Abstract

A new tabulation of electronic factors is reported for electron conversion for elements of Z from 5 to 126 and electronic factors for electron-positron pair conversion for elements of even Z from 4 to 100. The electronic factors for electron conversion, $\Omega_{CE}(E0)$, were calculated using a modified version of the *CATAR* program developed by Pauli and Raff with a relativistic-Hartree-Fock-Slater approach (Comp. Phys. Comm. **9** (1975) 392). The electronic factors for electron-positron pair conversion, $\Omega_{IPF}(E0)$, were calculated using the model developed by Wilkinson (Nucl. Phys. **A133** (1969) 1). The data tables presented here cover all atomic shells up to R2 and transition energies from 1 keV to 6000 keV and from 1100 keV to 8000 keV for pair conversion. A comparison with previous electronic factor tabulations is presented. Ratios of experimental $\Omega(E0)$ values for 83 E0 transitions in $8 \leq Z \leq 98$ are compared to this tabulation. Two examples of how to use the tabulation to extract E0 strengths are also included.

1. Introduction

Electric monopole (E0) transitions connect quantum states of the same spin-parity in atomic nuclei and are associated with collective excitations and phenomena such as shape coexistence, isotope and isomer shift, and volume oscillations. After more than 80 years since the first suggestion of an E0 transition, the 1.426 MeV transition in Radium C (^{214}Po) by Ellis and Aston [1], the characterization of E0 transitions still remains a challenge for both experimental nuclear spectroscopy and nuclear theory [2–5].

The geometrical model of Bohr and Mottelson [6] predicts two different types of oscillations in deformed nuclei with an ellipsoidal shape: (a) the β -vibration which preserves axial symmetry, and (b) the γ -vibration which does not. Rotational structures built on these states can be observed in the low energy spectrum of many deformed even-even nuclei. Transitions from the 0^+ β -vibrational state to the ground state were considered as the classical examples of pure E0 transitions. In nuclei of spherical ground state, two-phonon excitations also can produce excited 0^+ states. However, recently, both of these vibrational models have been questioned [7]. An alternative approach, developed initially for the interpretation of 0^+ states in the vicinity of double-magic nuclei, has been proposed. Classical examples of these multiparticle multihole excitations across the shell gap are the 0^+ states in ^{16}O and ^{40}Ca , which in fact are the first-excited states in both nuclei. These states are deformed and in single closed-shell nuclei bands built on such excited 0^+ states have been observed in many cases. A distinct feature of these nuclei is the co-existence of spherical and deformed states at similar excitation energies and the presence of E0 transitions.

While in some cases it is possible to develop a consistent description of electric monopole transitions [5], further theoretical progress is required for a unified picture. Our experimental knowledge of pure E0 transitions, those between 0^+ states, including branching ratios and absolute transition rates, $B(\text{E0})$, is far from complete. Pure E0 transitions are expected over the entire nuclear landscape. For a recent review, see [3]. For $J \rightarrow J$ transitions, where $J > 0$, E0 transitions mix with E2 and M1 transitions giving, in the general case, transitions of mixed E0+E2+M1 multipolarity. The last review of these type of electromagnetic transitions, by Lange, Kumar and Hamilton [8] included the E0/E2 and E2/M1 mixing ratios, which are required to fully characterize such transitions. However, this review was published more than 30 years ago. A more recent compilation of mixed E0+E2+M1 transitions can be found in Wood *et al.* [2], but a full review of the subject is long overdue.

Central to the characterization of the E0 transitions is the knowledge of the E0 electronic factors,

$\Omega(E0)$. The E0 transition rate can be factorized into an electronic and a nuclear contribution. The nuclear component contains all of the information about the nuclear structure while the electronic factor represents the contribution of the atomic electrons to the transition rate. The E0 electronic factors cannot be measured directly but can be calculated theoretically. Without the electronic factors, the nuclear component cannot be extracted from the E0 transition rate.

BrIcc is a currently existing database of the most up-to-date and most accurate internal conversion and pair-conversion coefficients for elements of Z between 5 to 126 [9]. The conversion coefficients are obtained from the Dirac-Fock calculations of Band *et al.* [10], and the pair-conversion coefficients from the work of Soff and Hofmann [11, 12]. The current $\Omega(E0)$ table adopted for *BrIcc* [9] is based on three different calculations [13–15], which have been calculated using different physical assumptions, and cover only the K, L1 and L2 atomic shells; the energy and Z range is also limited. $\Omega(E0)$ pair conversion coefficients were calculated only for $8 \leq Z \leq 40$ atomic numbers. Therefore, a new, more complete tabulation is warranted.

In this paper, we present tables of electronic factors, $\Omega(E0)$ of electric monopole conversion probabilities for all atomic shells up to the R2 with transition energies from 1 keV above atomic shell binding energies to 6000 keV. New tabulations of $\Omega_{IPF}(E0)$ for pair conversion are also presented. These tables cover even Z in the range of 4 to 100 and transition energies from 1100 keV to 8000 keV. This coverage is compatible with the range of the recent electron conversion coefficient calculations by Kibédi *et al.* [9]. The numerical calculations have been carried out with a modified version of the *CATAR* program by Pauli and Raff [16] and using the self-consistent-field calculated via a modified version of the *HEX* code by Liberman, Cromer and Waber [17]. The details of the programs used and the modifications made will be discussed in 3.1. The $\Omega_{IPF}(E0)$ values were calculated using *WspOmega*, a new code based on the Wilkinson formulation [18].

2. E0 transitions and $\Omega(E0)$ electronic factors

The theoretical background for the emission of radiation via E0 transitions is well documented [3, 14, 19–21]. The electric monopole operator couples the nucleons to the atomic electrons and the Dirac sea. This interaction is completely localized within the nucleus and therefore the E0 transition rate depends strongly on the charge distribution of the nuclear quantum states. It is widely accepted that E0 transitions depend on certain details of the nuclear structure and can be used as a sensitive probe of nuclear models.

Electric monopole transitions proceed via the emission of a conversion electron or, for nuclear transitions of energy greater than twice the electron rest mass, through the emission of an electron-positron pair. The emission of a single γ ray is strictly forbidden due to the conservation of the angular momentum, and the probability of emission of two γ rays or de-excitation via any other two-quantum process is sufficiently low as to be negligible [21]. Two-quantum processes are not considered in this work. With these assumptions, the E0 transition probability can be expressed as

$$W(\text{E0}) = \frac{1}{\tau(\text{E0})} = W_{ce}(\text{E0}) + W_{IPF}(\text{E0}), \quad (1)$$

where $\tau(\text{E0})$ is the partial mean life of the excited state with respect to the E0 decay, and W_{ce} and W_{IPF} are the transition probabilities for internal conversion and pair emission, respectively.

Church and Weneser [19] were the first to introduce the so-called electronic factor, $\Omega(\text{E0})$, to evaluate the E0 transition probability, $W(\text{E0})$. The E0 transition probability can be separated into an atomic ($\Omega(\text{E0})$) and a nuclear ($\rho(\text{E0})$) component:

$$W(\text{E0}) = \Omega(\text{E0}) \times |\rho(\text{E0})|^2. \quad (2)$$

The dimensionless monopole strength parameter, $\rho(\text{E0})$, contains all of the information about nuclear structure and is related to the monopole matrix element, $M(\text{E0})$, by

$$\rho(\text{E0}) = \frac{\langle f | M(\text{E0}) | i \rangle}{eR^2}, \quad (3)$$

where e is the electronic charge, $R = R_o A^{1/3}$ is the nuclear radius, A is the atomic mass number, and $R_o = 1.20$ fm. The electronic factor is largely independent of the nuclear properties, but it depends on the atomic number, the nuclear transition energy, and in the case of electron conversion, the atomic shell involved.

2.1. Internal Conversion and $\Omega(\text{E0})$ electronic factors

The internal conversion pathway of the E0 transition is well studied and the details of the formulae and assumptions used here are described in detail in the work of Pauli, Alder, and Steffen [20]. The E0 transition rate can be expressed as

$$W_{ce}(\text{E0}) = 2\pi(j+1) \frac{|\langle I\kappa | H_0^E | I\kappa \rangle|^2}{2I+1}, \quad (4)$$

where j and κ are the total and relativistic angular momentum of the emitted electron, and I is the initial and final nuclear spin, and $|\langle I\kappa | H_0^E | I\kappa \rangle|$ is the reduced E0 transition matrix element.

The E0 transition matrix element for internal conversion is

$$\langle f|H_{00}|i\rangle = \int_0^\infty dV_n \rho_n(r_n) \int_0^{r_n} dV_e \rho_e(r_e) \left(\frac{1}{r_n} - \frac{1}{r_e} \right), \quad (5)$$

where the subscripts n and e denote nuclear and electron coordinates, respectively. The electron density, $\rho_e(\mathbf{r}_e)$, can be replaced by the explicit expression in terms of the radial Dirac electron functions, giving:

$$\langle f|H_{00}|i\rangle = -e \int_0^\infty dV_n \rho_n(r_n) \int_0^{r_n} dr_e [u_\kappa(r_e)u_{\kappa_o}(r_e) + v_\kappa(r_e)v_{\kappa_o}(r_e)] \left(\frac{1}{r_n} - \frac{1}{r_e} \right), \quad (6)$$

where κ_o and κ are the Dirac quantum numbers for the bound and continuum conversion electron, respectively. The $u_\kappa(r_e)$ and $v_\kappa(r_e)$ are the large and small relativistic radial functions for the electron. They are defined through the relativistic electron wave function:

$$\langle \mathbf{r}|\kappa\mu\rangle = \psi_{\kappa\mu}(r) = \frac{1}{r} \begin{pmatrix} u_\kappa(r) & \phi_{\kappa\mu}(\hat{r}) \\ iv_\kappa(r) & \phi_{-\kappa\mu}(\hat{r}) \end{pmatrix}, \quad (7)$$

where $\phi_{\kappa\mu}$ are the Dirac angular momentum spinors.

Inside the nucleus, the radial functions can be expanded into a power series (see Eqn. 10.180 in [20]). Substituting the power series for the radial functions in Eqn. (6), and integrating over the electron coordinates, we obtain

$$\langle f|H_{00}|i\rangle = \int_0^\infty dV_n \rho_n(\mathbf{r}_n) \left(\sum_{m=0}^\infty \frac{\gamma_m}{(\bar{p} + 2m)(\bar{p} + 2m + 1)} \left(\frac{r_n}{R} \right)^{2m+\bar{p}} \right), \quad (8)$$

where the γ_m are the power series parameters for the radial wave functions, and \bar{p} , for E0 transitions, is $2|\kappa|$. From here, we can apply the Wigner-Eckhart theorem, by extracting $\Omega(\text{E0})$, and obtain $\rho(\text{E0})$.

The monopole transition strength can be expressed [20] as

$$\rho(\text{E0}) = \int dV_n \rho_n(r_n) \left(\frac{r_n}{R} \right)^{2|\kappa_o|} \left[1 + \left(\frac{r_n}{R} \right)^2 \frac{\gamma_1}{\gamma_o} \frac{2|\kappa_o|(2|\kappa_o| + 1)}{(2|\kappa_o| + 1)(2|\kappa_o| + 3)} + \dots \right], \quad (9)$$

and the $\Omega_{ce}(\kappa_o)$ electronic factor is defined as

$$\Omega_{ce}(\kappa_o) = 2\pi(2j + 1) \left(\frac{e\gamma_o}{2|\kappa_o|(2|\kappa_o| + 1)} \right)^2. \quad (10)$$

The Ω_{ce} electronic factor is related to the so-called E0 coefficient given by Hager and Seltzer [13], $A_{ce}(\text{E0})$, by

$$\Omega_{ce} = 8\pi\alpha k \times A_{ce}(\text{E0}) \times C, \quad (11)$$

where α is the fine structure constant, k is the transition energy in m_0c^2 units, and $C = 7.7631 \times 10^{20}$ is a unit conversion factor.

2.2. Internal pair formation and $\Omega(E0)$ electronic factors

For transitions with energies larger than twice the electron rest mass, an alternative process involving the emission of electron-positron pairs can compete with the conversion electron process. The theoretical development for internal pair formation is less well studied and a brief history of the development will be given here. The first theoretical description of internal pair conversion was given in 1933 by Nedelsky and Oppenheimer [22] for transitions of angular momentum $L > 0$ and the presence of electron-positron pairs for E0 transitions was first suggested by Fowler and Lauritsen [23] in 1939. Thomas [24] developed a more detailed model after the first calculation of the pair emission rate by Oppenheimer and Schwinger [25]. Using the Born approximation, Oppenheimer in 1941 [26] derived a simple equation for the energy and angular correlation of E0 pair emission. These expressions had limited validity for higher Z systems and for lower energy transitions. They did not take into account the finite size of the nucleus, the effect of atomic screening, and the nuclear Coulomb effects.

The next development in the description of internal pair formation for E0 transitions was described by Wilkinson in 1969 [18]. This formulation takes into account the effect of the nuclear Coulomb field on the emission process, the Coulomb correction, and the effect of atomic screening is also corrected for using a Thomas-Fermi-Dirac statistical model of the atom following the works of Durand, and Bahcall [27, 28].

The most realistic model for internal pair formation was developed in 1981 by Soff [11]. This model takes into account the finite size of the nucleus. Later in the 1990s Hofmann and Soff [12] extended the model to evaluate the double differential emission probability, $d\Omega_{IPF}(E0)/dE d\Theta_\pi$, where Θ_π is the separation angle between the electron and the positron. The theory of internal pair formation is well described in the work of Hofmann *et al.* [29] and the key points will be summarized here.

Internal pair formation results in the emission of an electron-positron pair with the kinetic energies of the electron and positron summing to that of the transition energy minus two times the rest mass of an electron. The rate of this competing process can be expressed just like that for internal conversion. $W_{IPF}(E0)$ is equal to the product of the E0 nuclear transition strength, $\rho^2(E0)$ multiplied by the electronic factor for internal pair formation, $\Omega_{IPF}(E0)$:

$$W_{IPF}(E0) = \rho^2(E0) \times \Omega_{IPF}(E0). \quad (12)$$

The total pair conversion transition rate can be expressed as

$$W_{IPF} = \frac{2\pi}{2J_i + 1} \sum_i \sum_f |U_{if}|^2 \delta(W + W' - \omega), \quad (13)$$

7

where we are averaging over the initial states, and summing over the final states. Energy conservation is enforced by the delta function, with the total electron energy (W'), and the total positron energy (W), summing to give the transition energy, ω . The U_{if} is the pair transition amplitude which for an E0 transition defined as,

$$U_{if} = \sum_{\kappa, \mu} \sum_{\kappa', \mu'} a_{\kappa', \mu'}^* a_{\kappa, \mu} U_{if}^{(L=0)} \quad (14)$$

and

$$U_{if}^{(L=0)} = -e \int_0^\infty dV_n \rho_n(r_n) \int_0^{r_n} dr_e [u_\kappa(r_e) u'_\kappa(r_e) + v_\kappa(r_e) v'_\kappa(r_e)] \left(\frac{1}{r_n} - \frac{1}{r_e} \right). \quad (15)$$

The matrix element $U_{if}^{(L=0)}$ is the same as that for internal conversion as shown in Eqn. (6) except that now the u_κ and v_κ are the large and small components for the positron, and the u'_κ and v'_κ are the large and small components for the electron.

For internal pair formation, we express the electron and positron in the final state as Coulomb-distorted plane waves, which are described by spherical Dirac waves in the form of Eqn. (7). The decomposition of the Coulomb-distorted planes waves is via the equation

$$\psi_{\mathbf{p}, \lambda}^{(\pm)} = \sum_{\kappa, \mu} a_{\kappa \mu}^{(\pm)}(\Omega, \lambda) \chi_{\kappa \mu}, \quad (16)$$

where the $a_{\kappa \mu}$ are the expansion coefficients relating a Coulomb-distorted plane wave of definite momentum, \mathbf{p} , and polarization, λ , to spherical Dirac waves of definite κ and μ . The electron and positron are expressed as converging partial waves and described by the $\psi^{(-)}$ -type wavefunction and the $a^{(-)}$ expansion coefficients. The expressions for $a_{\kappa \mu}^{(\pm)}$ and $\psi_{\mathbf{p}, \lambda}^{(\pm)}$ can be found in [29].

The differential probability of pair emission with respect to the positron energy is given below:

$$\frac{dP_{e^+e^-}}{dE} = \frac{2\pi}{2J_i + 1} \sum_{M_i, M_f} \sum_{\kappa, \kappa'} \sum_{\mu, \mu'} \sum_{\lambda, \lambda'} \int d\Omega \int d\Omega' a_{\kappa', \mu'}^* a_{\kappa', \mu'} a_{\kappa, \mu}' a_{\kappa, \mu}^* |U_{if}^{(L=0)}|^2. \quad (17)$$

Following the work of Wilkinson [18], we can make a number of approximations to simplify the problem and make it more tractable. We can approximate the electron and positron wavefunctions for a finite-sized nucleus by the pure Coulombic wavefunctions for a point nucleus evaluated at the nuclear radius. These wavefunctions are expressed in the notation of beta-decay by the Fermi functions. The Fermi functions represent the ratio of the relativistic electron density at the nucleus to the density at infinity [28]. Just as in beta-decay, the nuclear Coulomb effects must be taken into account. The nuclear Coulomb field has the effect of inhibiting the emission of a positron, and enhancing the emission of an electron. Its effect on electron-positron emission is energy dependent and is incorporated into

the Fermi functions. This also means that we only consider electron and positron final states of $j = \frac{1}{2}$ or $\kappa = \pm 1$. This is appropriate as the higher order moments (r^k , $k \geq 4$) in the monopole matrix operator are negligible [11, 19]. The screening of the nuclear charge by the atomic electrons can also be taken into account. This is easily done in this formalism by modifying the Fermi functions with the Thomas-Fermi-Dirac model of the atom according to the works of Durand, and Bahcall [27, 28].

By expressing wavefunctions of the electron and positron as pure Coulombic wavefunctions evaluated at the nuclear edge, we can express the integral as the product of two Fermi functions (one for the positron and one for the electron). The E0 transition rate for pair conversion is evaluated as [18]:

$$W_{IPF}(E0) = \frac{8}{9\pi} \frac{e^4 m_0^5 c^4}{\hbar^7} |M(E0)|^2 \frac{1}{(1 + \gamma)^2} \int_1^{E_\pi - 1} p_+ p_- (E_+ E_- - \gamma^2) F(Z, E_+) F(Z, E_-) dE_+, \quad (18)$$

where e is the electron charge, m_0 the electron rest mass and $\gamma = (1 - \alpha^2 Z^2)^{1/2}$. The positron/electron momenta in units of $m_0 c$ are denoted p_\pm and E_\pm are the positron/electron total energy in units of $m_0 c^2$ with $E_- + E_+$ equalling the transition energy. $F(Z, E_\pm)$ is the Fermi function and $M(E0)$ is the electric monopole matrix element.

In order to get an expression for the electronic factor for internal pair formation, we must divide the internal pair formation rate, $W(E0)_{IPF}$ by ρ^2 which is related to the monopole matrix element by Eqn. (3). We then obtain

$$\Omega_{IPF}(E0) = \frac{8}{9\pi} \frac{e^6 R^4 m_0^5 c^4}{\hbar^7} \frac{1}{(1 + \gamma)^2} \int_1^{E_\pi - 1} p_+ p_- (E_+ E_- - \gamma^2) F(Z, E_+) F(Z, E_-) dE_+. \quad (19)$$

By evaluating this equation we can obtain the electronic factor for internal pair formation, Ω_{IPF} , as a function of transition energy, and atomic number.

2.3. E0 electronic factors and nuclear structure

The electronic factors relate the transition probability for each E0 decay pathway to the nuclear E0 strength. The total E0 transition probability, $W(E0)$, sums over the different atomic shells and processes (electron conversion and internal pair formation) by

$$W(E0) = |\rho(E0)|^2 \times [\Omega_K(E0) + \Omega_{L1}(E0) + \dots + \Omega_{IPF}(E0)], \quad (20)$$

where the transition rate of each component is just

$$W_i(E0) = |\rho(E0)|^2 \times \Omega_i(E0), \quad (21)$$

and

$$W(E0) = \sum_i W_i(E0). \quad (22)$$

Experimentally, the monopole strength can be obtained directly if the partial mean life of the E0 transition, $\tau(E0)$, is known. Specifically,

$$\rho^2(E0) = \frac{1}{[\Omega_K(E0) + \Omega_{L1}(E0) + \dots + \Omega_{IPF}(E0)] \times \tau(E0)} . \quad (23)$$

For $J^\pi \rightarrow J^\pi$ transitions in which $J \neq 0$, the transition typically proceeds with a mixed M1+E2+E0 character and the $\rho^2(E0)$ monopole strength can be extracted as follows. The conversion coefficient of this transition involving the i -th subshell or IPF, α_i , can be written as

$$\alpha_i = \frac{I_i(M1) + I_i(E2) + I_i(E0)}{I_\gamma(M1) + I_\gamma(E2)}, \quad (24)$$

where $I_i(ML)$ is the intensity of conversion electrons or pair emission. $I_\gamma(ML)$ is the gamma-ray emission of multipolarity ML. Using the $\delta(E2/M1)$ mixing ratio, the ratio of the E2 to M1 γ -ray intensities, the theoretical $\alpha_i(E2)$ and $\alpha_i(M1)$ conversion coefficients, Eqn. (24) can be written as:

$$\alpha_i = \frac{\alpha_i(M1) + \delta^2(E2/M1)[1 + q_i^2(E0/E2)]\alpha_i(E2)}{1 + \delta^2(E2/M1)} . \quad (25)$$

The $q_i^2(E0/E2)$ is a quantity introduced by Church, Rose, and Weneser [30], which is the ratio of the E0 and E2 conversion electron (or electron positron pair) intensities:

$$q_i^2(E0/E2) = \frac{I_i(E0)}{I_i(E2)} . \quad (26)$$

If the E2 transition rate, $W_\gamma(E2)$, is known, the $\rho^2(E0)$ can be obtained from the following expression:

$$\rho^2(E0) = q_i^2(E0/E2) \times \frac{\alpha_i(E2)}{\Omega_i(E0)} \times W_\gamma(E2) , \quad (27)$$

where as above, the i subscript denotes the atomic shell or pair conversion.

3. $\Omega(E0)$ for conversion electrons

3.1. Numerical calculations

The electronic factors, Ω_{ce} , were calculated using a modified version of the *CATAR* program [16]. The details of the operation of the code can be found in [16], but a brief outline will be given here. The program solves the Dirac equation for the bound and free electron states in a central potential with a screening function given by the user input. These wave functions are used to calculate the electronic factors for internal conversion, Ω_{ce} . The static nuclear charge distribution of the nucleus is treated as a homogenously charged drop of radius $1.20A^{\frac{1}{3}}\text{fm}$.

The screening functions used to calculate the tabulated values and accompanying database were self-consistent Dirac-Fock-Slater (DFS) functions calculated for each element using a modified version of the *HEX* code developed by Liberman, Cromer and Waber [17]. The self-consistent potentials were calculated using a modified Kohn-Sham potential outlined in [17] and described in [31] and with the application of the so called Latter tail correction [32]. The atomic mass numbers and electronic configurations used in the calculation of each screening function were those found in [9], where applicable, and for elements of $Z \geq 111$, the configurations given in [33] were used.

The present calculations of the electronic factors use the so-called “No-Hole” approximation wherein the effect of the atomic vacancy on the atomic potential is disregarded. In other words, the self-consistent screening function is left unchanged before and after the conversion event. To improve the accuracy, especially for transition energies close to the atomic shell binding energies, when the kinetic energy of the outgoing electron is very low, the so-called “Frozen-Orbitals” approach [9] can be used. It was determined [9] that for the calculations of the conversion coefficients over the full energy range, the difference between the “No-Hole” and the “Frozen-Orbitals” approximations is about 1.6%. For the E0 transitions of interest, the energy of the continuum electrons is at least of the order of 100 keV, so the effect of the hole is expected to be minimal.

The published version of the *CATAR* program [16] contained some bugs. For the present calculations we used the same binding energies as for the *BrIcc* tabulations [9]. The interface to provide external screening function has also been modified. To calculate the screening function the *HEX* code was also modified by eliminating some bugs along with corrections given in [17].

For each element of Z from 5 to 126, the self-consistent DFS screening function was calculated using the *HEX* code. These were then used to calculate the $\Omega_i(E0)$ electronic factors for internal conversion electrons involving all atomic shells (up to R2) and transition energies from 1 keV above atomic shell binding energies to 6000 keV. For the N6 shell for $Z = 63$, the Q4 shell for $Z = 122$, and the O8 shell for $Z = 125$ and 126, the calculations could not be performed due to instability in the numerical solution of the bound electronic wave function.

Figure 1 shows the $\Omega_K(E0)$ values as a function of transition energy for selected atomic numbers. The electronic factors are increasing as a function of atomic number Z and transition energy. The same general dependence was found for all other shells. Compared to the K-shell conversion coefficients, α_K (see Fig. 2), the energy dependence of the $\Omega_{CE}(E0)$ values is opposite to that of the conversion coefficients. This energy dependence is valid for all atomic shells. On the other hand, the Z -dependence

Fig. 1: Plot of $\Omega_K(E0)$ electronic factors for the K shell as a function of energy and for atomic numbers $Z = 20, 40, 60, 80, 100$ and 120 .

is the same for both the E0 electronic factors and the internal conversion coefficients.

Figure 3 shows the ratio of the $\Omega_K(E0)$ to the $\Omega_{tot,CE}(E0)$ electronic factors. Here $\Omega_{tot,CE}(E0)$ only contains contributions from electron conversion. It is notable that the ratio has very little energy dependence, however it decreases with atomic number Z .

3.2. Comparison with previous $\Omega_{CE}(E0)$ tabulations

The previous E0 electronic factor tabulations are far from complete as the different tabulations used different physical assumptions, and covered different regions in terms of transition energy, atomic number, and atomic shell. Representative values obtained from the previous tabulations are compared in Table A with values from this new tabulation. In each case $\Omega_i(E0)$ values were obtained by numerical interpolations.

The 1969 tabulation by Hager and Seltzer [13] (*HsOmg*) was carried out for every fourth Z between $Z = 30$ and $Z = 102$. The values for the K, L1, and L2 shells were calculated, with transition energies ranging from 6 keV above the threshold to 1500 keV for the K shell, and 1100 keV for the L1 and L2 shells. The finite size of the nucleus was approximated as a Fermi distribution, and the wave functions were solved via a relativistic Hartree-Fock-Slater approach with the use of the Kohn-Sham corrections to the Slater approach [34].

Fig. 2: Plot of theoretical internal conversion coefficient for (a) M1, (b) E2 multipolarity and (c) E0 electronic factors for $Z=40$ as a function of transition energy. Note the logarithmic scale on both axes. For clarity, only the K, L1, L2, M1, M2 and O1 shells, as well as internal pair formation are shown. $\alpha(M1)$ and $\alpha(E2)$ conversion coefficients are from *BrIcc* [9]. The $\Omega(E0)$ values are from the present tabulation.

The second tabulation, by Bell *et al.* [14] (*BeOmg*) in 1970, included every second Z from $Z = 40$ to 102 and for the K, L1, and L2 shells. The electronic factors were calculated by modifying the analytic point-nucleus wave functions from Church and Weneser [19] to account for the finite nuclear size and atomic screening effects and covered an electron energy range from 51 keV to 2.5 MeV.

The third tabulation was by Passoja and Salonen in 1986 [15] (*PaOmg*). This tabulation covered every even Z from $Z = 8$ to $Z = 40$. The electronic factors for electron conversion were only from the K shell and calculated for transition energies from 511 keV to 12.8 MeV. The effects of the finite-sized nucleus and atomic screening were not taken into account and this leads to an overestimation of the $\Omega_K(E0)$ electronic factor. This is visible in Table A at $Z = 40$ compared to the other tabulations.

The agreement between *HsOmg*, *BeOmg* and the present *CATAR* calculations is reasonably good, except for L2 shell and $Z = 40$, where the *BeOmg* values are systematically lower. The present calculations are the only one for atomic shells higher than L2. Our calculation also treat the effects of the finite nuclear size as well as atomic screening consistently for all elements.

Fig. 3: Plot of the $\Omega_K/\Omega_{tot,CE}$ ratio as a function of transition energy and for atomic number $Z=20, 40, 60, 80, 100$ and 120 . Note, that $\Omega_{tot,CE}$ only contains contributions from electron conversion.

4. $\Omega(E0)$ for pair conversion

4.1. Numerical calculations

Our main aim is to present complete tables of $\Omega_{IPF}(E0)$ to be used with *BrIcc*. The electronic factors, $\Omega_{IPF}(E0)$, were calculated using *WspOmega*, a new computational tool developed from the work of Wilkinson [18]. $\Omega_{IPF}(E0)$ values have been calculated for even Z from 4 to 100 using the atomic masses of the most abundant isotopes adopted for *BrIcc* [9]. The range of nuclear transition energies was between 1100 keV and 8000 keV similar to the $L > 0$ pair conversion coefficients tabulations [35, 36]. The smooth dependence of $\Omega_{IPF}(E0)$ on Z and transition energy makes it easy to obtain values for odd Z by interpolating from neighbouring even Z values.

The electronic factors for internal pair formation were calculated by numerical integration of Eqn. 19 with the Simpson's rule. The calculation of the Fermi function is based on Eqn. 7 from [37]. The effect of the atomic screening is corrected for using a Thomas-Fermi-Dirac statistical model of the atom following the works of Durand and Bahcall [27, 28].

Only electron and positron states with $j = \frac{1}{2}$ or $\kappa = \pm 1$ were considered. This is because the effects of the higher order moments (r^k , $k \geq 4$) in the monopole matrix operator are negligible [11, 19]. The nuclear Coulomb effects have been taken into account but not the effect of the finite nuclear size. The Fermi functions correspond to Dirac wavefunctions for a point source nucleus, evaluated at the nuclear edge [18]. The effects of the finite nuclear size are expected to be important at high- Z systems and at transition energies close to the threshold of 1.022 MeV. Wilkinson [18] has estimated that these effects could alter the $\Omega_{IPF}(E0)$ by not more than 10%.

4.2. Comparison with previous $\Omega_{IPF}(E0)$ calculations

There are only a handful of theoretical calculations of numerical $\Omega_{IPF}(E0)$ values in the literature: the work of Lombard, Perdrisat and Brunner [38], Passoja and Salonen [15], and Soff [11]. There is only one published data table – the work of Passoja and Salonen – which only covers nuclei of $Z < 40$. The other two papers only contain $\Omega_{IPF}(E0)$ values for a small selection of nuclear transitions.

Table B compares the ratios of $\Omega(E0)$ values for the K-shell to pair conversion obtained from previous publications and the present calculations to available experimental intensity ratios of K-shell to pair formation.

Lombard, Perdrisat and Brunner [38] carried out so-called “exact” calculations of the internal pair formation electronic factor using a modified Born approximation and relativistic electron wave functions for a point nuclear charge calculated by Bhalla and Rose [39]. The published tables were for transition energies of 2.5, 3.0, 4.0, and 5.0 $m_e c^2$ or for 1278, 1533, 2044, 2555 keV, and only for $Z = 0, 34, 48, 58$, and 82. The finite nuclear size, and atomic screening was not taken into account. Their calculated values only agree with experiment at very low atomic numbers. the difference to the experiments and to the other calculations is quite significant for $Z = 20$ and above.

Passoja and Salonen [15] calculated the internal pair formation $\Omega_{IPF}(E0)$ electronic factors for atomic numbers $Z = 8-40$ and transition energies of 1430 to 12775 keV. To our knowledge, this is the only data table on $\Omega_{IPF}(E0)$; it was published in 1986 as an internal report of the University of Jyväskylä. This calculation is based on Born approximation with corrections for the nuclear Coulomb effects from Wilkinson [18] along with wavefunctions for a point nucleus. Atomic screening and finite nuclear size were both neglected in the calculations.

A more realistic model of the partial pair emission probability, $d\Omega_{IPF}(E0)/dE$ was developed in 1981 by Soff, Schlüter and Greiner [11]. Their model utilize relativistic electron and positron wavefunctions [40], which are solutions of the Dirac equation with a point nucleus potential. To include the effect of the finite nuclear size, the density of the electron states are included approximately, however the screening of atomic electrons is neglected. These calculations only provide numerical values of $\Omega_{IPF}(E0)/\Omega_K(E0)$ ratios and according to our knowledge the code is not available.

Table B compares the ratios of $\Omega(E0)$ values for the K-shell to the pair conversion calculated with the various models. The available experimental data for E0 intensity ratios between the K-shell and internal pair formation is also shown. The agreement between Passoja [15], Soff [11] and the present calculations is reasonably good. Note that in Table B, the K/IPF value for the 6048.2 keV transitions

in ^{16}O calculated in this work is significantly lower than in the works of Lombard *et al.*, Passoja and Salonen, and Soff. This difference may arise because the Ω_K values of Lombard *et al.*, Passoja and Salonen, and Soff were calculated with point nuclear wavefunctions and no atomic screening. As seen in Table A, the Ω_K values of Passoja and Salonen are characteristically larger than the values from the present calculations using *CATAR*, the Hager and Seltzer tabulation, and the Bell *et al.* tabulation. This will inflate the values of the K/IPF $\Omega(\text{E0})$ ratios.

Table B

Experimental data and theoretical values of K-shell electron to internal pair conversion probability ratios for E0 transitions.

Nucleus	Transition Energy [keV]	$\Omega_K(\text{E0})/\Omega_{IPF}(\text{E0})$

5. Numerical data tables

The new $\Omega_{CE}(\text{E0})$ and $\Omega_{IPF}(\text{E0})$ tabulations have been combined with our previous calculations of internal conversion electron coefficients [9, 41], as well as pair conversion coefficients calculated by Schultze [35] and Hofmann [36] as part of the *BrIcc* database (version 3.1). Details are given in Table C. For additional details about the *BrIcc* database, see [9]. The new data tables were assembled as a single file, containing probabilities of E0, E1 to E5 and M1 to M5 multipole orders, for electron and pair-conversion.

Table C

Tabulations of internal conversion coefficients and electronic factors available in *BrIcc* version 3.1.

Data Table	Reference	Z	Shell ^a	L	E_γ^b [keV]
Conversion electrons					
α_{IC} Conversion coefficient					
BrIccFO	[9, 10]	5 – 110	K - Q1	1 – 5	$\epsilon_{ic}+1$ – 6000
	[10, 41]	111 – 126	K - R2	1 – 5	$\epsilon_{ic}+1$ – 6000
$\Omega_{IC}(E0)$ electronic factors					
CATAR	Present work	5 – 126	K - R2	0	$\epsilon_{ic}+1$ – 6000
Electron-positron pair emission					
α_π Conversion coefficient					
ScPcc	[35]	0 – 49	IPF	1 – 3	1100 – 8000
HoPcc	[36]	50 – 100	IPF	1 – 3	1100 – 8000
$\Omega_{IPF}(E0)$ electronic factor					
WspOmega	Present work	4 – 100 (even)	IPF	0	1100 – 8000

^a IPF labels internal pair formation in the atomic shell field. See also Table D.

^b ϵ_{ic} is the binding energy for the i th atomic shell.

To obtain values for a given Z , transition energy, atomic shell, or multipolarity, the use of a cubic spline interpolation is recommended. The data tables listed in Table C are distributed in a fixed record size binary file, designed for modern computers and operating systems. Each record is 52 bytes long, can hold up to 12 single-precision numbers: transition energy, $\Omega(E0)$ electronic factor and ten α conversion coefficients for E1-E5 and M1-M5 multipolarities. The last 4 bytes are reserved for future developments. For each element, the data tables are generated for up to 40 atomic shells. Electron-positron pair conversion is considered for storage as one of the atomic shells as listed in Table D. Within a given shell, conversion coefficients were calculated for a number of transition energies. The numbers and values of the energies were chosen to minimize the uncertainty from the interpolation procedure to be well below 0.3% [9].

The first record of the data file has the version of the data base, followed by 126 blocks of 41 records for each Z . The conversion data starts at the 5169th record. Full details of the data file, including the list of the records, are given in the *ReadMe* file available with the auxiliary files of this paper.

Table D

Atomic shells used in the data tables.

Index	Shell	Atomic orbits
1	K	$1s_{1/2}$
2-4	L1-3	$2s_{1/2}, 2p_{1/2}, 2p_{3/2}$
5-9	M1-5	$3s_{1/2}, 3p_{1/2}, 3p_{3/2}, 3d_{3/2}, 3d_{5/2}$
10-16	N1-7	$4s_{1/2}, 4p_{1/2}, 4p_{3/2}, 4d_{3/2}, 4d_{5/2}, 4f_{5/2}, 4f_{7/2}$
17-25	O1-9	$5s_{1/2}, 5p_{1/2}, 5p_{3/2}, 5d_{3/2}, 5d_{5/2}, 5f_{5/2}, 5f_{7/2}, 5g_{7/2}, 5g_{9/2}$
26-32	P1-7	$6s_{1/2}, 6p_{1/2}, 6p_{3/2}, 6d_{3/2}, 6d_{5/2}, 6f_{5/2}, 6f_{7/2}$
33-37	Q1-5	$7s_{1/2}, 7p_{1/2}, 7p_{3/2}, 7d_{3/2}, 7d_{5/2}$
38-39	R1-2	$8s_{1/2}, 8p_{1/2}$
40	π	Internal electron-positron pair formation, IPF

6. Comparison with experiments

The basic relationship between E0 transitions rates and the electronic factor, $\Omega(\text{E0})$, is given in Eqn. (2). While the absolute E0 transition rates can be obtained from lifetime measurements or high-energy electron-scattering experiments, neither $\rho(\text{E0})$ nor $\Omega(\text{E0})$ can be determined independently from experiments. Accurate calculated values of $\Omega(\text{E0})$ are therefore essential to deduce $\rho(\text{E0})$ from absolute E0 transition rates. While $\Omega(\text{E0})$ cannot be experimentally determined, the ratio of E0 internal conversion electron and/or E0 pair conversion intensities is equal to the ratio of the corresponding $\Omega(\text{E0})$ electronic factors.

In Table 1, 128 experimental $\Omega(\text{E0})$ ratios are given, covering a wide range of atomic numbers (from $Z = 8$ to $Z = 98$), transition energies (from 171.077 keV in ^{114}Cd to 6048.2 keV in ^{16}O), and involving K- to N-shells and internal pair formation.

The corresponding theoretical $\Omega_{CE}(\text{E0})$ and $\Omega_{IPF}(\text{E0})$ values have been evaluated from the present calculations and listed in the “Theory” column of Table 1. The difference between the experimental intensity ratios ($\Omega_{\text{Exp}}^{\text{ratio}}$) and theoretical electronic factor ratios ($\Omega_{\text{Theory}}^{\text{ratio}}$), $\Delta\Omega^{\text{ratio}}$, is in percent and defined as:

$$\Delta\Omega^{\text{ratio}} = \frac{100 \times [\Omega_{\text{Exp}}^{\text{ratio}} - \Omega_{\text{Theory}}^{\text{ratio}}]}{\Omega_{\text{Theory}}^{\text{ratio}}}. \quad (28)$$

The uncertainty given for Ω^{ratio} only contains the contributions from the experimental values. References to the experimental data are given with their NSR [55] key numbers.

There is a significant variation in the experimental values and their uncertainties. In a few cases only a limit is known. Most of the conversion electron data is on K/L ratios and there are only a few

measurements on sub-shell ratios. To quantify the difference between the experimental and theoretical ratios, data points from Table 1 with relative uncertainty $\leq 25\%$ were selected.

These 83 data points are plotted in Fig. 4, where the horizontal axis is the percentage difference between theory and experiment, as defined in Eqn. (28). The data points are plotted by decreasing mass numbers. References are given on the right-hand side. Eight of the data points are K/IPF ratios which correspond to the following E0 transitions: 6048.2 keV ^{16}O , 3352.6 keV ^{40}Ca , 1837.3 keV ^{42}Ca , 2561.3 keV ^{54}Fe , 2284.87 keV ^{60}Ni , 1910 keV ^{64}Zn , and 1760.70 keV ^{90}Zr .

Considering electron conversion only, our calculations show (see Fig. 3) that between $Z = 32$ (Ge) and $Z = 98$ (Cf) the contribution of K conversion changes from $\sim 90\%$ to $\sim 80\%$. A visual examination of Fig. 4 indicates that the difference between experiment and theory does not have any significant Z dependence. The eight K/IPF ratios included also appear independent of Z .

To determine the average difference, we have used AveTools [56], which combines five different statistical methods to calculate averages of experimental data with uncertainties: (a) Limitation of Relative Statistical Weight (LWM) [58], (b) Normalised Residual Method (NRM) [58], (c) Rajeval Technique (RT) [58], (d) Bootstrap method (BS) [59], (e) Mandel-Paule approach (MP) [60]. A robust answer would be reached if all these methods gave the same answer, or the averages with their uncertainties are overlapping. The most precise experimental value is the K/L+M+N+O ratio of 8.70 (6) (0.69% relative uncertainty) of the 689.6 keV E0 transition in ^{72}Ge reported by Nessin et al. [43]. It is more than 5σ away from the corresponding theoretical value of 8.38. This point was marked as outlier by the LWM, NRM, RT methods, so its uncertainty was increased to 2%. The K to L ratio of the 1199.28 keV E0 transition in ^{178}Hf [61] has been reported with about 9% precision, however the deviation from the theoretical ratio is nearly 50%. This point has been excluded from the present analysis.

Table E

Average $\Delta\Omega^{\text{ratio}}$ differences for 83 E0 transitions shown in Fig. 4.

The averages have been determined using five statistical approaches.

Method	$\Delta\Omega^{\text{ratio}}$ (%)	Reduced χ^2
Limitation of Relative Statistical Weight [58]	-4.6(15)	1.56
Normalised Residual Method [58]	-4.9(7)	1.40
Rajeval Technique [58]	-4.9(6)	1.30
Bootstrap method [59]	-4.7(12)	1.51
Mandel-Paule Approach [60]	-5(4)	1.51

Average values for these $\Delta\Omega^{\text{ratio}}$ differences are given in Table E. All five methods indicate that the various ratios of E0 transition intensities are overestimated in the model by about 5%. The same data set was also compared with $\Omega(\text{E0})$ values from the old *BrIcc* database using $\Omega_{CE}(\text{E0})$ values from Hager and Seltzer [13], Bell *et al.* [14], and Passoja [15] along with $\Omega_{IPF}(\text{E0})$ values from Passoja [15]. The average difference was slightly greater at 5.5(17)%.

The average differences for the 10 experimental ratios involving IPF are: LWM: -2.6(18)%, NRM: -2.5(19)%, RT: -2.1(19)%, BS: -4(4)%, MP: -3.8(10)%. These values are overlapping and consistent with each other. There appears to be consistent overestimation of the ratio of K-shell conversion to internal pair formation of around 2.5%. Compared to the average difference of all data in Table E, the theory appears to be more accurate for the K-shell to pair formation ratio. More experimental data with increased accuracy is needed to establish a firm conclusion on the uncertainty of the K-shell and IPF $\Omega(\text{E0})$ values.

The average difference between experimental and theoretical E0 ratios in Table 1 is dominated by K/L ratios and more experimental data are needed to examine the model predictions for outer shells. However, it is possible that the -4.6(15)% difference could be due to a systematic underestimation of the electronic factors for the L and higher shells compared to the K-shell. The theoretical K/IPF ratios are significantly more consistent with the experimental values, suggesting that the K and IPF Ω values are more accurate than the values for the higher shells. The formation region for internal conversion of E0 transitions is wholly within the nuclear volume and is purely a penetration effect. This is in contrast to internal conversion processes of $L > 0$ where the formation region is outside the nuclear volume [62]. Thus the $\Omega(\text{E0})$ values are very sensitive to the electron wavefunctions inside the nucleus and so depend very strongly on the particulars of the calculated wavefunctions and electronic configurations. The outer shells are even more sensitive due to the effect of atomic screening on the wavefunctions from the inner shells. From the present work, shown in Table E, we have adopted a 5% uncertainty on the calculated $\Omega_{CE}(\text{E0})$ and $\Omega_{IPF}(\text{E0})$ values.

7. Using Ω_{CE} and Ω_{IPF} electronic factors for analyzing E0 transitions

Eqn. (20) describes the relation between E0 transition rate, the monopole strength parameter, $\rho(\text{E0})$, and the electronic factor, $\Omega(\text{E0})$. The conversion electron intensity for a particular shell (i) or for pair conversion (π) is proportional to $\Omega(\text{E0})$:

$$I_{i,IPF} \propto \Omega_{i,IPF}(\text{E0}) . \quad (29)$$

Using the present table one can evaluate the complete set of $\Omega_{i,IPF}(E0)$ values. Here we provide some examples on the use of $\Omega(E0)$ electronic factors to analyse pure E0 and mixed E0+E2+M1 transitions.

7.1. ^{42}Ca 1837.3 keV E0

The ratio of the K conversion electron and pair conversion of the pure E0 transition in ^{42}Ca was measured by Benzer-Koller *et al.* [44] (Table 8): $I_K/I_{IPF} = 0.111(22)$. This experimental ratio 17(20)% is lower than the calculated one using the present tabulation. Belyaev, Vasilenko and Kaminker [65] measured the pair production to K+L conversion electron ratio, $I_{IPF}/I_{K+L} = 6.1(8)$, which is 13(15)% higher than the calculated one. The 1837.31 keV 0^+ state also decays with a 312.60 keV E2 transition. The ratio of the K-shell conversion electron intensities of the E2 and E0 transitions is reported by Benzer-Koller *et al.* [44], $I_K(E2)/I_K(E0) = 1.03(10)$. To evaluate the ratio of the total E0 to E2 intensities here we only make use of the experimental $I_K(E2)/I_K(E0)$ value and the theoretical conversion coefficients and E0 electronic factors: $\alpha_K(E2) = 0.00310(5)$, $\alpha_{tot}(E2) = 0.00340(5)$, $\Omega_{IPF}(E0) = 2.54(13)E + 8$ and $\Omega_{tot}(E0) = 2.91(15)E + 8$. From these data the E0/E2 branching ratio was deduced as:

$$\frac{I_{tot}(E2)}{I_{tot}(E0)} = \frac{I_K(E2)}{I_K(E0)} \times \frac{1 + \alpha_{tot}(E2)}{\alpha_K(E2)} \times \frac{I_K(E0)}{I_{IPF}(E0)} \times \frac{\Omega_{IPF}(E0)}{\Omega_{tot}(E0)} = 32(7) \quad (30)$$

Using Eqn. 30 and the adopted half-life of the 1837.31 keV 0^+ state [63], $T_{1/2} = 387(6)$ ps the $\rho^2(E0)$ can be obtained as:

$$\rho^2(E0) = \frac{\ln(2)}{\Omega_{tot}(E0) \times (1 + \frac{I_{tot}(E2)}{I_{tot}(E0)}) \times T_{1/2}} = 0.19(4). \quad (31)$$

In comparison, the 2005 evaluation of E0 transition strengths by Kibédi and Spear [3] gave $\rho^2(E0) = 0.140(12)$. This value is based on the $I_{tot}(E0)/I_\gamma = 2.05(17)/100.0(18)$ from the 2001 ENSDF evaluation [64].

^a Data from [66]

The decay data of the 966.13 keV 2^+ state in ^{238}U was taken from the recent ENSDF evaluation of Browne and Tuli [66] and is listed in Table F. The 921.19 keV transition is a $2^+ \rightarrow 2^+$ transition. The experimental K-conversion coefficient, $\alpha_K(\text{exp})=0.191(30)$ is larger than the M1 ($\alpha_K(\text{M1})=0.0343$) or E2 ($\alpha_K(\text{E2})=0.00887$) values, indicating an E0 admixture. Using Eqn. (25) the E0/E2 mixing ratio can be extracted as:

$$\begin{aligned} q_K^2(\text{E0/E2}) &= \frac{\alpha_K(\text{exp}) \times (1 + \delta^2(\text{E2/M1})) - \alpha_K(\text{M1})}{\delta^2(\text{E2/M1}) \times \alpha_K(\text{E2})} - 1 \\ &= 20_{-4}^{+3}. \end{aligned} \quad (32)$$

The resulting E0/E2 mixing ratio is slightly asymmetric, however the total conversion coefficient, $\alpha_{\text{tot}} = 0.26(4)$ deduced from the theoretical $\alpha_i(\text{M1})$ and $\alpha_i(\text{E2})$ and $\Omega_i(\text{E0})$ values, using $\delta(\text{E2/M1})$ and $q_i(\text{E0/E2})$ mixing ratios ($i = \text{K, L1, L2, etc. atomic shells}$) has a symmetric uncertainty. It should be noted that the value of the E0/E2 mixing ratio is not the same for the various atomic shells or for pair conversion. Using the $\Omega(\text{E0})$ and $\alpha(\text{E2})$ values $q_j^2(\text{E0/E2})$ can be obtained from $q_i^2(\text{E0/E2})$ as:

$$q_j^2(\text{E0/E2}) = q_i^2(\text{E0/E2}) \times \frac{\Omega_j(\text{E0})}{\Omega_i(\text{E0})} \times \frac{\alpha_i(\text{E2})}{\alpha_j(\text{E2})}. \quad (33)$$

Using Eqn. 30 the E0 strength parameter:

$$\begin{aligned} \rho^2(\text{E0}) &= q_K^2(\text{E0/E2}) \times \alpha_K(\text{E2}) \times \frac{I_\gamma(\text{E2})}{\sum I_{\text{tot}}} \times \frac{\ln(2)}{T_{1/2}} \\ &= 0.0057_{-24}^{+22}, \end{aligned} \quad (34)$$

where $I_\gamma(\text{E2})$ and $\alpha_K(\text{E2})$ are the gamma-ray intensity and K-shell conversion coefficient of the 921.19 keV transition. Other parameters to deduce the total EM radiation intensity de-exciting the 966.13 keV level, $\sum I_{\text{tot}}$, were taken from Table F. The level half-life of $T_{1/2} = 2.4_{-7}^{+17}$ ps is very asymmetric, therefore a Monte-Carlo uncertainty propagation program [67] was used to evaluate the mean value and asymmetric uncertainties from the probability density function (PDF) of $\rho^2(\text{E0})$ shown in Fig. 5. The present value of $\rho^2(\text{E0}) = 0.0056_{-24}^{+22}$ is lower than the $\rho^2(\text{E0}) = 0.0099(18)$ reported by Gácsi *et al.* [68]. A large part of the difference can be attributed to the fact that in [68] the contribution of the M1 multipolarity to the K-shell conversion coefficient has not been taken into account.

8. Conclusion

Here we report on the calculation of E0 electronic factors for internal conversion and electron-positron pair conversion. These tables will replace the current ones in *BrIcc* [9].

For the electron conversion a modified version of the *CATAR* program [16] was used. $\Omega_{CE}(E0)$ values are presented for all nS and nP atomic shells in the $Z = 5$ to 126 elements and covering the same energy range as for the conversion coefficients in *BrIcc*. For pair conversion a new code has been developed using Wilkinson's formulation [18] for elements of even $Z = 4$ to 100 and 1100 to 8000 keV transition energies.

In Table B the calculated $\Omega_{CE}(E0)$ and $\Omega_{IPF}(E0)$ values are compared with available theoretical calculations and a satisfactory agreement was found. To our knowledge, there is no experimental data is available to make a direct comparison of $\Omega_{CE}(E0)$ or $\Omega_{IPF}(E0)$ values. In Table 1, 128 ratios of $\Omega(E0)$ values are compared with theoretical values. Fig. 4 shows the percentage differences between experiment and theory. No obvious Z or mass dependence is visible in the figure. The average difference between the experimental and theoretical values is $-4.6(15)\%$, indicating that the theoretical ratios are overestimating experiments. Further theoretical work is needed to improve the calculations of $\Omega(E0)$.

Based on the above analysis, a general 5% uncertainty was adopted for the accuracy of the present numerical tables. A new data table has been built using electron and pair conversion coefficients for $L > 0$ multipolarities from our previous calculations [9, 41] and combined with the present calculations for E0 transitions. The binary table is available as an auxiliary file to this publication and will be available in the new version of *BrIcc*.

Fig. 4: Percentage differences between experimental E0 intensity ratios and theoretical $\Omega(E0)$ electronic factor ratios, $\Delta\Omega^{\text{ratio}}$. See Eqn. (28) for definition. Experimental data with less than $\pm 25\%$ relative uncertainty taken from Table 1. The average difference of $\Delta\Omega^{\text{ratio}} = -4.6(15)\%$ is indicated by a shaded area.

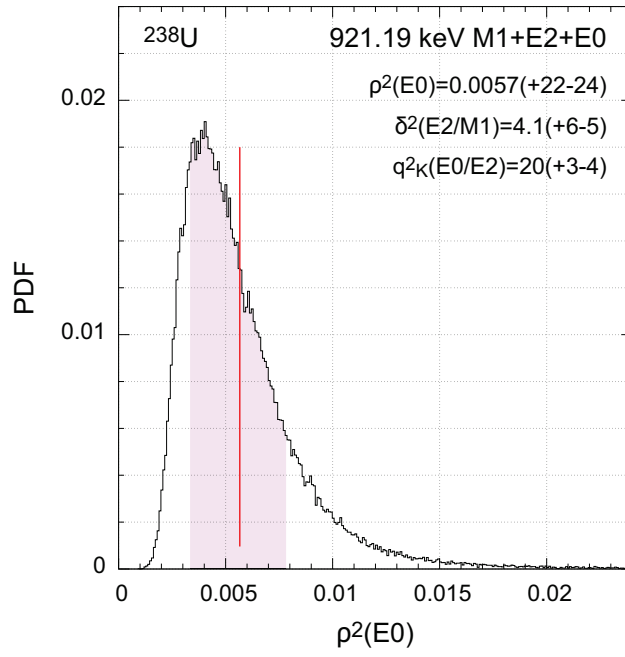

Fig. 5: Plot of probability density function of $\rho^2(E0)$ evaluated using Eqn. (35). The red line indicates the mean value of $\rho^2(E0)$ and the shaded area corresponds to the upper and lower 1σ boundaries.

Acknowledgments

We would like to thank G. Gosselin, V. Meot and M. Pascal (CEA, DAM, DIF, Arpajon F-91297, France), who havefig:ExpTheor carried out the initial calculations of electronic factors for conversion electrons. This work was supported by the Australian Research Council Discovery Grants DP140102986 and DP170101673.

Table 1. Ratio of experimental conversion electron (CE) and electron-positron pair conversion intensities for E0 transition in even–even atomic nuclei.

(Throughout this table, italicized numbers refer to the uncertainties in the last digits of the quoted values.)

Nuclide	The even Z , even N nuclide studied
E_{tran}	Energy of the E0 transition in keV either from the Adopted levels and gammas of the Nuclear Data Sheet or from cited literature
Shell	Atomic electron shell (K,L,M, etc), or electron-positron pair (IPF)
$\Omega_{\text{Exp}}^{\text{ratio}}$	Ratio of the experimental pure E0 intensities
$\Omega_{\text{Theory}}^{\text{ratio}}$	Ratio of the calculated $\Omega(\text{E0})$ electronic factors from the present tabulation
Difference	Relative percentage difference between the experimental E0 intensity ratio, $\Omega_{\text{Exp}}^{\text{ratio}}$ and the calculated $\Omega(\text{E0})$ electronic factor ratio, $\Omega_{\text{Theory}}^{\text{ratio}}$. See Eqn. 28
References	NSR [55] key numbers of the source of the experimental intensity ratios.

Table 1

Ratio of experimental conversion electron (CE) and electron-positron pair conversion intensities for E0 transition in even-even atomic nuclei. See page 32 for explanation of the tables.
