Abstract

We study the energy levels of graphene magnetic circular quantum dot surrounded by an infinite graphene sheet in the presence of an electrostatic potential. We solve Dirac equation to derive the solutions of energy spectrum associated with different regions composing our system. Using the continuum model and applying boundary conditions at the interface, we obtain analytical results for the energy levels. The dependence of the energy levels on the quantum dot radius, magnetic field and electrostatic potential is analyzed for the two valleys K and K' . We show that the energy levels exhibit characteristics of interface states and have an energy gap.

I Introduction

Graphene has been the subject of massive research throughout the world since the first experiments in 2004 [1, 2] because of its unique electronic properties that could be important for nanoelectronics applications [3–5]. Graphene was prepared using several techniques, including silicon carbide surface precipitation [6, 7], mechanical exfoliation from graphite and chemical vapor deposition growth on a catalytic metal surfaces [8–10]. The electronic structure of graphene is well described elsewhere [11] involving two nodal zero-gap points (K, K'), called Dirac points, in the first Brillouin zone at which the conduction and valence bands touch. That leads to a number of its unusual peculiar electronic properties such as linear dispersion relation, gapless energy spectrum and so on [11–13].

Graphene quantum dots (QDs) are small graphene fragments, where electronic wavefunction is confined in disk of radius R . Excitons in graphene have an infinite Bohr diameter. Thus, graphene fragments of any size will show quantum confinement effects. As a result, graphene QDs have a non-zero bandgap and luminescence on excitation. This bandgap is tunable by modifying the size and surface chemistry of the graphene QDs. After its discovery, researchers have attempted to confine electrons in graphene-based QDs because of the wide range of new applications of QDs for example in electronic circuits, photovoltaic systems [14], qubits [15] and gas detection [16]. Graphene as the basis of these QDs could enable fast and flexible devices. In general, the ultra-relativistic nature of graphene charge carriers has led researchers to wonder how they would react to confinement [17]. However, it is precisely this particular property that prohibits the use of traditional manufacturing techniques such as local electrostatic bias to confine carriers. The Klein tunneling effect [18] allows electrons to use hole states in the gated region to escape the QD. For instance, one has tried using magnetic fields [19, 20], cutting the flake into small nanostructures [21, 22] or using the substrate to induce a band gap [23]. However, magnetic fields bring along many difficulties in nano-sized systems [24]. The question of confining Dirac Fermions in graphene QDs has resulted in many propositions. QDs made from nanostructures are highly sensitive to the precise shape of the edge, which is hard to control [19].

To complete our literature review we would like to mention previous work on graphene QDs. The circularly symmetric graphene nanostructures in the form of graphene rings, dots, and antidots were studied by demonstrating an excellent agreement with atomistic models for small structures [25]. Experimentally, electrostatically confined monolayer graphene QDs with orbital and valley splittings was realized [26]. The hybrid monolayer-bilayer graphene QDs were investigated in [21] by considering a circular single-layer graphene quantum dot surrounded by an infinite bilayer graphene sheet as well as a circular bilayer graphene quantum dot surrounded by an infinite single-layer graphene. Here the QD boundary conditions (zigzag or armchair) between the QD and its surrounding infinite graphene medium are very important, the QD energy levels exhibit interface states characteristics. Unlike our system (monolayer magnetic QD embedded in an infinite graphene sheet) the external electrostatic field can induce a tunable energy gap in the energy spectrum in such case. By solving Dirac equation an analytical solution to calculate energy levels and wave functions of mono- and bilayer graphene quantum dots was presented in [27]. All these important works are different from the present work but some common features of graphene QD will be pointed out in the conclusion, such as the decrease of the energy band gap as the size of the QD increases.

We study the confinement of the charge carriers in a magnetic circular quantum dot in graphene surrounded by an infinite graphene sheet. In our case we are dealing with a graphene magnetic circular quantum dot whose boundaries are defined by the profile of the applied magnetic field, hence we do not have terminated boundaries that result in dangling bonds. Hence zigzag and armchair boundary conditions are not relevant to our situation, contrary to previous works [21, 27]. The corresponding band structures will be analyzed by deriving the solutions of the energy spectrum. Subsequently, by applying the boundary condition at the interface we obtain an equation describing the energy levels in terms of the physical parameters characterizing our system. We numerically investigate the dependence of such energy levels on quantum dot radius, magnetic field and electrostatic potential. In

particular, we show that the energy levels exhibit different symmetries and energy gap under various conditions. Indeed, we show that the energy levels are degenerate in the case where the QD radius goes to zero ($R \rightarrow 0$). However as long as R increases we obtain two set of energies showing the symmetric and asymmetric behaviors. In addition, under some conditions we show that the electron density can be modified by the presence of electrostatic potential.

The present paper is organized as follows. In section 2, we solve Dirac equation to obtain the eigen-spinors describing fermions in graphene magnetic quantum dot surrounded by an infinite graphene sheet. These solutions will be used together with the continuity condition to determine the corresponding energy levels. We numerically discuss the energy spectrum and the electron density under various choices of the physical parameters in section 3. We conclude our results in the final section.

II Model and theory

We consider a graphene based quantum dot of radius R with magnetic circular geometry surrounded from exterior with an infinite graphene sheet, schematically depicted in Figure 1. The dynamics of carriers in the honeycomb lattice of covalent-bond carbon atoms of single layer graphene can be described by the Hamiltonian

$$H = v_F \vec{\sigma} \cdot (\vec{p} + e\vec{A}) + U(r)\mathbb{I} \quad (1)$$

where $v_F = 10^6$ m/s is the Fermi velocity, $p = (p_x, p_y)$ is the two-dimensional momentum operator, $\sigma = (\sigma_x, \sigma_y)$ are Pauli spin matrices in the basis of the two sublattices of A and B atoms, $U(r)$ is an axially symmetric electrostatic potential applied to the system, \vec{A} is the vector potential in the symmetric gauge and \mathbb{I} is the 2×2 identity matrix.

Figure 1 – (color online) Schematic diagram of graphene magnetic circular Quantum dot of radius R surrounded by an infinite graphene sheet in the presence of perpendicular magnetic field B inside the quantum dot.

We assume that the carriers are confined in a circular area of radius R . Due to the circular symmetry we have $[H, J_z] = 0$ with $J_z = -i\hbar\partial_\varphi + \hbar\sigma_z/2$ is the total angular momentum. This implies that the two component wavefunctions in the polar coordinates (r, φ) take the form

$$\Psi^\tau(r, \varphi) = e^{im\varphi} \begin{pmatrix} \varphi_A^\tau(r) \\ ie^{-i\tau\varphi} \varphi_B^\tau(r) \end{pmatrix} \quad (2)$$

where $m = 0, \pm 1, \pm 2 \dots$ being the orbital angular momentum quantum number. The radial components φ_A^τ and φ_B^τ express amplitude probabilities on the two carbon sublattices of graphene, the quantum number $\tau = \pm 1$ distinguishes the two valleys K and K' . It is worth mentioning that the low energy effective theory of graphene results in two equivalent or degenerate valleys that contribute equally to the transport properties. These valleys are located at two inequivalent points at the edge of the Brillouin zone called K and K' . Whenever an external applied field couples differently to the carriers in the two valleys, then the valley degeneracy is lifted and interesting physical observation

might be realized. The mathematical distinction between these two valleys is easily associated with a valley tag or quantum number that takes the value of $+1$ and -1 in these respective valleys. Different proposals have been advanced to create such a valley polarization in graphene. The main ingredient in application would be to control the single valley carrier occupancy in graphene, hence resulting in the so-called valley polarization. So much in the same way as the electron spin is used in spintronics or quantum computing, the valley quantum number can be used in "valleytronics", the valley quantum number so to speak has also two values $+1$ and -1 [28].

To discuss the localized-state solutions in the present system, we consider a circularly symmetric QD subject to the following magnetic field

$$\vec{B} = \begin{cases} B\vec{e}_z, & r < R \\ 0, & r > R \end{cases} \quad (3)$$

and due to continuity, the corresponding vector potential reads

$$\vec{A} = \begin{cases} \frac{B}{2r}(r^2 - R^2)\vec{e}_\varphi, & r < R \\ 0, & r > R \end{cases} \quad (4)$$

and \vec{e}_φ is the unitary vector. To go further in obtaining the solutions of the energy spectrum, one has to distinguish two different cases. Indeed for $r > R$ (absence of magnetic field) the Hamiltonian (1) reduces to the following

$$H = \begin{pmatrix} U & \pi_+ \\ \pi_- & U \end{pmatrix} \quad (5)$$

where the momentum operators are given by

$$\pi^\pm = -i\hbar v_F e^{\pm i\tau\varphi} \left(\frac{\partial}{\partial r} \pm \frac{\tau i}{r} \frac{\partial}{\partial \varphi} \right). \quad (6)$$

Using the eigenvalue equation $H\Psi_\tau^> = E\Psi_\tau^>$ along with the two component wavefunctions (2) we obtain

$$\left(\frac{\partial}{\partial \rho} + \frac{m\tau}{\rho} \right) \varphi_A^\tau(\rho) = -(\varepsilon - u)\varphi_B^\tau(\rho) \quad (7)$$

$$\left(\frac{\partial}{\partial \rho} + \frac{m\tau - 1}{\rho} \right) \varphi_B^\tau(\rho) = (\varepsilon - u)\varphi_A^\tau(\rho) \quad (8)$$

where all energies are measured in units of $E_0 = \frac{\hbar v_F}{R}$ and dimensionless units $\rho = \frac{r}{R}$, $\varepsilon = \frac{E}{E_0}$, $u = \frac{U}{E_0} R$ have been introduced, the subscript $>$ means that this solution holds for $r > R$. Now injecting (7) into (8) to get the second order differential equation for $\varphi_A^\tau(\rho)$

$$\left[\rho^2 \frac{\partial^2}{\partial \rho^2} + \rho \frac{\partial}{\partial \rho} + a^2 \rho^2 - m^2 \right] \varphi_A^\tau(\rho) = 0 \quad (9)$$

which has as one of its solutions the Bessel function of the first kind that is regular at the origin

$$\varphi_A^\tau(\rho) = C_\tau^> J_m(a\rho) \quad (10)$$

with $a = \varepsilon - u$ and $C_\tau^>$ is the constant of normalization. The second component of eigenspinor can be derived from (7) as

$$\varphi_B^\tau(\rho) = -iC_\tau^> e^{-i\tau\varphi} J_{m-\tau}(a\rho). \quad (11)$$

Finally in region $r > R$, the eigenspinors have the form

$$\Psi_\tau^>(\rho, \varphi) = C_\tau^> e^{im\varphi} \begin{pmatrix} J_m(a\rho) \\ -ie^{-i\tau\varphi} J_{m-\tau}(a\rho) \end{pmatrix}. \quad (12)$$

As far as the second region $r < R$ is concerned, the magnetic field B forces the momentum operator π^+ and π^- to take the forms

$$\pi^\pm = -i\hbar v_F e^{\pm i\tau\varphi} \left(\frac{\partial}{\partial r} \pm \frac{\tau i}{r} \frac{\partial}{\partial \varphi} \mp i\tau \frac{eBr}{2\hbar} \right) \quad (13)$$

in the symmetric gauge $\vec{A} = \frac{Br}{2} \vec{e}_\varphi$. Solving the equation $H\Psi_\lessdot^\tau = E\Psi_\lessdot^\tau$ we get

$$\left(\frac{\partial}{\partial \rho} + \frac{m\tau}{\rho} + \tau\beta\rho \right) \varphi_A^\tau(\rho) = -(\varepsilon - u) \varphi_B^\tau(\rho) \quad (14)$$

$$\left(\frac{\partial}{\partial \rho} + \frac{m\tau - 1}{\rho} - \tau\beta\rho \right) \varphi_B^\tau(\rho) = (\varepsilon - u) \varphi_A^\tau(\rho) \quad (15)$$

where $\beta = \frac{eB}{2\hbar} R^2$ is a dimensionless parameter. These can be combined to derive a second order differential equation

$$\left[\rho^2 \frac{\partial^2}{\partial \rho^2} + \rho \frac{\partial}{\partial \rho} + k_\pm^2 \rho^2 - m^2 - 2\beta(m - \tau) + (\varepsilon - u_1)^2 \rho^2 - \beta^2 \rho^4 \right] \varphi_A^\tau(\rho) = 0 \quad (16)$$

which can be solved by considering the following ansatz

$$\varphi_A(\rho) = \rho^{|m|} e^{-\frac{\beta\rho^2}{2}} \chi(\rho^2) \quad (17)$$

yielding the confluent hypergeometric ordinary differential equation

$$\left[x \frac{\partial^2}{\partial x^2} + (b - x) \frac{\partial}{\partial x} - a \right] \chi(x) = 0 \quad (18)$$

where we put $x = \beta r^2$ and set the parameters

$$b = 1 + |m|, \quad a = -\frac{(\varepsilon - u_1)^2}{4\beta} + \frac{m - \tau + |m| + 1}{2}. \quad (19)$$

Consequently, the solution is

$$\varphi_A(\rho) = \rho^{|m|} e^{-\frac{\beta\rho^2}{2}} C_\lessdot^\tau \tilde{M}(a, b, \beta\rho^2) \quad (20)$$

C_\lessdot^τ is the constant of normalization and $\tilde{M}(a, b, \beta\rho^2)$ are the confluent hypergeometric functions [32], the subscript \lessdot means solution for $r < R$. The second component can be extracted from (14) as

$$\varphi_B(\rho) = i \frac{C_\lessdot^\tau \rho^{|m|} e^{-\frac{\beta\rho^2}{2}} e^{-i\tau\varphi}}{\varepsilon - u} \left[\left(\frac{\tau m}{\rho} + \beta\tau\rho \right) \tilde{M}(a, b, \beta\rho^2) - a \tilde{M}(a + 1, b + 1, \beta\rho^2) \right]. \quad (21)$$

Combining all, we end up with the eigenspinors in the magnetic region $r < R$

$$\Psi_\lessdot^\tau(\rho, \varphi) = C_\lessdot^\tau \rho^{|m|} e^{-\frac{\beta\rho^2}{2}} e^{im\varphi} \left(\begin{array}{c} \tilde{M}(a, b, \beta\rho^2) \\ \frac{ie^{-i\tau\varphi}}{\varepsilon - u} \left[\left(\frac{\tau m}{\rho} + \beta\tau\rho \right) \tilde{M}(a, b, \beta\rho^2) - a \tilde{M}(a + 1, b + 1, \beta\rho^2) \right] \end{array} \right) \quad (22)$$

Now we look for the energy levels of our system that cannot be obtained by directly solving the eigenvalue equation. Nevertheless, we can still apply the boundary condition at the interface $\rho = 1$ or $r = R$, namely $\Psi_\gtrdot^\tau(1) = \Psi_\lessdot^\tau(1)$. This operation yields

$$C_\gtrdot^\tau J_m(a) = C_\lessdot^\tau e^{-\frac{\beta}{2}} \tilde{M}(a, b, \beta) \quad (23)$$

$$C_\gtrdot^\tau J_{m-\tau}(a) = -C_\lessdot^\tau \frac{e^{-\frac{\beta}{2}}}{\varepsilon - u} \left[(\tau m + \beta\tau) \tilde{M}(a, b, \beta) - a \tilde{M}(a + 1, b + 1, \beta) \right] \quad (24)$$

which can be cast in matrix form as

$$M^\tau \begin{pmatrix} C_{>}^\tau \\ C_{<}^\tau \end{pmatrix} = 0 \quad (25)$$

such that the matrix is given by

$$M^\tau = \begin{pmatrix} J_m(a) & -e^{-\frac{\beta}{2}} \tilde{M}(a, b, \beta) \\ J_{m-\tau}(a) & \frac{e^{-\frac{\beta}{2}}}{\varepsilon-u} \left[(\tau m + \beta\tau) \tilde{M}(a, b, \beta) - a \tilde{M}(a+1, b+1, \beta) \right] \end{pmatrix}. \quad (26)$$

The only allowed energy levels are given by $\det M^\tau = 0$, which leads to the following eigenvalue equation

$$J_m(a) \frac{e^{-\frac{\beta}{2}}}{\varepsilon-u} \left[(\tau m + \beta\tau) \tilde{M}(a, b, \beta) - a \tilde{M}(a+1, b+1, \beta) \right] + J_{m-\tau}(a) e^{-\frac{\beta}{2}} \tilde{M}(a, b, \beta). \quad (27)$$

Recall that the energy levels are embedded in the parameter $a = \varepsilon - u$. This equation will be numerically solved to extract the energy levels, which will then allow us to study the basic properties of our system. In fact, we will discuss such levels under various configurations of the physical parameters such as the quantum dot radius R , magnetic field B and electrostatic potential.

III Numerical results

In Figure 2, we show the energy levels as a function of the quantum dot radius R for $b = 10$ T and three different values of angular quantum number such that (a): $m = -1$, (b): $m = 0$, (c): $m = 1$ with $U = 0$ meV and (d): $m = -1$, (e): $m = 0$, (f): $m = 1$ with $U = 100$ meV. Note that, full and dashed lines are describing energy associated with the two valleys K ($\tau = 1$) and K' ($\tau = -1$), respectively. We observe that when $R \rightarrow 0$, the energies of K ($\tau = 1$) and K' ($\tau = -1$) are degenerate for all τ , which means that $E(m, \tau) = E(m, -\tau)$. However when R increases, two sets of energy levels appear, one shows the symmetry $E(m, \tau) = E(m, -\tau)$ and approaches the Landau levels (LLs) corresponding to graphene QD [21], the other one shows a lack of symmetry $E(m, \tau) \neq E(m, -\tau)$. It is clearly seen that an energy gap is opened for a non zero angular momentum m as shown in Figures 2(a,c,d,f) and there is a zero energy for $m = 0$ as in Figures 2(b,e). On the other hand, the influence of potential U makes it possible to move the energy levels vertically by U , namely we have

$$E(m, \tau, U) = E(m, \tau) + U. \quad (28)$$

The energy levels as a function of the magnetic field are presented in Figure 3 for $R = 70$ nm, (a): $m = -1$, (b): $m = 0$, (c): $m = 1$ with $U = 0$ meV and (d): $m = -1$, (e): $m = 0$, (f): $m = 1$ with $U = 100$ meV. For small magnetic field ($B \rightarrow 0$), we observe that the energy levels display a continuum energy band and also there are many degenerate zero-energy states corresponding to all angular momenta m for both K and K' , i.e. $E(m, \tau) = E(m, -\tau)$ [21]. Now by increasing B , one notices that the degeneracy of the energy levels is lifted and then we have $E(m, \tau) \neq E(m, -\tau)$, which finally connects to the LLs of graphene subject to magnetic field [31]

$$E_{nm} - U = \pm E_0 \sqrt{2\beta(2n + m + |m| + 1 - \tau)}, \quad n = 0, 1, 2, \dots \quad (29)$$

which can be derived from the relation between the Laguerre function and confluent hypergeometric function \tilde{M} under suitable conditions, more detail can be found in [33]. There are some other features, e.g. for $B \neq 0$ an energy gap appears between the conduction and valence bands, which is quantum number m dependent. The behavior of the potential on the electronic properties of the energy levels for K and K' shows that (28) is qualitatively similar to the behavior seen in Figure 2.

Figure 2 – (color online) Energy levels as a function of the quantum dot radius R for $B = 10$ T. (a): $m = -1$, (b): $m = 0$, (c): $m = 1$ with $U = 0$ meV. (d): $m = -1$, (e): $m = 0$, (f): $m = 1$ with $U = 100$ meV. $\tau = 1$ for blue line and $\tau = -1$ for red dashed line.

Figure 3 – (color online) Energy levels as a function of the magnetic field B with $R = 70$ nm. (a): $m = -1$, (b): $m = 0$, (c): $m = 1$ for $U = 0$ meV. (d): $m = -1$, (e): $m = 0$, (f): $m = 1$ for $U = 100$ meV. Blue color for $\tau = 1$ and red dashed color for $\tau = -1$.

Figure 4 – (color online) Radial probability $\rho_m(\rho)$ as a function of the quantum dot radius $\rho = \frac{r}{R}$ with $U = 100$ meV. (a): $B = 0$ T, (b): $B = 0.5$ T, for $\tau = \pm 1$ and $E = 0.1$ meV. Total angular quantum number $m = -1$ (green), $m = 0$ (black) and $m = 1$ (red).

The radial probability $\rho_m(\rho)$ as a function of the QD radius ρ are shown in Figure 4, for $U = 100$ meV, with $E = 0.1$ meV, total angular quantum number $m = -1$ (green), $m = 0$ (black) and $m = 1$ (red). In the absence of the magnetic field (Figure 4(a)), for $m = 0$ (black) and $m = 1$ (red), we clearly see that the maxima of the radial probability $\rho_m(\rho)$ close to $\rho = 0$. This maximum corresponds to the electron state strongly trapped in the quantum dot, but with the increase of ρ , $\rho_m(\rho)$ tends to 0. On the other hand, for $m = -1$, we have zero radial probability in the vicinity of $\rho = 0$, however when ρ increases $\rho_m(\rho)$ increases to a maximum value around the point $\rho = 0.2$ and after that it has a damped oscillatory behavior. For a non-zero magnetic field Figure 4(b)), the radial probability $\rho_m(\rho)$ starts its behavior with a maximum value at point from $\rho = 0.15$ for each value of m . Note that for $m = 0$ and $m = -1$, the probability decreases with the increase of ρ , in particular we have $\rho_m(\rho)$ from $\rho = 0.35$. For $m = 0$, the radial probability has an approximately oscillatory dependence damped particularly for large ρ .

In Figure 5, we show the energy levels as a function of the confining potential U for $R = 70$ nm and $B = 10$ T with (a): $m = -1$, (b): $m = 0$, (c): $m = 1$. We observe that they have a linear form and are twofold degenerate due to the symmetry $E(m, \tau) = E(-m, -\tau)$ for $m \neq 0$ and $E(m, \tau) = E(m, -\tau)$ for $m = 0$. It is clearly seen that an energy gap is opened for all the values of m between conduction and valance bands.

Figure 5 – (color online) Energy levels as a function of the potential U with $B = 10$ T. (a): $m = -1$, (b): $m = 0$, (c): $m = 1$ for $R = 70$ nm. Blue color for $\tau = 1$ and red dashed color for $\tau = -1$.

The resulting eigenenergies E_{nm} (29) are plotted in Figure 6 for $U = 0$ in the panels (a,b) and $U = 20$ meV in the panels (c,d) with Landau levels $n = 0, \dots, 4$. It is noticed that the two valleys are

Figure 6 – (color online) Energy levels E_{nm} , given in (29), as a function of angular momentum m with $B = 10$ T for Landau levels $n = 0, \dots, 4$. (a): $U = 0$ meV, (c): $U = 20$ meV for $\tau = -1$, (b): $U = 0$ meV, (d): $U = 20$ meV for $\tau = 1$.

non degenerate in the eigenenergy spectra $E_{nm}(\tau) \neq E_{nm}(-\tau)$. The eigenenergies exhibit asymmetric behavior with respect to the sign of the quantum number m i.e. $E_{nm}(m, \tau) \neq E_{nm}(-m, \tau)$. For the valley K the energy spectrum $E_{nm}(\tau = 1)$ has a zero gap, but for the valley K' the energy spectrum $E_{nm}(\tau = -1)$ has a non-zero gap. It is clearly seen that the existence of the potential U allows to move the energy levels vertically as shown in panels (c,d). For larger $|m|$, larger gap are observed between valance and conduction bands for the two valleys $\tau = \pm 1$.

Figure 7 shows the electron density $|\psi_{nm}|^2$ of the charge carriers in graphene magnetic quantum dot of radius $R = 70$ nm and subject to the field $B = 10$ T for the potential $U = 0$ meV and $U = 100$ meV, with some selected values of the quantum numbers n and m . We observe that the electron density for $m = 0$ and $n = 0$ exhibits a maximum at the center of QD in panels (a,d), while in the panels (g,h,i,j,k,l) for $m = 0$ and $n = 1, 2, 3$ a minimum is observed at the center of the QD. Note that the low contribution of the other modes of the point leads to the slight asymmetry of the electron density. To analyze the effect of the potential U on $|\psi_{nm}|^2$, we presents the panels (g,h,i,j,k) for a given value $U = 100$ meV. Indeed, by comparison we notice that for $U = 0$ meV the density is substantial at the center as shown in panels (b,c) but for $U = 100$ meV it has a minima in the center of QD see panels (e,f). Also the density $|\psi_{n0}|^2$ possesses different behaviors in the absence (panels (g,h,i)) and presence (panels (j,k,l)) of the potential. It is clearly seen that $|\psi_{00}|^2$ has the same behavior with and without the potential U . The interesting result is that the electron density inside the quantum dot is dramatically increased, which is a sign of temporary particle trapping.

Figure 7 – (color online) Spatial density $|\psi_{nm}|^2$ in the vicinity of the quantum dot. (a): ($n = 0, m = 0$), (b): ($n = 0, m = -1$), (c): ($n = 0, m = 1$), (g): ($n = 1, m = 0$), (h): ($n = 2, m = 0$), (i): ($n = 3, m = 0$) for $U = 0$ meV. (d): ($n = 0, m = 0$), (e): ($n = 0, m = -1$), (f): ($n = 0, m = 1$), (j): ($n = 1, m = 0$), (k): ($n = 2, m = 0$), (l): ($n = 3, m = 0$) for $U = 100$ meV. In all the panels $B = 10$ T, $R = 70$ nm.

IV Conclusion

We have studied the confinement of charge carriers in a graphene quantum dot submitted to a perpendicular magnetic field and electrostatic potential. Solving the two-band DiracWeyl Hamiltonian, in the vicinity of both K and K' valleys, we have obtained analytically the eigenspinors. The boundary conditions were used to obtain an equation describing the energy levels in terms of the physical parameters characterizing our quantum dot and the strength of the applied magnetic field.

We have discussed our results numerically for various choices of the physical parameters. Indeed, the dependence of the spectrum on the radius R of the QD has been investigated the energy spectrum

has the asymmetry $E(m, \tau) = E(m, -\tau)$ for all the values of τ when the limit $R \rightarrow 0$ is satisfied. As long as R increases, two sets of energy levels appear, one satisfies the symmetry $E(m, \tau) = E(m, -\tau)$ and the other is not symmetric $E(m, \tau) \neq E(m, -\tau)$. An energy gap for $m \neq 0$ and at zero energy for $m = 0$ has been obtained. According to Figure 2, we have observed that the energy band gap decreases when the size of the QD increases. As far as the magnetic field dependence is concerned, we have shown that the degeneracy of the valley exists when the magnetic field $B \rightarrow 0$. By increasing B , we have seen that the spectrum exhibits anti-crossings and the levels merge at the Landau levels for monolayer graphene, which indicates that the carriers become strongly localized at the center of the graphene magnetic quantum dot. Furthermore the influence of the electrostatic potential U makes it possible to shift the energy levels vertically by U , such that $E(m, \tau, B, U) = E(m, B, \tau) + U$. Finally, we have shown that for some values of the quantum number n and m , the electron density in QD is strongly increased, which indicates a temporary electron trapping.
