Abstract

Compared with ferromagnetic counterparts, antiferromagnetic materials are considered as the future of spintronic applications since these materials are robust against the magnetic perturbation, produce no stray field, and display ultrafast dynamics. There are (at least) two sets of magnetic moments in antiferromagnets (with magnetization of the same magnitude but antiparallel directions) and ferrimagnets (with magnetization of the different magnitude). The coupled dynamics for the bipartite collinear antiferromagnets is modeled by a coupled system of Landau-Lifshitz-Gilbert equations with an additional term originated from the antiferromagnetic exchange, which leads to femtosecond magnetization dynamics. In this paper, we develop three Gauss-Seidel projection methods for micromagnetics simulation in antiferromagnets and ferrimagnets. They are first-order accurate in time and second-order in space, and only solve linear systems of equations with constant coefficients at each step. Femtosecond dynamics, Néel wall structure, and phase transition in presence of an external magnetic field for antiferromagnets are provided with the femtosecond stepsize.

Keywords: Antiferromagnet, Landau-Lifshitz-Gilbert equation, Guass-Seidel projection methods, antiferromagnetic exchange, micromagnetics simulation

1. Introduction

An electron has both charge and spin properties. The active manipulation of spin degrees of freedom in solid-state systems is known as spintronics [1, 2]. Most of researches have been focused on ferromagnets (FMs) for GHz-frequency magnetization dynamics in the past decades and the domain wall velocity can reach \( \sim 100 \text{ m/s} \). In early days, antiferromagnets (AFMs), however, are thought to be less effective for spintronic manipulations since they are robust against the magnetic perturbation and produce no stray field [3]. In fact, it was latter realized that the robustness of AFMs with respect to the magnetic perturbation makes them better candidates for spintronic applications due to the high stability of domain wall structures. In addition, one striking feature in AFMs is the femtosecond magnetization dynamics due to the antiferromagnetic exchange coupling, which has been employed to generate THz-frequency magnetization dynamics [4, 5, 6], and boosts the domain wall velocity in AFMs to \( \sim 10,000 \text{ m/s} \) [7, 8, 9]. Moreover, room-temperature antiferromagnetic order has been found

over a broad range of materials, such as metal, semiconductor, and insulator, which can be
used in spintronics devices such as racetrack memories, memristors, and sensors [6, 3, 10, 11].

From the modeling perspective, magnetization \( M \) is the basic quantity of interest. In ferromagnetic materials, its dynamics is modeled by the Landau-Lifshitz-Gilbert (LLG) equation [12, 13] with the property that \(|M| = M_s\) where \( M_s \) is the saturation magnetization. In general, an AFM contains \( n \) magnetic sublattices and the magnetization \( M = \sum_{\lambda=1}^{n} M_\lambda = 0 \) with \( M_\lambda \neq 0 \). Most common AFMs, such as FeMn and NiO, have two sublattices \( A \) and \( B \), associated with two magnetization fields \( M_A \) and \( M_B \) satisfying \( M = M_A + M_B = 0 \).

For each sublattice, its magnetization satisfies a LLG equation with an antiferromagnetic exchange term which couples these two equations. In the physics community, by introducing another order parameter \( L = M_A - M_B \), reduced models for AFMs are developed for describing magnetization dynamics [5, 3].

In this work, we focus on numerical methods for AFMs and ferrimagnets described by the coupled system of LLG equations. By ferrimagnets such as \( Fe_{3}O_{4} \), we mean \(|M_A| \neq |M_B|\).

A large volume of methods have been proposed for FMs; see [14, 15, 16] for reviews and references therein. For the temporal discretization, there are explicit schemes [17, 18], implicit schemes [19, 20, 21], and semi-implicit schemes [22, 23, 24, 25, 26, 27]. However, there is no work on numerical methods for AFMs in the literature.

At a first glance, numerical methods for FMs can be directly applied to AFMs and ferrimagnets with minor modifications. However, pros and cons of different methods for FMs may not be directly transferred. For example, explicit methods require sub-picosecond stepsize in micromagnetics simulation. For AFMs or ferrimagnets, the stepsize becomes sub-femtosecond for explicit methods while the time scale of interest is of nanoseconds. The underlying reason is that the antiferromagnetic exchange term poses an characteristic time scale of femtoseconds on magnetization dynamics. Even unconditionally stable implicit and semi-implicit schemes have to resolve the magnetization dynamics at femtosecond scales in order to capture the correct physics. Implicit schemes solve a nonlinear system of equations at each step. From FMs to AFMs, the dimension of the nonlinear system is doubled with possibly more solutions (locally stable magnetic structures). In semi-implicit schemes, the nonlinear structure of the coupled system does not bring any difficulty in an explicit way and only the computational complexity is doubled. Therefore, semi-implicit methods provide the best compromise between stability and efficiency. Gauss-seidel projection methods (GSPMs) [22, 23] are of our first choice since only linear systems of equations with constant coefficients needs to be solved at each step. As shown in the paper, the coupled system of LLG equations can be solved by GSPMs with the computational complexity doubled at each step. Due to the antiferromagnetic exchange, the stepsize in GSPMs is femtosecond as expected.

The rest of this paper is organized as follows. We introduce the model for AFMs and
ferrimagnets in Section 2. The corresponding Gauss-Seidel projection methods are described in Section 3. Their accuracy with respect to temporal and spatial stepsizes is validated in Section 4. Femtosecond magnetization dynamics, Néel wall structures, and phase transition in presence of a magnetic field are simulated for AFMs in Section 5. Conclusions are drawn in Section 6.

2. Model for antiferromagnets: A coupled system of Landau-Lifshitz-Gilbert equations

Consider a bipartite collinear magnetic material occupied by $\Omega \in \mathbb{R}^3$. Its magnetization structure can be a ferromagnetic phase (Fig. 1(a)), a ferrimagnetic phase (Fig. 1(b)), or an antiferromagnetic phase (Fig. 1(c)). The dynamics of the two-sublattices system is modeled by a coupled system of phenomenological LLG equations [3]

$$\begin{align*}
\partial_t M_A &= -\mu_0 \gamma M_A \times H_A + \frac{\alpha}{M_s} M_A \times \partial_t M_A, \\
\partial_t M_B &= -\mu_0 \gamma M_B \times H_B + \frac{\alpha}{M_s} M_B \times \partial_t M_B.
\end{align*}$$

(1)

$\alpha$ is the dimensionless damping parameter, $\gamma$ is the gyromagnetic ratio, and $\mu_0$ is the magnetic permeability of vacuum. For each sublattice $\lambda = A, B$, we have magnetization $M_\lambda = (M_{\lambda 1}, M_{\lambda 2}, M_{\lambda 3})^T$ with $|M_\lambda| = M_s$. For ferrimagnets, $M_s$ is different for $A$ and $B$. $H_\lambda = -\delta W/\delta M_\lambda$ with $W$ being the magnetic energy density of an antiferromagnetic or ferrimagnetic system including magnetic anisotropy, ferromagnetic exchange, antiferromagnetic exchange, and Zeeman energy (external magnetic field) [4, 6]

(2)

(1) can be viewed as two sets of LLG equations for $M_A$ and $M_B$ with the antiferromagnetic exchange coupling in (2).

Details of the four terms in (2) are described as follows:

1. **Anisotropy energy**: Magnetization usually favors an easy-axis direction of the form

$$W_a[M_A, M_B] = \int_{\Omega} \Phi(M_A) + \Phi(M_B),$$
where $\Phi : \Omega \rightarrow \mathbb{R}^+$ is a smooth function. Suppose the easy-axis direction is the x-axis for a uniaxial material, the total anisotropy energy of two sublattices is

$$W_a[M_A, M_B] = \frac{K_u}{M_s^2} \int_{\Omega} (M_A^2 + M_A^2 + M_B^2 + M_B^2) dx,$$

where $K_u$ is the material parameter.

2. **Ferromagnetic exchange**: Magnetization of each sublattice experiences a ferromagnetic exchange energy of the form

$$W_e[M_A, M_B] = \frac{A}{M_s^2} \int_{\Omega} |\nabla M_A|^2 + |\nabla M_B|^2,$$

where $A$ presents the exchange constant of the material.

3. **Antiferromagnetic exchange**: Magnetization of sublattice A and sublattice B favors alignment along an antiparallel direction, thus the exchange energy is of the form

$$W_{ae}[M_A, M_B] = \frac{4A_{AFM}}{a^2 M_s^2} \int_{\Omega} M_A \cdot M_B,$$

where $A_{AFM}$ is the antiferromagnet exchange parameter and $a$ is the atomic lattice constant. For a positive $A_{AFM}$, the system favors a ferromagnetic state. For a negative $A_{AFM}$, however, an antiferromagnetic state is preferred.

4. **Zeeman energy**: In the presence of an external magnetic field $H_{ext}$, the interaction energy is of the form

$$W_{ext}[M_A, M_B] = -\mu_0 \int_{\Omega} H_{ext} \cdot (M_A + M_B).$$

Thus, the free energy of an antiferromagnetic or ferrimagnetic material is explicitly written as

$$W[M_A, M_B] = \int_{\Omega} \Phi(M_A) + \Phi(M_B) + \frac{A}{M_s^2} \int_{\Omega} |\nabla M_A|^2 + |\nabla M_B|^2$$

$$+ \frac{4A_{AFM}}{a^2 M_s^2} \int_{\Omega} (M_A \cdot M_B) - \mu_0 \int_{\Omega} H_{ext} \cdot (M_A + M_B).$$

The system of LLG equations (1) can be rewritten equivalently as

$$\begin{cases}
\frac{\partial M_A}{\partial t} = -\frac{\mu_0 \gamma}{1 + \alpha^2} M_A \times H_A - \frac{\alpha \mu_0 \gamma}{(1 + \alpha^2) M_s} M_A \times (M_A \times H_A), \\
\frac{\partial M_B}{\partial t} = -\frac{\mu_0 \gamma}{1 + \alpha^2} M_B \times H_B - \frac{\alpha \mu_0 \gamma}{(1 + \alpha^2) M_s} M_B \times (M_B \times H_B),
\end{cases}$$

and the effective fields are

$$H_A = -\frac{2K_u}{M_s^2} (M_{A2} e_2 + M_{A3} e_3) + \frac{2A}{M_s^2} \Delta M_A - \frac{4A_{AFM}}{a^2 M_s^2} M_B + \mu_0 H_{ext},$$

$$H_B = -\frac{2K_u}{M_s^2} (M_{B2} e_2 + M_{B3} e_3) + \frac{2A}{M_s^2} \Delta M_B - \frac{4A_{AFM}}{a^2 M_s^2} M_A + \mu_0 H_{ext}.$$
with $e_2 = (0, 1, 0)$ and $e_3 = (0, 0, 1)$.

To ease the description, we now nondimensionalize (5). Defining $M_\lambda = M_\lambda m_\lambda$, $H_{\text{ext}} = M_\lambda h_\lambda$, $x = Lx'$ with $L$ the diameter of $\Omega$, and $W[M_A, M_B] = \langle \mu_0 M_z^2 \rangle W'[m_A, m_B]$, we have

\[
W'[m_A, m_B] = q \int_{\Omega'} \left( m_{A2}^2 + m_{A3}^2 + m_{B2}^2 + m_{B3}^2 \right) + \epsilon \int_{\Omega'} |\nabla m_A|^2 + |\nabla m_B|^2 \\
+ \delta \int_{\Omega'} (m_A \cdot m_B) - \int_{\Omega'} h_\epsilon \cdot (m_A + m_B),
\]

where $q = 2K_a/(\mu_0 M_z^2)$, $\epsilon = 2A/(\mu_0 M_z^2 L^2)$, and $\delta = 4A_{AFM}/(\mu_0 a^2 M_z^2)$. Upon rescaling time $t \rightarrow (1 + \alpha^2)(\mu_0 \gamma M_z)^{-1} t$, (5) can be rewritten as

\[
\begin{cases}
\frac{\partial m_A}{\partial t} = -m_A \times h_A - \alpha m_A \times (m_A \times h_A), \\
\frac{\partial m_B}{\partial t} = -m_B \times h_B - \alpha m_B \times (m_B \times h_B),
\end{cases}
\]

where

\[
h_A = -q(m_{A2}e_2 + m_{A3}e_3) + \epsilon \Delta m_A - \delta m_B + h_\epsilon, \\
h_B = -q(m_{B2}e_2 + m_{B3}e_3) + \epsilon \Delta m_B - \delta m_A + h_\epsilon.
\]

Homogeneous Neumann boundary conditions are used

\[
\frac{\partial m_A}{\partial \nu}|_{\Gamma} = 0, \quad \frac{\partial m_B}{\partial \nu}|_{\Gamma} = 0,
\]

where $\Gamma = \partial \Omega$ and $\nu$ is the unit outward normal vector along $\Gamma$. It’s worth mentioning that the above model is also used for ferrimagnetic materials with one of magnetization, $|m_B| < 1$.

It is easy to check from (7) that the following statement is true.

**Lemma 1.** For $\lambda = A, B$, we have

\[
|m_\lambda(t, x)| = |m_\lambda(t_0, x)|, \quad \forall x \in \Omega, \quad \forall t > t_0.
\]

The antiferromagnetic exchange (3) plays an important role in AFMs. Consider the case when $\delta \rightarrow \infty$ and the system (7) reduces to

\[
\begin{cases}
\frac{\partial m_A}{\partial t} = \delta m_A \times m_B + \alpha \delta m_A \times (m_A \times m_B), \\
\frac{\partial m_B}{\partial t} = \delta m_B \times m_A + \alpha \delta m_B \times (m_B \times m_A).
\end{cases}
\]

Combining the above two equations with $m = (m_A + m_B)/2$, we get an equation of Bernoulli type

\[
\frac{\partial m}{\partial t} = \alpha \delta (2|m|^2 - 1) m - \alpha \delta m.
\]

**Lemma 2.** $\forall x \in \Omega$, if the antiferromagnetic exchange parameter $\delta > 0$, the system favors the antiferromagnetic state, and if $\delta < 0$, the system favors the ferromagnetic state.
Proof. The analytic solution of (11) is

\[ |\mathbf{m}|^2 = \frac{1}{1 - C \exp(4\alpha\delta t)} \]

with \( C \) a positive constant determined by the initial condition.

Therefore, when \( \delta > 0 \), \( t \to \infty \), we have \( |\mathbf{m}|^2 \to 0 \), \( \forall x \in \Omega \). When \( \delta < 0 \), \( t \to \infty \), we have \( |\mathbf{m}|^2 \to 1 \), \( \forall x \in \Omega \).

The definition of \( \mathbf{m} \) yields

\[ |\mathbf{m}|^2 = \left| \frac{\mathbf{m}_A + \mathbf{m}_B}{2} \right|^2 \]

\[ = \frac{1}{4} \left( |\mathbf{m}_A|^2 + |\mathbf{m}_B|^2 + 2(\mathbf{m}_A, \mathbf{m}_B) \right) \]

\[ = \frac{1}{2} \left( 1 + (\mathbf{m}_A, \mathbf{m}_B) \right) \]

\[ = \frac{1}{2} \left( 1 + \cos(\mathbf{m}_A, \mathbf{m}_B) \right) \]

As a consequence, \( \mathbf{m}_A = -\mathbf{m}_B \) and \( \mathbf{m}_A = \mathbf{m}_B \) for \( \delta > 0 \) and \( \delta < 0 \), respectively. \qed

Lemma 2 implies that the coupled system convergences to an antiferromagnetic state exponentially fast with the exponent proportional to the antiferromagnetic exchange parameter \( \delta \). This is indicated numerically by the energy decay in Fig. 5.

3. Gauss-Seidel projection methods for antiferromagnetics

In this section, we introduce three Gauss-Seidel projection methods for (7). The finite difference method is used for spatial discretization with unknowns \( \mathbf{m}_\lambda(i) = \mathbf{m}_\lambda((i - \frac{1}{2})\Delta x) \) in 1D and \( \mathbf{m}_\lambda(i, j, k) = \mathbf{m}_\lambda((i - \frac{1}{2})\Delta x, (j - \frac{1}{2})\Delta y, (k - \frac{1}{2})\Delta z) \) in 3D, where \( i = 0, 1, \cdots, M, M + 1 \), \( j = 0, 1, \cdots, N, N + 1 \), and \( k = 0, 1, \cdots, K, K + 1 \) and \( M, N, K \) represent the number of segments for each direction.

3.1. Original Gauss-Seidel Projection Method

This is a direct generalization of the original GSPM [22] to the antiferromagnetic or ferrimagnetic case. For (7), the GSPM works as follows. Define the vector field for the splitting procedure:

\[ \mathbf{h}_A = \epsilon \Delta \mathbf{m}_A + \mathbf{f}_A, \]

\[ \mathbf{h}_B = \epsilon \Delta \mathbf{m}_B + \mathbf{f}_B, \]

where \( \mathbf{f}_A = -Q(m_{A2}\mathbf{e}_2 + m_{A3}\mathbf{e}_3) - \delta \mathbf{m}_B + \mathbf{h}_c \) and \( \mathbf{f}_B = -Q(m_{B2}\mathbf{e}_2 + m_{B3}\mathbf{e}_3) - \delta \mathbf{m}_A + \mathbf{h}_c \).

The GSPM solves (7) in three steps:
• Implicit Gauss-Seidel:

\[ g_{A_i}^n = (I - \Delta t \Delta_h)^{-1}(m_{A_i}^n + \Delta t \hat{f}_{A_i}^n), \quad i = 2, 3, \]

\[ g_{A_1}^n = (I - \Delta t \Delta_h)^{-1}(m_{A_1}^n + \Delta t \hat{f}_{A_1}^n), \quad i = 1, 2, \]

\[
\begin{align*}
(m_{A_i}^n) & = (m_{A_i}^0 + (g_{A_2}^n m_{A_2}^n - g_{A_2}^n m_{A_2}^n)) \\
(m_{A_2}^n) & = (m_{A_2}^0 + (g_{A_3}^n m_{A_1}^n - g_{A_1}^n m_{A_2}^n)), \\
(m_{A_3}^n) & = (m_{A_3}^0 + (g_{A_3}^n m_{A_1}^n - g_{A_1}^n m_{A_2}^n)), \\
\hat{f}_{B_i}^n & = -Q(m_{B_2} e_2 + m_{B_3} e_3) - \delta m_A + h_e, \\
g_{B_i}^n & = (I - \Delta t \Delta_h)^{-1}(m_{B_i}^n + \Delta t \hat{f}_{B_i}^n), \quad i = 2, 3, \\
(m_{B_i}^n) & = (m_{B_i}^0 + (g_{B_2}^n m_{B_3}^n - g_{B_1}^n m_{B_2}^n)) \\
(m_{B_2}^n) & = (m_{B_2}^0 + (g_{B_3}^n m_{B_1}^n - g_{B_1}^n m_{B_3}^n)), \\
(m_{B_3}^n) & = (m_{B_3}^0 + (g_{B_3}^n m_{B_1}^n - g_{B_1}^n m_{B_2}^n)), \\
\hat{f}_{A_1}^n & = -Q(m_{A_3} e_2 + m_{A_3} e_3) - \delta m_B + h_e, \\
\hat{f}_{B_1}^n & = -Q(m_{B_2} e_2 + m_{B_3} e_3) - \delta m_A + h_e.
\]

• Heat flow without constraints:

\[
\begin{align*}
(m_{A_1}^{*+}) & = (m_{A_1}^0 + \alpha \Delta t(\Delta_h m_{A_1}^{*+} + \hat{f}_{A_1}^n)) \\
(m_{A_2}^{*+}) & = (m_{A_2}^0 + \alpha \Delta t(\Delta_h m_{A_2}^{*+} + \hat{f}_{A_2}^n)), \\
(m_{A_3}^{*+}) & = (m_{A_3}^0 + \alpha \Delta t(\Delta_h m_{A_3}^{*+} + \hat{f}_{A_3}^n)), \\
(m_{B_1}^{*+}) & = (m_{B_1}^0 + \alpha \Delta t s^2(\Delta_h m_{B_1}^{*+} + \hat{f}_{B_1}^n)) \\
(m_{B_2}^{*+}) & = (m_{B_2}^0 + \alpha \Delta t s^2(\Delta_h m_{B_2}^{*+} + \hat{f}_{B_2}^n)), \\
(m_{B_3}^{*+}) & = (m_{B_3}^0 + \alpha \Delta t s^2(\Delta_h m_{B_3}^{*+} + \hat{f}_{B_3}^n)).
\end{align*}
\]

• Projection onto $S^2$:

\[
\begin{align*}
\begin{pmatrix}
(m_{A_1}^{n+1} \\
(m_{A_2}^{n+1} \\
(m_{A_3}^{n+1})
\end{pmatrix} & = \frac{1}{|m_A|^2} \begin{pmatrix}
(m_{A_1}^{*+}) \\
(m_{A_2}^{*+}) \\
(m_{A_3}^{*+})
\end{pmatrix}, \\
\begin{pmatrix}
(m_{B_1}^{n+1} \\
(m_{B_2}^{n+1} \\
(m_{B_3}^{n+1})
\end{pmatrix} & = s \frac{1}{|m_B|^2} \begin{pmatrix}
(m_{B_1}^{*+}) \\
(m_{B_2}^{*+}) \\
(m_{B_3}^{*+})
\end{pmatrix}.
\end{align*}
\]

Note that $0 < s \leq 1$ within the definition $|m_B| = s$. $s = 1$ is for AFMs and $s < 1$ is for ferrimagnetics.

3.2. Scheme A

Both Scheme A and Scheme B are based on improved GSPMs for ferromagnetics [23]. In Scheme A, we do not treat the gyromagnetic term and the damping term separately. Instead, the implicit Gauss-Seidel method is applied to the gyromagnetic term and the damping term simultaneously, and a projection step follows up.

• Implicit Gauss-Seidel step:

\[ g_{A_i}^n = (I - \Delta t \Delta_h)^{-1}(m_{A_i}^n + \Delta t \hat{f}_{A_i}^n), \quad i = 1, 2, 3, \]

\[ g_{A_1}^n = (I - \Delta t \Delta_h)^{-1}(m_{A_1}^n + \Delta t \hat{f}_{A_1}^n), \quad i = 1, 2, \]
3.3. Scheme B

Scheme B reduces the computational cost further by the introduction of two sets of approximations. At each step, one set of solution is updated in the implicit Gauss-Seidel step and the other is updated in the projection step.

- Implicit Gauss-Seidel step:

\[ g_{Bi}^{n+1} = (I - \Delta t \Delta h)^{-1}(m_{Bi}^* + \Delta t f_{Bi}^*), \quad i = 1, 2, 3, \]

\[ m_{A1}^* = m_{A1}^n - (m_{A2}^ng_{A1} - m_{A3}^ng_{A2}) - \alpha(m_{A1}g_{A1} + m_{A2}g_{A2} + m_{A3}^n g_{A3})m_{A1}^n + \alpha g_{A1}^n, \]

\[ m_{A2}^* = m_{A2}^n - (m_{A3}^ng_{A2} - m_{A1}^n g_{A3}) - \alpha(m_{A1}g_{A1} + m_{A2}g_{A2} + m_{A3}^n g_{A3})m_{A2}^n + \alpha g_{A2}^n, \]

\[ m_{A3}^* = m_{A3}^n - (m_{A3}^n g_{A2} - m_{A2}^n g_{A3}) - \alpha(m_{A1}g_{A1} + m_{A2}g_{A2} + m_{A3}^n g_{A3})m_{A3}^n + \alpha g_{A3}^n, \]

- Projection step:

\[
\begin{pmatrix}
  (m_{A1}^{n+1})_1 \\
  (m_{A2}^{n+1})_2 \\
  (m_{A3}^{n+1})_3
\end{pmatrix}
= \frac{1}{m_A^*}
\begin{pmatrix}
  (m_{A1}^*)_1 \\
  (m_{A2}^*)_2 \\
  (m_{A3}^*)_3
\end{pmatrix},
\]

\[
\begin{pmatrix}
  (m_{B1}^{n+1})_1 \\
  (m_{B2}^{n+1})_2 \\
  (m_{B3}^{n+1})_3
\end{pmatrix}
= \frac{s}{m_B^*}
\begin{pmatrix}
  (m_{B1}^*)_1 \\
  (m_{B2}^*)_2 \\
  (m_{B3}^*)_3
\end{pmatrix}.
\]
\[ m_{B1}^* = m_{B1}^n - (m_{B2}^n g_{B1}^n - m_{B3}^n g_{B2}^n - \alpha (m_{B1}^n g_{B1}^n + m_{B2}^n g_{B2}^n + m_{B3}^n g_{B3}^n) m_{B1}^n + \alpha ((m_{B1}^n)^2 + (m_{B2}^n)^2 + (m_{B3}^n)^2) g_{B1}^n, \]
\[ m_{B2}^* = m_{B2}^n - (m_{B3}^n g_{B1}^n + m_{B1}^n g_{B3}^n) - \alpha (m_{B1}^n g_{B1}^n + m_{B2}^n g_{B2}^n + m_{B3}^n g_{B3}^n) m_{B2}^n + \alpha ((m_{B1}^n)^2 + (m_{B2}^n)^2 + (m_{B3}^n)^2) g_{B2}^n, \]
\[ m_{B3}^* = m_{B3}^n - (m_{B1}^n g_{B2}^n + m_{B2}^n g_{B1}^n) - \alpha (m_{B1}^n g_{B1}^n + m_{B2}^n g_{B2}^n + m_{B3}^n g_{B3}^n) m_{B3}^n + \alpha ((m_{B1}^n)^2 + (m_{B2}^n)^2 + (m_{B3}^n)^2) g_{B3}^n. \]

- Projection step:

\[
\begin{pmatrix}
  m_{A1}^{n+1} \\
  m_{A2}^{n+1} \\
  m_{A3}^{n+1}
\end{pmatrix}
= \frac{1}{|m_A^*|}
\begin{pmatrix}
  m_{A1}^* \\
  m_{A2}^* \\
  m_{A3}^*
\end{pmatrix},
\]
\[
\begin{pmatrix}
  m_{B1}^{n+1} \\
  m_{B2}^{n+1} \\
  m_{B3}^{n+1}
\end{pmatrix}
= \frac{s}{|m_B^*|}
\begin{pmatrix}
  m_{B1}^* \\
  m_{B2}^* \\
  m_{B3}^*
\end{pmatrix}.
\]

The above three GSPMs for AFMs and ferrimagnetics have different computational complexity originating from the number of linear systems of equations with constant coefficients to be solved at each step. For comparison, we list the number of linear systems to be solved at each step in Table 1. It is easy to see that the computational complexity of GSPM for AFMs is only doubled compared to that for FM.

4. Accuracy check

In this section, by a series of examples in both 1D and 3D, we show the accuracy of GSPMs for AFMs and ferrimagnets. For convenience, the model used here is

\[
\begin{align*}
\frac{\partial m_A}{\partial t} &= -m_A \times h_A - \alpha m_A \times (m_A \times h_A) + f_A \\
\frac{\partial m_B}{\partial t} &= -m_B \times h_B - \alpha m_B \times (m_B \times h_B) + f_B
\end{align*}
\]

(12)

with \( h_A = \Delta m_A + \delta m_B, h_B = \Delta m_B + \delta m_A, \) and \( f_A \) are forcing terms specified by exact solutions.

**Example 4.1** (1D). Consider a set of orthogonal solutions for (12) in \( \Omega = [0, 1] \):

\[
\begin{align*}
  m_A &= (\cos(x^2(1-x)^2) \sin(t), \sin(x^2(1-x)^2) \sin(t), \cos(t)), \\
  m_B &= (s \cos(x^2(1-x)^2) \cos(t), s \sin(x^2(1-x)^2) \cos(t), -s \sin(t)).
\end{align*}
\]
Parameters are $\alpha = 0.1$, $\delta = 2.0$ and $T = 1.0e - 03$. The error is defined $\|m_e - m_h\|_\infty$ with $m_h$ being the numerical solutions and $m_e$ being the exact solution. The accuracy of GSPMs is $O(\Delta t + \Delta x^2)$ as shown in Tables 2 and 3.

Example 4.2 (3D). As in the 1D case, we use a set of orthogonal solutions for (12) in $\Omega = [0, 1] \times [0, 1] \times [0, 1]$ for the spatial accuracy and $\Omega = [0, 0.2] \times [0, 0.1] \times [0, 0.02]$ with a $64 \times 32 \times 5$ mesh for the temporal accuracy

$$ m_A = \left( \cos(\bar{x}\bar{y}\bar{z}) \sin(t), \sin(\bar{x}\bar{y}\bar{z}) \sin(t), \cos(t) \right), $$

$$ m_B = \left( s \cos(\bar{x}\bar{y}\bar{z}) \cos(t), s \sin(\bar{x}\bar{y}\bar{z}) \cos(t), -s \sin(t) \right) $$

with $\bar{x} = x^2(1-x)^2$, $\bar{y} = y^2(1-y)^2$, $\bar{z} = z^2(1-z)^2$. Parameters are $\alpha = 0.1$ and $\delta = 2.0$. The first order accuracy in time and the second order accuracy in space are shown in Tables 4 and 5.

5. Femtosecond magnetization dynamics in antiferromagnets

The presence of the antiferromagnetic exchange term makes magnetization dynamics richer compared with ferromagnetic counterparts. In the simulations, the size of the thin film material is 100 nm $\times$ 100 nm $\times$ 10 nm and the grid size is 2 nm $\times$ 2 nm $\times$ 2 nm. Physical parameters [4] are listed in Table 6. For the given parameters, we have $\delta/q = 240$ and $\delta/\epsilon = 4.8 \times 10^4$. Therefore for micromagnetics simulation in AFMs, the temporal stepsize is limited by the antiferromagnetic exchange parameter.

![Fig. 2. Performance of three GSPMs with respect to the antiferromagnetic exchange parameter $\delta$ in both time and space. The antiferromagnetic exchange parameter $\delta = \pm 0.1, \pm 5.0, \pm 100.0.$](image)

5.1. Antiferromagnetic/ferromagnetic stable phase

In this case, we choose the initial state as $\mathbf{m}_A = (1, 0, 0)^T$, and $\mathbf{m}_B = (0, 1, 0)^T$, and solve (7). Note that the easy-axis direction is the $x$-axis. In the absence of an external field, the system shall relax to a ferromagnetic phase or an antiferromagnetic phase, depending on the
sign of the antiferromagnetic exchange parameter $\delta$. Since the temporal stepsize is limited by the antiferromagnetic exchange parameter, we observe that all GSPMs lose their accuracy if the stepsize is much larger than the femtosecond scale. More seriously, the numerical solution of Scheme B blows up with stepsize $\Delta t = 1$ ps. Therefore, in what follows, we set $\Delta t = 1$ fs to get reliable numerical solutions.

There are two characteristic time scales of the magnetization dynamics in AFMs when the external field is applied. The first one is due to the antiferromagnetic exchange, which yields an intermediate antiferromagnetic/ferromagnetic state at $\sim 1$ ps. The second one is due to the magnetic anisotropy, which yields a stable antiferromagnetic/ferromagnetic states at $\sim 10$ ps or longer. Fig. 3 visualizes an intermediate antiferromagnetic state at 2 ps and an stable antiferromagnetic state at 6 ps when the antiferromagnetic exchange parameter $A_{AFM} = 3.0 \times 10^{-12}$ J/m. Fig. 4 visualizes an intermediate ferromagnetic state at 2 ps and a stable antiferromagnetic state at 500 ps when $A_{AFM} = -3.0 \times 10^{-12}$ J/m.

In addition, we record the system energy with respect to time for $A_{AFM} = 3.0 \times 10^{-12}$ J/m (antiferromagnetism), $A_{AFM} = -3.0 \times 10^{-12}$ J/m (ferromagnetism), and $A_{AFM} = 0$ (no coupling) in Fig. 5 with random initial conditions for $\mathbf{m}_A$ and $\mathbf{m}_B$. As mentioned above, two distinct time scales are observed for nonzero antiferromagnetic exchange parameter while the shorter time scale is missing if $A_{AFM} = 0$. Although the energy in Fig. 5 seems to be saturated, the stable ferromagnetic state has not been obtained yet. It actually takes longer to achieve the stable state as shown in Fig. 4b.

5.2. Néel wall structure in an antiferromagnet

Consider an initial state with a Néel wall profile as in Fig. 6a. When the antiferromagnetic exchange parameter $A_{AFM} = -3.0 \times 10^{-12}$, and $\mathbf{m}_A = \mathbf{m}_B$, it is expected that the system
Fig. 4. Arrow plot of the magnetization in the centered slice along the z direction. Arrows are plotted by the first two components of the magnetization and the color is plotted by the third component \((m_A^3 + m_B^3)/2\). We set \(\Delta t = 1\) fs and \(T = 2\) ns although it stabilizes at 500 ps. (a) An intermediate antiferromagnetic state; (b) Stable antiferromagnetic state.

Fig. 5. The system energy as a function of time for random initial conditions when \(A_{AFM} = 3 \times 10^{-12}\) (antiferromagnetism), \(A_{AFM} = -3 \times 10^{-12}\) (ferromagnetism), and \(A_{AFM} = 0\) (no coupling) with \(\Delta t = 1\) fs and \(T = 20\) ps.
relaxes to a Néel wall structure of ferromagnetic type; see Fig. 6. When $A_{AFM} = 3.0 \times 10^{-12}$, the system relaxes to a Néel wall structure of antiferromagnetic type; see Fig. 7.

5.3. Phase diagram under the external field

It is known that AFMs are robust against magnetic perturbation, therefore the phase diagram requires stronger external fields. The external field can be applied in three different ways. First, when an external field is applied perpendicular to the easy-axis direction, magnetic moments of two sublattices and hence the magnetization $m = (m_A + m_B)/2$ tend to align up with the field gradually until the net magnetization saturated. The external field is parallel to the easy-axis direction in the second and third cases. When the anisotropy energy is much smaller than the antiferromagnetic exchange energy, the phase transition is known as the spin flop transition. When the anisotropy energy is much larger than the antiferromagnetic exchange energy, magnetization jumps from zero to the saturation magnetization directly, which is known as the spin flip transition [3, 28].
Fig. 7. Magnetization profile of the antiferromagnetic state in the centered slice along the $z$ direction. Arrows are plotted by the first two components of the magnetization and the color is plotted by the third component. $\Delta t = 1$ fs and $T = 1$ ns. (a) $l = \frac{m_A - m_B}{2}$ at 1 ns; (b) $m = \frac{m_A + m_B}{2}$; (c) Stable state of sublattice A. (d) Stable state of sublattice B.
In Table 6, the anisotropy energy is much smaller than the antiferromagnetic energy, and thus the spin flop transition happens. To observe the spin flip transition, we reduce the antiferromagnetic exchange parameter $A_{AFM}$ to $3.0 \times 10^{-15}$ J/m. The whole simulation is started with an initial state $m_A = -m_B$ along the $x$-axis and the external applied field $H_{ext} = 0 \text{T} \sim 300 \text{T}$. For both the $H_\perp$ and the $H_\parallel$ phase transitions, an external field with $0 \text{T}$ is applied and the system relaxes to a stable state. Afterwards, we increase the external field by a certain amount $\Delta H_{ext}$ and let the system relax to an stable state. The external field is successively increased until $H_{ext} = 300 \text{T}$. Averaged net magnetization is recorded as a function of $H_{ext}$. The stopping criterion for a steady state is that the relative change of the total energy is less than $10^{-9}$. Results shown in Fig. 8 are in qualitative agreements with the experimental results of MnF$_2$ [29].

![Fig. 8. Phase diagram under the external field with parameters in Table 6 and $A_{AFM} = 3.0 \times 10^{-15}$ in the case of the spin-flip magnetic field.](image)

6. Conclusion

In this paper, we develop three Gauss-Seidel projection methods for the coupled system of Landau-Lifshitz-Gilbert equations with an antiferromagnetic exchange coupling. Performance of these methods is verified in terms of accuracy and stability. In addition, femtosecond magnetization dynamics, Néel wall structure, and phase transition under the external magnetic field in antiferromagnets are studied. It is interesting that phase transitions observed in the simulation are qualitatively consistent with the experimental results of MnF$_2$. In addition to experiments, the proposed methods open up an alternative way to understand femtosecond magnetization dynamics in antiferromagnetic and ferrimagnetic materials.
