{Tr}(K_i\rho_i K_i^\dagger N_i) = \text{Tr}(K_i\rho_i K_i^\dagger).$$  
(32)

Then in each run (when there is an output state), the worst-case failure probability is given by

$$\max_{F_e(\mathcal{E}, \mathcal{K}) \leq 1 - \epsilon} \frac{\sum_i p_i \text{Tr}[\mathcal{E}(\rho_i)N_i]}{\sum_i p_i \text{Tr}[\mathcal{E}(\rho_i)]} = \max_{F_e(\mathcal{E}, \mathcal{K}) \leq 1 - \epsilon} \frac{\text{Tr}(\Xi \mathcal{E})}{\text{Tr}[\mathcal{E}(\rho)]},$$  
(33)

where $\bar{\rho} := \sum_i p_i \rho_i$. Given that $N_i \leq \mathbb{1}$, Eq. (32) is equivalent to that

$$\frac{\text{Tr}(\Xi \mathcal{E})}{\text{Tr}[\mathcal{E}(\rho)]} = 1.$$  
(34)

For the Choi state $\mathcal{Y}_\mathcal{K}$, the one-way ($A \rightarrow S$) adaptive QSV protocol takes on the general form

$$\Omega = \sum_i M_i \otimes N_i,$$

(35)

such that $\{M_i\}_i$ is a POVM on the ancilla system $A$, i.e., $\sum_{i=1}^a M_i = \mathbb{1}$ and $\{N_i, \mathbb{1} - N_i\}$ is a pass or fail test on system $S$ which depends on the measurement outcome of $\{M_i\}_i$. To ensure that the target state always passes the test, $\Omega$ also needs to satisfy

$$\text{Tr}(\Omega \rho_\mathcal{K}) = \frac{\text{Tr}(\Omega \mathcal{Y}_\mathcal{K})}{\text{Tr}(\mathcal{Y}_\mathcal{K})} = 1.$$  
(36)
Now, we can convert any one-way adaptive QSV for $\rho_K$ in Eq. (35) to a PMPV of the form in Eq. (31) by letting

$$p_i = \frac{\text{Tr}(M_i)}{d}, \quad \rho_i = \frac{M_i^T}{\text{Tr}(M_i)};$$

(37)

where $\sum_i p_i = 1$ follows from $\sum_i M_i = 1$. Further, we have

$$\bar{\rho} = \sum_i p_i \rho_i = \frac{I}{d}, \quad \text{Tr}(\Upsilon_K) = \text{Tr}[\mathcal{K}(I)] = d\text{Tr}[\mathcal{K}(\bar{\rho})].$$

(38)

Then, one can easily verify that

$$\Xi = \frac{1}{d}\Omega, \quad \frac{\text{Tr}(\Xi \Upsilon_K)}{\text{Tr}[\mathcal{K}(\bar{\rho})]} = 1.$$

(39)

from Eqs. (36), (37), and (38). Similarly, we can also show that

$$\text{Tr}[\mathcal{E}(\bar{\rho})] = \text{Tr}[\mathcal{E}(\frac{I}{d})] = \frac{1}{d}\text{Tr}(\Upsilon_\mathcal{E}).$$

(40)

Thus, we have the following proposition for the resources required in the derived PMPV protocol.

**Proposition 5.** For any quantum process with post-selection $\tilde{K}(\rho) = K\rho K^\dagger/\text{Tr}(K\rho K^\dagger)$, the one-way $(A \rightarrow S)$ adaptive QSV protocol $\Omega$ can always be converted to a PMPV protocol $\Xi$ with the worst-case failure probability satisfying

$$\max_{F(e,\mathcal{E},K) \leq 1-\epsilon} \frac{\text{Tr}(\Xi \Upsilon_\mathcal{E})}{\text{Tr}[\mathcal{K}(\bar{\rho})]} = \max_{F(e,\mathcal{E},\rho_K) \leq 1-\epsilon} \text{Tr}(\Omega \rho_\mathcal{E}) = 1 - \nu(\Omega).$$

(41)

Hence, to verify the quantum process with post-selection $\tilde{K}(\rho) = K\rho K^\dagger/\text{Tr}(K\rho K^\dagger)$, the efficiency of the deduced PMPV protocol $\Xi$ is equal to the efficiency of the AAPV protocol $\Omega$.

**Appendix B: More applications**

In this Appendix, we present the verification of more quantum gates using the AAPV and PMPV protocols.

1. **Identity**

The identity $I(\rho) = \rho$ represents a trivial process. The corresponding Choi state is the maximally entangled state itself, i.e.,

$$\Upsilon_I = |\psi\rangle\langle\psi| = \begin{bmatrix} 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 \end{bmatrix}. $$

(42)

Then, the AAPV protocol to verify $I$ is given by

$$\Omega_{\Upsilon_I} = \frac{1}{2}(P_{XX}^+ + P_{ZZ}^+),$$

(43)

and the spectral gap is $\nu(\Omega_{\Upsilon_I}) = 1/2$. Accordingly, the PMPV protocol is given by

$$\Xi_{\Upsilon_I} = \frac{1}{4}(|+\rangle\langle+| \otimes |+\rangle\langle+| + |+\rangle\langle-| \otimes |-\rangle\langle-| + |0\rangle\langle0| \otimes |0\rangle\langle0| + |1\rangle\langle1| \otimes |1\rangle\langle1|),$$

(44)

where $|\pm\rangle = \frac{1}{\sqrt{2}}(|0\rangle \pm |1\rangle)$. The verification operator $\Xi_{\Upsilon_I}$ tells us all the P&M with their corresponding probability distributions.

Note that the protocol $\Omega_{\Upsilon_I}$ in Eq. (43) is not actually optimal. The efficiency can be further improved by using more measurement settings such that

$$\Omega'_{\Upsilon_I} = \frac{1}{2}(P_{XX}^+ + P_{YY}^- + P_{ZZ}^+),$$

(45)
then the spectral gap is \( \nu(\Omega_{\mathcal{Y}_S}) = 2/3 \). Similar results can be obtained for the PMPV protocol, where the efficiency can be improved by involving more different kinds of input states.

Furthermore, the above protocols can be directly adapted for verifying any single-qubit gate \( U \) by the following substitutions,

\[
X \otimes X \to X \otimes UXU^\dagger, \quad Y \otimes Y \to Y \otimes UYU^\dagger, \quad Z \otimes Z \to Z \otimes UZU^\dagger. \tag{46}
\]

See below for some concrete examples.

2. The bit-flip gate

The bit-flip gate is \( X = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \), which is actually the Pauli-X operator. The corresponding Choi state is

\[
\mathcal{Y}_X = (I \otimes \mathcal{X})(|\psi\rangle\langle\psi|) = \frac{1}{2} \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}. \tag{47}
\]

Then, the AAPV protocol to verify \( X \) is given by

\[
\Omega_{\mathcal{Y}_X} = \frac{1}{2} \left( P_{XX}^+ + P_{ZZ}^+ \right) \tag{48}
\]

with the spectral gap being \( \nu(\Omega_{\mathcal{Y}_X}) = 1/2 \). Accordingly, the PMPV protocol is given by

\[
\Xi_{\mathcal{Y}_X} = \frac{1}{4} \left( |+\rangle\langle+| \otimes |0\rangle\langle0| + |−\rangle\langle−| \otimes |1\rangle\langle1| + |0\rangle\langle0| \otimes |+\rangle\langle+| + |1\rangle\langle1| \otimes |−\rangle\langle−| \right). \tag{49}
\]

3. The Hadamard gate

The Hadamard gate is \( H = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ 1 & −1 \end{bmatrix} \), with the corresponding Choi state

\[
\mathcal{Y}_H = (I \otimes \mathcal{H})(|\psi\rangle\langle\psi|) = \frac{1}{2} \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 \\ −1 & −1 & −1 & −1 \end{bmatrix}. \tag{50}
\]

Then, the AAPV protocol is given by

\[
\Omega_{\mathcal{Y}_H} = \frac{1}{2} \left( P_{XX}^+ + P_{ZZ}^+ \right) \tag{51}
\]

with the spectral gap being \( \nu(\Omega_{\mathcal{Y}_H}) = 1/2 \). Accordingly, the PMPV protocol is given by

\[
\Xi_{\mathcal{Y}_H} = \frac{1}{4} \left( |0\rangle\langle0| \otimes |0\rangle\langle0| + |1\rangle\langle1| \otimes |1\rangle\langle1| + |0\rangle\langle0| \otimes |+\rangle\langle+| + |1\rangle\langle1| \otimes |−\rangle\langle−| \right). \tag{52}
\]

4. The phase gate

The one-qubit phase gate is written as \( S = \begin{bmatrix} 1 & 0 \\ 0 & i \end{bmatrix} \), with the corresponding Choi state

\[
\mathcal{Y}_S = (I \otimes \mathcal{S})(|\psi\rangle\langle\psi|) = \frac{1}{2} \begin{bmatrix} 1 & 0 & 0 & −i \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}. \tag{53}
\]

Then, the AAPV protocol is given by

\[
\Omega_{\mathcal{Y}_S} = \frac{1}{2} \left( P_{XX}^+ + P_{YY}^+ \right) \tag{54}
\]

with the spectral gap being \( \nu(\Omega_{\mathcal{Y}_S}) = 1/2 \). Accordingly, the PMPV protocol is given by

\[
\Xi_{\mathcal{Y}_S} = \frac{1}{4} \left( |0\rangle\langle0| \otimes |0\rangle\langle0| + |1\rangle\langle1| \otimes |1\rangle\langle1| + |+\rangle\langle+| \otimes |\top\rangle\langle\top| + |−\rangle\langle−| \otimes |\bot\rangle\langle\bot| \right), \tag{55}
\]

where \(|\top\rangle = \frac{1}{\sqrt{2}}(|0\rangle + i|1\rangle)\) and \(|\bot\rangle = \frac{1}{\sqrt{2}}(|i0\rangle + |1\rangle)\).
corresponding Choi state is $I \otimes C \approx N$ which uses six stabilizer generators. The spectral gap is equivalent to that of $C$ as a special example. Here, we only show the verification of the derivation of Eq. (56). Then after the unitary gate $1_f$, if instead $\nu(\Omega) = 1$, the process of the algorithm is the trivial identity $|\psi\rangle = (|00\rangle + |11\rangle)^{\otimes n}$, we use $|\tilde{\psi}\rangle = (|0\rangle|+\rangle + |1\rangle|-angle)^{\otimes n} = CZ^{\otimes n}|+\rangle^{\otimes 2n}$, which is equivalent to $|\psi\rangle$ up to a local unitary transformation. Note also that we have omitted the normalization in the derivation of Eq. (56). Then after the unitary gate $1_f \otimes C^{(n+1)}Z$, the output Choi state is a hypergraph state as shown in Fig. 1. One can easily see that the hypergraph is $n + 1$ colorable, as illustrated in the figure. Thus, by using the coloring protocol proposed in Ref. [21], we can construct the AAPV protocol with the spectral gap given by $\nu = 1/(n + 1)$, Hence, the number of input states required for verifying the $C^{(n+1)}Z$ gate to the fidelity $1 - \epsilon$ and the confidence level $1 - \delta$ is $N \approx (n + 1)\epsilon^{-1} \ln \delta^{-1}$. Similarly, one gets the PMPV protocol by using the relation in Eq. (16).

5. $C^{(n+1)}Z$ and $C^{(n+1)}X$ gates

As the last example for quantum gates, we consider the $C^{(n+1)}Z$ and $C^{(n+1)}X$ gates, with the Toffoli (ccnot) gate as a special example. Here, we only show the verification of $C^{(n+1)}Z$ gates. The verification of $C^{(n+1)}X$ gates is equivalent to that of $C^{(n+1)}Z$ gates up to some local unitary transformations.

For the construction of the Choi state, instead of choosing the input state as $|\psi\rangle = (|00\rangle + |11\rangle)^{\otimes n}$, we use $|\tilde{\psi}\rangle = (|0\rangle|+\rangle + |1\rangle|-angle)^{\otimes n} = CZ^{\otimes n}|+\rangle^{\otimes 2n}$, which is equivalent to $|\psi\rangle$ up to a local unitary transformation. Note also that we have omitted the normalization in the derivation of Eq. (56). Then after the unitary gate $1_f \otimes C^{(n+1)}Z$, the output Choi state is a hypergraph state as shown in Fig. 1. One can easily see that the hypergraph is $n + 1$ colorable, as illustrated in the figure. Thus, by using the coloring protocol proposed in Ref. [21], we can construct the AAPV protocol with the spectral gap given by $\nu = 1/(n + 1)$, Hence, the number of input states required for verifying the $C^{(n+1)}Z$ gate to the fidelity $1 - \epsilon$ and the confidence level $1 - \delta$ is $N \approx (n + 1)\epsilon^{-1} \ln \delta^{-1}$. Similarly, one gets the PMPV protocol by using the relation in Eq. (16).

Appendix C: Verification of the Deutsch-Jozsa algorithm

The Deutsch-Jozsa algorithm [38] is used to determine whether a given function $f(x)$ is constant or balanced. The process of this algorithm is different depending on the function type of $f(x)$. Below we show the verification of a few typical cases by using our protocols.

First, we consider the case when $f(x)$ is a constant function. If $f(x) = 0$, the process is the trivial identity $I^{\otimes (n+1)}$. If instead $f(x) = 1$, the process of the algorithm is $I^{\otimes n} \otimes Z$ which can also be efficiently verified. For demonstration, we consider the 3-qubit case, i.e., $I^{\otimes 2} \otimes Z$. The corresponding Choi state is given by $\Upsilon_{f(x)=1} = |\phi_1\rangle \langle \phi_1|$, where $|\phi_1\rangle = |000000\rangle - |001001\rangle + |010010\rangle - |011011\rangle + |100100\rangle - |101101\rangle + |110110\rangle - |111111\rangle$. Then, we can construct the AAPV protocol as

$$
\Omega_{\Upsilon_{f(x)=1}} = \frac{1}{6}(P_{ZZZZZZ}^+ + P_{ZZYZZY}^+ + P_{ZZXXZZZ}^+ + P_{ZYZZYZZ}^+ + P_{ZZXZZZZZ}^+ + P_{ZYYZYZZZ}^+),
$$

which uses six stabilizer generators. The spectral gap is $\nu(\Omega_{\Upsilon_{f(x)=1}}) = 1/6$, so the number of input states required is $N \approx 6\epsilon^{-1} \ln \delta^{-1}$ with fidelity $1 - \epsilon$ and the confidence level $1 - \delta$.

Next, we consider the balanced case which may have many different varieties of $f(x)$. Take the 3-qubit case $I \otimes C_{\text{NOT}}$ as an example, in which the function is completely determined by the second qubit, namely $f(x) = x_2$. The corresponding Choi state is

$$
\Upsilon_{f(x)=x_2} = |\phi_b\rangle \langle \phi_b|,
$$

where $|\phi_b\rangle$ is a balanced state.
where
\[ |\phi_b\rangle = |000000\rangle + |001001\rangle + |011010\rangle + |010011\rangle + |100100\rangle + |101101\rangle + |111110\rangle + |110111\rangle. \] (61)

Then, the AAPV protocol is constructed as
\[ \Omega_{f(x) = x_2} = \frac{1}{6} (P_{ZZZZZZ} + P_{ZZYZZY} + P_{ZZXZZX} + P_{ZYZZYZ} + P_{ZXZZXZ} + P_{YZZYZZ}), \] (62)
which also utilizes six stabilizer generators, and the spectral gap is \( \nu(\Omega_{f(x) = x_2}) = 1/6 \). Accordingly, the PMPV protocols for all the cases studied above can be easily constructed by using Eq. (16).
