Hazardous tsunamis are known to be generated predominantly at subduction zones by large earthquakes on dip (vertical)-slip faults. However, a moment magnitude ($M_w$) 7.5 earthquake on a strike (lateral)-slip fault in Sulawesi (Indonesia) in 2018 generated a tsunami that devastated the city of Palu. The mechanism by which this large tsunami originated from a strike-slip earthquake has been debated. Here we present near-field ground motion data from a GPS station that confirms that the 2018 Palu earthquake attained supershear speed, i.e., a rupture speed greater than the speed of shear waves in the host medium. We study the effect of this supershear rupture on tsunami generation by coupling the ground motion to a one-dimensional non-linear shallow-water wave model that accounts for both the time-dependent bathymetric displacement and velocity. With the local bathymetric profile of the Palu bay around a tidal station, we find that these simulations reproduce the tsunami arrival and motions observed by CCTV camera records, with only minimal tuning of parameters. We conclude that Mach (shock) fronts, generated by the supershear speed of the earthquake, interacted with the bathymetry and contributed to the tsunami. This suggests that rupture speed should be considered in tsunami hazard assessments.
bay in which hundreds were killed and tens of thousands more displaced from their homes.\textsuperscript{7} However, this was an unexpected event since the earthquake was associated with the predominantly in-plane ground motion produced by strike-slip ruptures. As these motions are not known to excite notable waves, the underlying physical mechanisms behind the tsunami have largely remained a mystery.\textsuperscript{8} Many studies conducted to explain the phenomenon have not arrived at definitive conclusions\textsuperscript{9} nor have adequately captured observed records\textsuperscript{10,12} the main consensus appears to be that some form of ground motion (e.g., landslides\textsuperscript{15} or the reverse-slip motion of the fault\textsuperscript{14})), amplified by the bay, is to blame.

However, a key notable feature of this earthquake is that it ruptured at supershear speed\textsuperscript{15,16} which results in a manifestation of two shock (or Mach) fronts carrying substantial vertical velocity with relatively slow attenuation over large distances.\textsuperscript{17} The existence of supershear earthquakes has been proven theoretically and experimentally since the early 1970s\textsuperscript{18-24} The $M_{w} 6.5$ Imperial Valley earthquake (California, 1979) was the first naturally observed supershear earthquake rupture.\textsuperscript{25} Since then, many more (although rare) earthquakes have been recorded to propagate at supershear speeds: the $M_{w} 7.4$ 1999 Izmit in Turkey,\textsuperscript{26} the $M_{w} 7.8$ 2001 Kunlun\textsuperscript{27} and the $M_{w} 7.8$ 2002 Denali\textsuperscript{28,29} to name a few.

Although the overall tsunami behaviour at Palu is likely a combination of several effects that include these supershear dynamics as well as landslides, recent studies\textsuperscript{10,12,30} suggest that the influence from phenomena such as the latter may be secondary: the rupture itself may have created adequate seafloor movement to excite the tsunami, which was subsequently amplified by the shallow and narrow two-dimensional (2D)/3D geometric features of the Palu bay. Indeed, high-frequency waveform observations (1Hz) from carefully calibrated analysis of CCTV and social media camera footage near the Pantoloan (PANT) station suggest a near instantaneous, high-frequency, tsunami arrival\textsuperscript{31}—consistent with a co-seismic source near the coast. This arrival is not captured by observations that were made by the one working acoustic sensor at the PANT tidal gauge\textsuperscript{32} whose resolution (0.02Hz, or one measurement per minute) is too coarse to have captured the much shorter wavelength (a 1-2 minute period\textsuperscript{31}) of the tsunami as observed by the high-resolution camera analysis.

Hence the primary objective of this work is to explain this earlier arrival time by elucidating the tsunami generation process of the supershear strike-slip Palu earthquake in order to more fully understand the role played by the corresponding rupture dynamics on the observed timing and first motions of the subsequent tsunami. In particular, we incorporate a feature neglected in previous modelling studies on Palu\textsuperscript{10,12} that is a defining characteristic of supershear earthquakes: the velocity of the ground motion.\textsuperscript{17} Using a model validated by the first near-field evidence of supershear at Palu, our results imply that ground velocities, which better represent the intricacies of the Mach fronts, may further explain the observed motions of the tsunami. Since other studies (including those investigating landslides and liquefaction) have adequately captured much of the observed run-up amplitudes and some local inundations,
the scope of this paper is to focus on the arrival, first motions and phases inferred from CCTV camera records near the PANT station[31,32].

Evidence of a supershear rupture

The most unmistakable signature of a supershear rupture is that the fault parallel particle velocity dominates over the fault normal velocity[29,33] (when the rupture velocity \(v\) is greater than \(\sqrt{2}c_s\) for a shear wave speed \(c_s\)). The opposite signature is expected for a subshear rupture. Fig. 1a shows the Palu-Koro fault system with the location of the high-rate, 1Hz, PALP GPS station. Figs. 1b-c show the particle velocities recorded during the Sulawesi earthquake, clearly demonstrating a fault parallel particle velocity greater than the fault normal velocity (\(\sim 1.0\) m/s versus \(\sim 0.7\) m/s). This proves that the rupture, as it passed by the PALP station, definitively went supershear and hence attained a speed between \(\sqrt{2}c_s\) and the P-wave speed, \(c_p\), of the medium (the absolute limiting speed of the rupture). This represents the first-ever observation of a supershear rupture by a high-rate GPS station. Socquet et al.[16] and Bao et al.[15] have also inferred that this earthquake went supershear, but mainly through far-field observations employing geodetic and teleseismic data, respectively. The only other near-field evidence of a supershear earthquake was obtained using an accelerometer (250Hz) at Pump Station 10 (PS10) during the 2002 Mw 7.9 Denali earthquake[28,29].

We can further compare the PALP records against a 3D supershear earthquake simulation[17] whose rupture propagates at a speed of \(v = 1.6c_s\) and whose corresponding particle velocities are computed at 100Hz and then decimated to match the 1Hz sampling rate of the GPS observations (see Methods). The synthetic data and the GPS records are in excellent agreement for the main rupture pulse (Figs. 1b-c). Subsequent arrivals are not as well-captured since the numerical model does not account for local velocity structure nor detailed fault geometry. A similar comparison with synthetic velocities computed for a subshear rupture \((v = 0.8c_s)\) finds that they are in poor agreement with GPS data (Figs. 1d-e). This clearly suggests that the supershear rupture speed was \(1.6c_s\) (around 5.3 km/s) when it passed by PALP (Ulrich et al.[12] also find a speed greater than \(\sqrt{2}c_s\)). We have thus provided the first near-field high-rate GPS-based evidence that the Sulawesi earthquake rupture actually did go supershear as claimed and, further, have validated the numerical data employed to source the tsunami model in what follows.

Modelling the effect of supershear velocity on tsunami generation

Using the synthetic particle motions generated by the 3D supershear earthquake model (which, again, agree with PALP GPS records and are reasonably assumed to sweep past the bay near Pantoloan), a 1D non-linear shallow water wave model incorporating time-dependent ground movements of velocity and displacement[34] has been utilised to simulate the generation and propagation of the tsunami. This
employs the depth-averaged shallow water approximation of the Euler equations that can be written as a system of coupled hyperbolic partial differential equations given by

\[
\begin{align*}
\frac{\partial H}{\partial t} + \frac{\partial (Hu)}{\partial y} &= 0, \\
\frac{\partial (Hu)}{\partial t} + \frac{\partial (Hu^2)}{\partial y} + gH \frac{\partial \eta}{\partial y} &= 0, \
&\quad 0 \leq y \leq L, \quad t \geq 0. \quad (1)
\end{align*}
\]

Here, \(u(y, t)\) is the fluid velocity, \(\eta(y, t)\) is the sea surface height and \(H(y, t) = \eta(y, t) + h_0(y) - h(y, t)\) is the absolute height from the bed-level to the water surface for an initial at-rest bathymetry \(h_0(y)\). The entire domain of length \(L\) is subjected to a time-dependent ground perturbation \(h(y, t)\) which—together with the corresponding ground velocity \(\partial h(y, t)/\partial t\) included in Equation (1)—sources the subsequent tsunami dynamics. In what follows, these values are determined from the 3D supershear earthquake model\(^{17}\) The constant \(g\) is the acceleration due to gravity.

The specific Palu bay configuration is outlined in Fig. 2a along the horizontal \(y\)-axis, where \(z = \eta(y, t)\) represents the water height relative to the background sea level. The bathymetry shape closely approximates that of the segment demarcated by the dotted green line near the Pantoloan tidal gauge in Fig. 1a (basin width 9.2 km, maximum depth 710 m and an average slope of 7° to the east and 27° to the west of the bay). The shallowest part is taken to be 1 m, and the distance between the virtual gauge and the fault is 4.3 km. The complete computational domain is taken to be twice the basin width \((L = 18.4\) km\)). Fig. 2b presents a temporal snapshot in the \((x, y)\)-plane (the ground surface) illustrating the dynamic vertical velocity field (and associated Mach fronts) which is input as a synthetic source in conjunction with its corresponding time-dependent displacement field. The fault and the sense of slip (left-lateral) are indicated in red, and the data applied to perturb the bathymetry is taken along the green dotted line (whose locations correspond to the same markers indicated in Fig. 2a). For an example point located at \((x_0, y_0)\) and highlighted in a larger light green circle, Fig. 2c additionally presents the temporal evolution of both the vertical velocity (which can reach \(\sim 1\) m/s along the domain) as well as its corresponding ground displacement (which, in the 1D setting, can reach \(\sim 40\) cm). As already noted, the shapes and the maximum values of these profiles remain fairly unattenuated at large distances from the original earthquake—a hallmark of the energy carried by supershear shock fronts\(^{17}\) For the results that follow, Figs. 2d-e additionally present the analogous inputs for classical modelling of seismogenic tsunamis. In a classical setting\(^{15}\) the source is often modelled as a static displacement perturbation applied to the bathymetry (rather than dynamic ground motion), i.e., a static \(h(y, t) = h(y)\) that neither accounts for the time-dependence nor the velocity of the sea floor (other simple approximations to more complicated sources are also standard\(^{15,17}\)). From the supershear earthquake results, this corresponds to the final, permanent ground displacement at the end of the profiles in Fig. 2c and is expectedly on the order of a few centimeters.
Capturing the arrival and first motions at Pantoloan

Numerical solution of the non-linear shallow water wave equations has been facilitated by a spectral Fourier continuation (FC) methodology\cite{38,39} employing the bathymetry described above (see also Figs. 1 and 2). Such a solver enables high-order accuracy, mild constraints on the temporal discretisation and nearly dispersionless resolution of propagating waves over large distances\cite{38} (see Methods). Figs. 3a,b present results of the water height $z = \eta^*(y,t)$, normalised by the absolute maximum from the dynamic case (i.e., $\eta^*(y,t) = \eta(y,t)/\max(|\eta_{\text{dynamic}}(y,t)|)$), at various synthetic stations (whose locations are indicated in Fig. 3c) simulated by both the dynamic and static (classical) sources generated from the same supershear earthquake simulation (see Extended Data Fig. 1 for the complete spatiotemporal evolution).

The numerical modelling has been conducted at a much higher temporal resolution (time step, $\Delta t = 2.62 \times 10^{-3}$ s), but plotted at 10Hz. The effects of the dynamic source, which is on the order of seconds, clearly produces high-frequency and high-amplitude waves in contrast with the static source (see Fig. 3d for a comparison of the spectral content between the two). These high-energy waves are generated earlier than those of the static case but start shedding their high energy content as they slow down in their progress towards the coastline; the two begin to resemble one another in shape (see Extended Data Fig. 2 for an alternate visualisation in the form of snapshots in time across the bay). We note that, for comparison throughout, we have presented normalised water heights: since more energy of the Mach fronts is carried along the fault\cite{17} running in the direction $x$ (Fig. 2), the 1D model in $y$ will naturally generate lower amplitudes (on the order of half a meter). However, similar tsunami signatures can still be expected and, indeed, Elbanna et al.\cite{40} demonstrated that, by incorporating horizontal motions in generic 2D/3D bay-like bathymetry, similar behaviour can be observed but with amplitudes on the order of metres.

Although the final waveforms are similar, a notable feature of Fig. 3b is the earlier arrival at the coastline for the dynamic case. This is more clearly illustrated in Fig. 4a, which presents the corresponding simulated time histories at the PANT station (whose geographic location is indicated in Fig. 1a) and, more importantly, presents a comparison between the waveforms of these models with those generated at 1Hz by carefully calibrated, and timed, CCTV and other video sources in the vicinity of the PANT tidal gauge.\cite{31} The simulations and camera records indicate an arrival that is expectedly\cite{32} not captured by the coarse (0.02Hz) tidal gauge at PANT, whose corresponding comparison to simulations is presented in Fig. 4b. Remarkably, the arrival and first motions observed from the camera records in Fig. 4a are in excellent agreement with the 1D approximation generated by excitation from the dynamic source. Later phases, which can be attributed to wave reflections within the bay, are not as well-captured since our model does not fully account for the localised effects of the 2D/3D bathymetric profile. Nevertheless, the tsunami arrival and primary dynamics are correctly reproduced.
By contrast, the static source model predicts a much later arrival. However, this is to be expected since we have employed a common approach of the classical modelling community where static results are shifted by the earthquake duration (i.e., the time taken to establish the final vertical displacement that is used for the static source, or about 42 seconds at Sulawesi\textsuperscript{11}). This is a reasonable assumption for far-field tsunamis, but it is not clear that this is justifiable for a near-field source like at Palu bay, nor is it clear how much of a shift should be introduced\textsuperscript{12}. The correct timing prediction is only possible through simulations informed by the full supershear dynamics (which need not make any such assumptions), where the corresponding comparisons in Fig. 4 suggest an essentially Occam’s razor explanation for the arrival observed by the PANT video waveforms: when the Sulawesi rupture went supershear, the high-frequency ground velocities carried by the shock fronts initiated a tsunami in Palu bay at the instance when the rupture swept past the station at $t \approx 13s$ (see also Extended Data Figs. 1 and 2).

Hence we confirm that the Sulawesi earthquake went supershear via the first near-field high-rate GPS-based evidence of such a rupture and that, by modelling the corresponding effect on the generation of tsunamis in a shallow geometry, we conclude that the ground motion resulting from the associated Mach fronts (which carry minimally attenuated velocities to large distances) may well have contributed to the initiation of the Palu tsunami. This work provides a robust proof of concept, albeit in 1D, on the contribution of shock fronts in tsunami generation. In order to gain further insight into this process, more detailed modelling in 3D is needed to account for, e.g., geometrical spreading, attenuation and geological structure. Regardless, since nothing geologically specific about the bay has been introduced, our results signify the importance of such configurations for tsunami hazard assessment due to strike-slip earthquakes. The same physical ingredients (supershear rupture and a shallow bay) may combine to produce similar effects elsewhere, including the Tomales bay in California (which is crossed offshore by the San Andreas fault system\textsuperscript{13}) and the Izmit bay in Turkey (which is crossed by the North Anatolian fault\textsuperscript{44}). Both these regions, as well as the Palu bay, have suffered from historical tsunamis. On the contrary, the 2012 Off Northern Sumatra earthquake and the 2013 Craig, Alaska earthquake both went supershear but caused negligible (or no) tsunamis since they occurred in deep ocean without any shallow bay near them. Additionally, the 1999 Izmit earthquake was subshear as it passed through the Izmit bay and thus generated only a negligible tsunami. Hence we reemphasise that supershear rupture and a shallow bay are key to generate contributions to tsunami motions. We thus suggest that any rapid assessment of tsunami hazard after a strike-slip earthquake should also involve a rapid assessment of the earthquake rupture velocity as we have shown that ultimately the focal mechanism, the depth and the speed of the rupture all contribute towards the generation of tsunamis.
Methods

**GPS data.** The dual-frequency GPS has been processed using the scientific GIPSY-OASIS II software version 6.4. The (post-processing) Precise Point Positioning (PPP) method was used in kinematic (1 s) mode to derive precise absolute coordinates for the PALP station. Precise ephemeris of GPS satellites (non-fiducial style, using high-rate 30 s clocks) along with Earth rotation parameters (ERP) in the IGS14 framework were obtained from the Jet Propulsion Laboratory (JPL). A satellite elevation mask angle of 7 degrees and absolute International GNSS Service (IGS) antenna phase centre corrections were applied. The Vienna tropospheric Mapping Functions (VMF1) was used (in estimating both zenith delay and gradients) and downloaded from the Global Geodetic Observing System website (http://vmf.geo.tuwien.ac.at/). The global ocean tide model applied in the GPS data processing was (FES2014b), and the ocean loading parameters were retrieved from the Onsala Space Observatory website (http://holt.oso.chalmers.se/loading/). To enhance the coordinate solutions, the daily global wide lane phase bias (wlpb) files from JPL were used to resolve the phase cycle ambiguities. Although each kinematic position has a higher uncertainty and is affected by biases which usually cancel out over long periods of measurements, the instantaneous co-seismic displacements at PALP were much higher than the high-frequency noise of around 1 cm and 2 to 3 cm for, respectively, the horizontal and vertical positions. Finally the GPS time tags were corrected to UTC time by subtracting 18 s. The co-seismic displacement of the station simply follows from epoch-to-epoch coordinate differences. The standard available script was modified to properly weigh the phase/code measurements of the stations and also to output the correlations. The XYZ Cartesian component positions were then converted to the north-east-up positions along with their formal standard deviations. They are scaled using the weighted-root-mean-square of all the positions up to the time of the earthquake and generally reach a relative precision ($3\sigma$) of about 30 mm on the horizontal components. The resulting displacement field was then differentiated by computing adaptive linear fits adapted to satisfy an error to fit criteria. The slope of the linear fit then gives the local velocity. The resulting data was then resampled again at 1Hz by linear interpolation.

**Supershear earthquake dynamics and rupture modelling.** We have used the existing numerical simulations conducted by Dunham and Bhat. Additional details can be found in the cited manuscript. Numerical simulations were conducted using a staggered-grid finite-difference (FD) code with the fault boundary conditions implemented using the staggered-grid split-node (SGSN) method. As the authors had provided non-dimensionalised results we simply dimensionized their results for the Palu earthquake by using a shear modulus of 30 GPa, stress drop of 20 MPa and the shear wave speed of 3.5 km/s. The depth of the rupture was assumed to be 7.5 km. The resulting particle velocities and displacements are shown in Fig. 2.
Numerical analysis of shallow water wave equations. The complete non-linear system given by (1) is solved using a numerical scheme based on an accelerated Fourier continuation (FC) methodology for accurate Fourier expansions of non-periodic functions.\textsuperscript{38, 39, 55} Considering an equispaced Cartesian spatial grid on, for example, the unit interval \([0, 1]\) (given by the discrete points \(y_i = i/(N - 1), i = 0, \ldots, N - 1\)), Fourier continuation algorithms append a small number of points to the discretised function values \(\eta(y_i), u(y_i)\) in order to form \((1 + d)\)-periodic trigonometric polynomials \(\eta_{\text{cont}}(y), u_{\text{cont}}(y)\) that are of the form

\[
\eta_{\text{cont}}(y) = \sum_{k=-M}^{M} a_k e^{2\pi i ky/(1+d)}, \quad u_{\text{cont}}(y) = \sum_{k=-M}^{M} b_k e^{2\pi i ky/(1+d)}
\]  

and that match the given discrete values of \(\eta(y_i), u(y_i)\), i.e., \(\eta_{\text{cont}}(y_i) = \eta(y_i), u_{\text{cont}}(y_i) = u(y_i)\) for \(i = 0, \ldots, N - 1\). Spatial derivatives in equation (1) are then computed by exact term-wise differentiation of (2) as

\[
\frac{\partial \eta}{\partial y}(y_i) = \frac{\partial \eta_{\text{cont}}}{\partial y}(y_i) = \sum_{k=-M}^{M} \left(\frac{2\pi ik}{1+d}\right) a_k e^{2\pi i ky_i/(1+d)},
\]

\[
\frac{\partial u}{\partial y}(y_i) = \frac{\partial u_{\text{cont}}}{\partial y}(y_i) = \sum_{k=-M}^{M} \left(\frac{2\pi ik}{1+d}\right) b_k e^{2\pi i ky_i/(1+d)}.
\]  

In essence, FC algorithms add a handful of additional values to the original discretized function in order to form a periodic extension in \([1, 1 + d]\) that transitions smoothly from \(\eta(1)\) back to \(\eta(0)\) (similarly for \(u\)). The resulting continued functions can be viewed as sets of discrete values of periodic and smooth functions that can be approximated to high-order on slightly larger intervals by a trigonometric polynomial. Once these discrete periodic continuation functions have been constructed, corresponding Fourier coefficients \(a_k, b_k\) in equation (2) can be obtained rapidly from applications of the Fast Fourier Transform (FFT). A detailed presentation on accelerated construction of Fourier continuations can be found in, e.g., Amlani and Bruno.\textsuperscript{38}

Employing these discrete continuations in order to evaluate spatial function values and derivatives on the discretised physical domain modelled by equation (1), the algorithm is completed by employing the explicit fourth-order Adams-Bashforth scheme to integrate the corresponding ordinary differential equations in time from the given initial conditions \(\eta(y_i, t) = u(y_i, t) = 0\) up to a final given time. The final full solver enables high-order accuracy and nearly dispersionless resolution of propagating waves with mild, linear Courant-Friedrichs-Lewy constraints on the temporal discretisation—properties that are important for adequate resolution of the different spatial and temporal scales involved between the supershear source dynamics and the subsequent tsunami dynamics. Both implicit and explicit FC-based partial differential equation solvers have been successfully constructed and utilised for a variety of physical problems including those governed by classical wave and diffusion equations,\textsuperscript{19, 31} radiative transfer equations,\textsuperscript{52} non-linear Burgers systems,\textsuperscript{53} Euler equations,\textsuperscript{54} Navier-Stokes fluid equations,\textsuperscript{55, 57} Navier-
Cauchy elastodynamics equations and fluid-structure hemodynamics equations.

Bruno at Caltech for inspiring the numerical technique used in this study. A.S. would like to acknowledge the European Research Council grant REALISM (2016-grant 681346). A.J.R. was supported by the Caltech/MCE Big Ideas Fund (BIF). A.E. acknowledges support by the National Science Foundation (CAREER Award Number 1753249). The continued (long-term) operation of the GPS stations in Central Sulawesi, Indonesia data has been co-facilitated by the EU-ASEAN SEAMERGES (2004-2006) and GEO2TECDI-1/2 projects (2009-2013) in cooperation with the Geospatial Information Agency of Indonesia (BIG). The GPS data acquisition and research was also partly funded by grants from the Dutch NWO User Support Programme Space Research (2007-2018). We would like to express our special thanks to the local staff of the Indonesian Meteorology, Climatology, and Geophysical Agency (BMKG) offices in Palu, both for hosting the GPS station and for being available 24/7 to assist us with optimal operation of the GPS equipment. A special thanks to our local
survey staff, B.R. Umar and A. Urif, for their continued support, including directly after the earthquake for inspecting the GPS stations. H.S.B. would like to acknowledge K. Kiara and T. Aziliz for inspiring this work.

**Author contributions**

F.A. and H.S.B. designed and conceived the project and conducted numerical modelling studies. W.J.F.S., J.E. and C.V. have maintained the (high-rate) PALP station and obtained all GPS data. W.J.F.S. did the kinematic GPS data analysis. F.A. and H.S.B. wrote the manuscript. All authors contributed to analysis, interpretation and manuscript preparation.
