Submitted November 5, 2019

We present results of nuclear magnetic resonance (NMR) experiments in superfluid $^3\text{He}$ in two samples of nematic aerogel consisting of nearly parallel mullite strands. The samples were cut from the same piece of the aerogel, but one of them was squeezed by 30% in the direction transverse to the strands. In both samples the superfluid transition of $^3\text{He}$ occurred into the polar phase, where no qualitative difference between NMR properties of $^3\text{He}$ in these samples was found. The difference, however, has appeared on further cooling, after the transition to the polar-distorted A phase (PdA phase) with the orbital part of the order parameter in the 2D Larkin-Imry-Ma (LIM) state. In the squeezed sample the 2D LIM state is anisotropic that results in changes in the NMR, which can be used as an additional marker of the PdA phase and have allowed us to measure the value of the anisotropy.

1. INTRODUCTION

Nematic aerogels consist of strands with diameter of $\sim 10$ nm, which are oriented along the same direction $[1]$. In liquid $^3\text{He}$ in these aerogels, the strands result in an anisotropy of $^3\text{He}$ quasiparticle scattering $[3]$. It makes favorable new superfluid phases: polar, polar-distorted A (PdA) and polar-distorted B (PdB) $[2, 4, 5]$. The superfluid order parameter of polar and PdA phases has the form:

$$A_{nk} = \Delta_0 e^{i\varphi} d_0 (am_k + ibn_k),$$

(1)

where $\Delta_0$ is the gap parameter, $e^{i\varphi}$ is the phase factor, $d_0$ is the unit spin vector oriented normal to the magnetization, $m$ and $n$ are mutually orthogonal unit vectors in orbital space, and $a^2 + b^2 = 1$. The PdA phase ($a^2 > b^2$) is an intermediate state between the polar phase ($a = 1, b = 0$) and the A phase ($a = b$) which exists in bulk $^3\text{He}$. The A and PdA phases are chiral and have a superfluid gap with two nodes along $\ell = m \times n$ while the polar phase is not chiral, it is characterized only by one orbital vector $m$, and its gap is zero in the plane normal to $m$. The phases described by Eq. (1) belong to a class of Equal Spin Pairing (ESP) states.

Previous experiments with $^3\text{He}$ in nematic aerogel were done using samples with strands of AlOOH (Obninsk aerogel) or $\text{Al}_2\text{O}_3$ (nafen) with various porosities and degree of the anisotropy $[8, 7, 5, 10, 11, 12]$. It was found that on cooling from the normal phase, the superfluid transition of $^3\text{He}$ occurs into the PdA phase (in Obninsk aerogel) or into the polar phase (in nafen).

On further cooling, transitions from polar to PdA phase, and then into PdB phase were observed.

Here, using continuous wave (cw) nuclear magnetic resonance (NMR), we investigate the ESP phases of $^3\text{He}$ in a new type of nematic aerogel, strands of which are made of mullite. We assume that the mullite aerogel is closer to an ideal array of parallel cylinders because it is more transparent than Obninsk aerogel or nafen and more easily splits along the strands. Two samples of mullite nematic aerogel are used: the original (undeformed) sample and the sample squeezed by 30% in the direction transverse to the strands. In particular, we investigate how the squeezing changes NMR properties of chiral PdA phase and non-chiral polar phase.

2. SAMPLES AND METHODS

Two samples were cut from the same piece of aerogel with overall density 150 mg/cm$^3$, porosity $\approx 96\%$, and diameter of strands $\lesssim 10$ nm. One sample (mullite-F) was placed freely in a separate cell of our experimental chamber with a filling factor $\approx 80\%$, another sample (mullite-S) was unidirectionally squeezed by 30% inside its cell in the direction transverse to the strands by a movable wall that was glued after. Both samples have a cuboid shape of sizes 3–4 mm. The chamber was made of Stycast-1266 epoxy and was similar to that described in Ref. $[6]$.

Measurements of spin diffusion in normal $^3\text{He}$ in present samples were done at 2.9 bar using spin echo techniques. It allowed us to determine effective mean free paths of $^3\text{He}$ quasiparticles along ($\lambda_\parallel$) and trans-
verse to the strands ($\lambda_\perp$) in the limit of zero temperature (see Table 2).

Experiments were carried out using linear cw NMR in magnetic fields 139–305 Oe (NMR frequencies 450–990 kHz) at pressures 7.1–29.3 bar. We were able to rotate the external steady magnetic field $\mathbf{H}$ by an arbitrary angle $\mu$ with respect to the direction of strands ($\hat{z}$) as shown in Fig. 1a. Additional gradient coils were used to compensate the magnetic field inhomogeneity. The necessary temperatures were obtained by a nuclear demagnetization cryostat and determined using cw NMR measurements of the Leggett frequency in bulk $^3$He-B.

To avoid a paramagnetic signal from surface solid $^3$He and stabilize the polar phase [12], the samples were pre-plated by $\sim 2.5$ atomic layers of $^3$He.

Identification of the ESP phases can be made by measurements of the cw NMR frequency shift ($\Delta \omega$) from the Larmor value ($\omega_L = \gamma H$, where $\gamma$ is the gyromagnetic ratio of $^3$He). The shift appears due to a dipole interaction and depends on the order parameter, its spatial distribution, angle $\mu$, and in the isotropic 2D LIM state it is given by [6, 9, 16]:

$$2\omega_L \Delta \omega = k(4 - 6b^2)\Omega_A \cos^2 \mu = K\Omega_A \cos^2 \mu,$$

where $K = k(4 - 6b^2)$ and, in a weak coupling approximation,

$$k = \frac{1}{3} - 4a^2b^2.$$ 

Here $\Omega_A = \Omega_A(T, P) \propto \Delta_0$ is the Leggett frequency of the A phase. This frequency grows from 0 up to $\sim 100$ kHz on cooling from the superfluid transition. If the superfluid transition temperature of $^3$He in aerogel ($T_{ca}$) is close to the transition temperature ($T_c$) in bulk $^3$He, then $\Omega_A(T_{ca})/\Omega_{A0}(T/T_c) = T_{ca}/T_c$ [8], where $\Omega_{A0}$ is the Leggett frequency of bulk $^3$He-A, which is known. Then measurements of $\Delta \omega$ allow to determine $K$ and to identify the phases (in the A phase $K = k = 1/2$, while in the polar phase $K$ should be...
equal to 4/3). However, it is known that the weak coupling limit is a good approximation only at low pressures \[17\], so, for the identification of the phases at high pressures, an experimentally measured dependence of \(K_p\) on pressure should be used. Experiments show that \(K_p\) decreases from 4/3 at 0 bar down to \(\approx 1.15\) at 29.3 bar \[3\], so \(k\) in the polar phase \((k_p)\) decreases from 1/3 down to 0.29.

In squeezed nematic aerogel (Fig. 1) Eq. (2) is modified for A and PdA phases due to the anisotropy of the 2D LIM state \[9\]. In particular, the shifts \(\Delta\omega_{\parallel}\) (at \(\mu = 0\)) and \(\Delta\omega_{\perp}\) (at \(\mu = \pi/2\) and \(\mathbf{H} \parallel \hat{y}\)) are given by:

\[
2\omega_L\Delta\omega_{\parallel} = 4 \left(1 - b^2 - b^2 \langle \ell_y^2 \rangle \right) k\Omega_A^2, \quad \mu = 0, \tag{4}
\]

\[
2\omega_L\Delta\omega_{\perp} = 4b^2 \left(1 - 2 \langle \ell_y^2 \rangle \right) k\Omega_A^2, \quad \mu = \pi/2. \tag{5}
\]

It follows from Eq. (5) that at \(\mu = \pi/2\) there is a qualitative difference between PdA (or A) and polar phases: in the polar phase \(\Delta\omega_{\perp} = 0\), while in the PdA phase the shift is nonzero (positive for \(\langle \ell_y^2 \rangle < 1/2\)). The latter can be used as an additional marker of the PdA phase. At low pressures (where the weak coupling model works) measurements of \(\Delta\omega_{\parallel}\) and \(\Delta\omega_{\perp}\) allow to determine \(b^2\) and the value of anisotropy of the 2D LIM state \(\langle \ell_y^2 \rangle\) in the PdA phase. In order to estimate \(\langle \ell_y^2 \rangle\) and \(b^2\) at high pressures, we can use experimental value of \(K_p = 4k_p\) and assume that, for small distortions from the polar phase, strong coupling corrections do not change qualitatively the dependence of \(k\) on \(b^2\); that is, \(k(P)/k_p(P) = 3/(3 - 4a^2b^2)\).

### 4. RESULTS AND DISCUSSIONS

The superfluid transition of \(^3\)He in mullite-F occurs into the polar phase at \(T = T_{ca} \approx 0.988 T_c\) (at \(P = 29.3\) bar) as it is seen from measurements of \(\Delta\omega_{\parallel}\) (open circles in Fig. 2). On further cooling, a second-order transition into the PdA phase takes place at \(0.95 T_c\) as the data deviate from the curve expected for the polar phase. The shift for \(\mu = \pi/2\) (filled circles) is absent that indeed agrees with Eq. (2).

In mullite-S the superfluid transition to the polar phase occurs at \(P = 29.3\) bar is observed at \(T = T_{ca} \approx 0.980 T_c\), and just below this temperature data for \(\Delta\omega_{\parallel}\) (open triangles in Fig. 2) follow the curve with the same slope as for mullite-F. On cooling, the polar phase persists, until the positive shift for \(\mu = \pi/2\) (filled triangles) appears at \(T = T_{PdA} \approx 0.915 T_c\) indicating a transition to the PdA phase. We note that the data for \(\Delta\omega_{\parallel}\) in mullite-S start clearly deviate from the curve for the polar phase (the dashed line) far below \(T_{PdA}\). It agrees with Eq. (4) from which it follows that \(\Delta\omega_{\parallel}\) in PdA phase in the anisotropic 2D LIM state is greater than in the isotropic state and can even exceed the shift in polar phase if \(4b^2 < 1 - 3 \langle \ell_y^2 \rangle\).

Using Eqs. (4, 5) and the measured (and extrapolated to a given temperature) values of \(\Delta\omega_{\parallel}\) and \(\Delta\omega_{\perp}\) we have obtained temperature dependencies of \(b^2\) and \(\langle \ell_y^2 \rangle\) in the PdA phase (Fig. 3). Points in this figure correspond to \(K_p = 1.15\) and \(T_{ca} = 0.980 T_c\), and error bars show how the results are changed if we vary \(K_p\) by 1%. It is seen that \(b^2\) increases from 0 to 0.26 on cooling from \(T_{PdA}\) in agreement with Ref. [2], while \(\langle \ell_y^2 \rangle\) levels off at \(\approx 0.33\) confirming the anisotropy of the
In recent theoretical paper [18] it was stated that Anderson theorem for s-wave superconductors is applicable to superfluid $^3$He in ideal nematic aerogel; that is, in the case of ideally parallel strands and for specular reflection of $^3$He quasiparticles. In particular, the change of $\Delta \omega$ near the absolute zero should be proportional to $-T^3$ that was confirmed in recent experiments [19]. Our results agree with another prediction of Ref. [18]; that is, the range of temperatures where the polar phase exists is inversely proportional to $\lambda_\perp$ (see Fig. 4) and data for $\lambda_\perp$ for mullite samples in Table 2. We also note that the suppression of the superfluid transition temperature of $^3$He in mullite-F (with porosity 96%) is essentially (about 1.4 times) smaller than in $^3$He in nafen-90 with higher porosity (97.8%) and is nearly the same as in nafen-72 with porosity 98.2%. It agrees with one more prediction of Ref. [18] that in the ideal case $T_{ca} \equiv T_c$.

5. CONCLUSIONS

Using cw NMR we have investigated the ESP phases of $^3$He in two samples of new (mullite) nematic aerogel. In both samples the superfluid transition of $^3$He occurs into the polar phase with no qualitative difference between NMR properties of $^3$He in these samples. But the difference is observed on further cooling, after the transition to the PdA phase with $\ell$ forming the 2D LIM state, which is anisotropic in the squeezed sample. In the latter case we have determined the value of this anisotropy and the degree of the polar distortion. The results, in general, provide an additional proof of existence of the polar phase at $T_{PdA} < T < T_{ca}$ and also support the application of Anderson theorem to superfluid $^3$He in nematic aerogel.
