(Dated: November 11, 2019)

A new bound for the quantum capacity of the $d$-dimensional depolarizing channels is presented. Our derivation make use of a flagged extension of the depolarizing map where the receiver obtains a copy of a state $\sigma_0$ whenever the messages are transmitted without errors, and a copy of a state $\sigma_1$ when instead the original they get fully depolarized. By varying the overlap between the flags states, the resulting transformation nicely interpolates between the depolarizing map (when $\sigma_0 = \sigma_1$), and the $d$-dimensional erasure channel (when $\sigma_0$ and $\sigma_1$ have orthogonal support). In our analysis we compute the product-state classical capacity, the entanglement assisted capacity and, under degradability conditions, the quantum capacity of the flagged channel. From this last result we get the upper bound for the depolarizing channel, which by a direct comparison appears to be tighter than previous available results for $d > 2$, and for $d = 2$ it is tighter in an intermediate regime of noise. In particular, in the limit of large $d$ values, our findings presents a previously unnoticed $O(1)$ correction.

I. INTRODUCTION

Quantum Shannon theory [1, 2] provides a characterization of the maximum rates (capacities) achievable in sending classical or quantum data through a quantum channel. The evaluation of most capacities cannot be performed algorithmically, since it requires in principle an infinite sequence of optimizations, at variance with the classical case [3]. Even for one of the simplest examples of non-unitary quantum channel, the depolarizing channel, the so-called quantum capacity [4–6] is not known in general, and considerable effort has been spent on finding bounds for this capacity [7–12]. For a particular kind of channels, the degradable channels, the quantum capacity is given by the one-shot quantum capacity, which is a single-letter formula [14]. Unfortunately, the depolarizing channel is not degradable and the one-shot quantum capacity is known to be just a lower bound.

In this paper, we study a class of quantum channels which are extensions of the depolarizing channel, the flagged depolarizing channels (FDC): if Alice sends the state $\rho$, with probability $p$ Bob receives the state $\rho$ together with a state $\sigma_0$, and with probability $1 - p$ the completely mixed state together with a state $\sigma_1$: $\sigma_0$ and $\sigma_1$ behave as flags that encode information about what happened to the input. When $\sigma_0$ and $\sigma_1$ are perfectly distinguishable, Bob can know exactly if he received the original message or an error, and the channel is equivalent to the erasure channel. By tracing on the system where $\sigma_0$ and $\sigma_1$ live, Bob effectively receives the output of the depolarizing channel. This means that FDC is at least as good as a communication resource as the depolarizing channel with the same $p$, therefore every capacity of an FDC is larger than the corresponding depolarizing channel. On the other hand, it is possible to find $\rho, \sigma_0, \sigma_1$ such a way that FDC is degradable, obtaining a bound for the quantum capacity of the depolarizing channel. In previous works [7–9, 12], degradable extensions with orthogonal flags have been used to get bounds on the quantum capacity of the depolarizing channel. An example of flagged channel is the dephrasure channel, which shows superadditivity of coherent information [13]. When compared with previous result our best bound provides a better estimate of the quantum capacity of the depolarizing channel for all choices of $d$ and $p$, except for $d = 2$. In this case the bounds in [7, 11] perform better at low noise, while for higher noise the new bound is better, surpassing also the one in [12] in an intermediate region. Most notably the improvement increases in the large $d$ limit: the gap between the best upper bound and lower bound of the quantum capacity is given by a $O(1)$ function of $p$ which is differentiable in $p = 0$, in contrast with previous bounds for which the $O(1)$ term of the gap is the binary entropy $h(p)$.

Moreover, FDC is not merely of interest as a technical tool, as it can also be seen as a toy model for a realistic scenario in quantum communication. Indeed, in the usual setting it is assumed that the noisy quantum channel connecting Alice and Bob can be exactly determined, which means that the interaction between the system and

---

†Electronic address: marco.fanizza@sns.it
†Electronic address: farzad.kianvash@sns.it
environment, the time of the interaction, and the state of environment are exactly known. It may be conceivable that some of this information is not available, for example the state of the environment may change in time. Monitoring the environment can modeled as receiving a copy of it as a quantum flag, each time the channel it is used: to each environment state is associated a different effective channel, and Bob can do his best to use the additional limited information encoded in the flag to decode the message. FDC, being a channel with non-orthogonal quantum flags, represent a further step in studying the genuinely quantum setting.

The paper is structured as follows: in the first section we review some facts about quantum channels, and we list the capacities that we consider, recalling their characterization in terms of maximization of entropic quantities; in the second section we introduce the model; in the third section we compute the capacities of the FDC. In the fourth section we find sufficient conditions for degradability. In the last section we state our best bound to the quantum capacity of the depolarizing channel, and compare it with previous results.

II. PRELIMINARIES

In this section we recall some definitions and facts about quantum channels. Quantum channels represent the transformations of quantum states allowed by the rules of quantum mechanics and each of them can be described by a Completely Positive Trace Preserving (CPTP) map. Given a Hilbert space \( \mathcal{H} \), we write the space of linear operators on \( \mathcal{H} \) as \( \mathcal{L}(\mathcal{H}) \) and the set of density operators as \( \mathcal{S}(\mathcal{H}) \). When \( \mathcal{H}_A \) and \( \mathcal{H}_B \) have finite dimension, the action of quantum channel \( \Lambda : \mathcal{L}(\mathcal{H}_A) \to \mathcal{L}(\mathcal{H}_B) \) on \( \theta \in \mathcal{L}(\mathcal{H}_A) \) can be written in the Stinespring representation as following

\[
\Lambda(\theta) = \text{tr}_E(U_{AE} \theta_A \otimes |e\rangle \langle e|_E U_{AE}^\dagger),
\]

where \( |e\rangle_E \) is the state of environment interacting with the system \( A \), and \( U_{AE} \) is an unitary interaction acting on \( \mathcal{H}_A \otimes \mathcal{H}_E \cong \mathcal{H}_B \otimes \mathcal{H}_{E'} \). In this setting the complementary channel \( \tilde{\Lambda} : \mathcal{L}(\mathcal{H}_A) \to \mathcal{L}(\mathcal{H}_{E'}) \) is defined as the CPTP mapping

\[
\tilde{\Lambda}(\theta) := \text{tr}_B(U_{AE} \theta_A \otimes |e\rangle \langle e|_E U_{AE}^\dagger).
\]

Now the channel \( \Lambda \) is said to be degradable if there exists a third CPTP channel \( W : \mathcal{L}(\mathcal{H}_B) \to \mathcal{L}(\mathcal{H}_{E'}) \) (dubbed degrading channel) such that

\[
W \circ \Lambda = \tilde{\Lambda}.
\]

Similarly it is said to be anti-degradable if instead there exists a CPTP channel \( V : \mathcal{L}(\mathcal{H}_{E'}) \to \mathcal{L}(\mathcal{H}_B) \) such that

\[
V \circ \tilde{\Lambda} = \Lambda.
\]

Degradability allows for an easier evaluation of the optimal communication performance through a channel, in a sense that we will recall in the next paragraphs.

Suppose Alice wants to send information to Bob using the quantum channel \( \Lambda \). Depending on the type of the information that Alice wants to send, and the resource that they share, different type of capacities can be defined. The first that we consider is the classical capacity. Suppose that Alice wants to encode her classical information into the information that Alice wants to send, and the resource that they share, different type of capacities can be defined.
share unlimited resource of entanglement. In this case the evaluation of the rate is simpler as it is provided by the following single letter formula\[18\]

\[ C_E(\Lambda) = \max_\rho I(\rho, \Lambda), \]

(7)

where the mutual information for a state \( \rho \) and channel \( \Lambda \) is defined as

\[ I(\rho, \Lambda) := S(\rho) + S(\Lambda(\rho)) - S(\Lambda(\rho)), \]

(8)

The last capacity we consider is the quantum capacity \( Q(\Lambda) \) which gives the highest rate at which quantum information can be transmitted over many uses of a quantum channel. In Refs.\[6,19\] it was shown that in this case the following formula holds

\[ Q(\Lambda) = \lim_{n \to \infty} Q_n(\Lambda) = \lim_{n \to \infty} \max_{\rho \in (\mathcal{H}_\Lambda^\otimes n)} \frac{1}{n} J(\rho, \Lambda^\otimes n), \]

(9)

with

\[ J(\rho, \Lambda^\otimes n) := S(\Lambda^\otimes n(\rho)) - S(\tilde{\Lambda}^\otimes n(\rho)), \]

(10)

being the \( n \)-fold coherent information of the channel and the maximization being performed over the set of all possible density matrices \( \rho \in \mathcal{S}(\mathcal{H}_\Lambda^\otimes n) \) of \( n \) copies of the input system. Interestingly enough for a degradable channel the regularization limit on \( n \) is not needed and the quantum capacity reduces to single-letter formula

\[ Q(\Lambda) = Q_1(\Lambda) := \max_{\rho \in (\mathcal{H}_\Lambda)} J(\rho, \Lambda). \]

(11)

We conclude the section by recalling a useful result reported in Ref.\[7\]. We call \( N \) a degradable extension of \( \Lambda \) if \( N \) is degradable and there is a second channel \( R \) such that \( R \circ N = \Lambda \). In Ref.\[7\] it has been shown that if \( N_0 \) is a degradable extension of \( \Lambda_0 \) and \( N_1 \) is a degradable extension of \( \Lambda_1 \) then for every \( 0 \leq \lambda \leq 1 \)

\[ N = \lambda N_0 \otimes |0\rangle \langle 0| + (1 - \lambda) N_1 \otimes |1\rangle \langle 1|, \]

(12)

is a degradable extension of \( \Lambda = \lambda \Lambda_0 + (1 - \lambda) \Lambda_1 \), and the quantum capacities satisfy the following relation

\[ Q(\Lambda) \leq Q_1(N) \leq \lambda Q_1(N_0) + (1 - \lambda) Q_1(N_1). \]

(13)

This theorem can be used to show if we have upper bounds for the quantum capacity of two channels, all obtained from degradable extensions, the convex combination of the bounds is also an upper bound for the respective convex combination of the channels. We clarify this with an example: Consider the depolarizing channel i.e. \( \Lambda_p^d[\cdots] = (1 - p)[\cdots] + p \text{Tr}[\cdots] \frac{\mathbb{I}}{d} \). The set of all values of \( p \) for which \( \Lambda_p^d \) is a CPTP is \( P \), and \( N_p \) is a degradable extension of \( \Lambda_p^d \) for all \( p \in P \). If \( p_0, p_1 \in P \), then \( N_{p_0}, N_{p_1} \) are degradable extensions of \( \Lambda_{p_0}^d, \Lambda_{p_1}^d \) respectively, then

\[ Q(\Lambda_{p_0}^d) \leq g(p_0) := Q_1(N_{p_0}), \quad Q(\Lambda_{p_1}^d) \leq g(p_1) := Q_1(N_{p_1}). \]

(14)

Therefore

\[ N = \lambda N_{p_0} \otimes |0\rangle \langle 0| + (1 - \lambda) N_{p_1} \otimes |1\rangle \langle 1|, \]

(15)

is a degradable extension of \( \Lambda_{\lambda p_0 + (1 - \lambda) p_1}^d \), then using\[13\] we get

\[ Q(\Lambda_{\lambda p_0 + (1 - \lambda) p_1}^d) \leq \lambda g(p_0) + (1 - \lambda) g(p_1). \]

(16)

As this holds for all \( p_0, p_1 \in P \), therefore \( \text{conv}\{g(p)\} \) is also an upper bound for the quantum capacity of \( \Lambda_p^d \), where

\[ \text{conv}\{g(p)\} := \inf_{p_0, p_1 \in P, 0 \leq \lambda \leq 1} \{ \lambda g(p_0) + (1 - \lambda) g(p_1) : p = \lambda p_0 + (1 - \lambda) p_1 \}. \]

(17)

In particular, given \( g_1(p), ..., g_n(p) \), all upper bounds for the quantum capacity of depolarizing channel all derived from degradable extensions, then \( g_{\text{min}}(p) := \min\{g_1(p), ..., g_n(p)\} \) is also an upper bound and therefore

\[ \text{conv}\{g_1(p), ..., g_n(p)\} := \text{conv}\{g_{\text{min}}(p)\} \]

(18)

is also an upper bound too.
III. THE MODEL

Here we introduce the class of channels that we shall study in this work, first motivated as a toy model for a realistic scenario. In a standard approach to quantum communication the interaction between the quantum carriers of the information and their environment, the associated interaction time, as well as the state of environment are assumed to be known. However, it is possible to think about the scenarios where the state of environment is changing in time and it can be monitored with quantum measurements. In this setting, suppose that with probability \( p_i \) the state of environment is the state \( \sigma_i \), and that when this happens information carrier get transformed by \( \Lambda \) a given CPTP transformation. If there was no other information except the probability distribution of environment, the complete channel would be just the weighted sum of each individual map, i.e. \( \Lambda := \sum_i p_i \Lambda_i \). Instead, we assume that in our case Bob collects a copy of the environment: in this case the complete channel can be written as

\[
\Lambda[\cdots] := \sum_i p_i \Lambda_i[\cdots] \otimes \sigma_i ,
\]

where now the \( \sigma_i \)'s live on an ancillary space \( \mathcal{H}_1 \) on which Bob has complete access. More abstractly, this model can be also seen as a quantum channel with *quantum flags*, where with probability \( p_i \) the channel acts as \( \Lambda_i \) and Bob receives a quantum flag \( \sigma_i \) which encodes in a quantum state then information about which channel is acting. As \( \Lambda \) can be obtained from \( \Lambda \) by simply tracing away the flags, it turns out the capacities of the latter provides natural upper bound for the corresponding ones of the former, i.e.

\[
Q(\Lambda) \leq Q(\Lambda) ,
\]

where we specified this property in the special case of the quantum capacity. A special case of a channel of the form \([19]\) was considered in \([7, 9]\) where it was assumed that the \( \sigma_i \)'s formed a set of orthogonal pure states. Here, on the contrary we allow the \( \sigma_i \)'s to be mixed and not necessarily orthogonal and focus into the case where the resulting mapping has the form

\[
\Lambda^d_p[\cdots] = (1 - p)[\cdots] \otimes \sigma_0 + p \text{Tr}[^{\cdots}] \frac{I_d}{d} \otimes \sigma_1 .
\]

This is a channel that acts on a \( d \) dimensional Hilbert space and it is in the form of Eq. \([19]\) with two components, the first associated with the identity channel, and the second associated instead with a completely depolarizing transformation that replaces every input with the completely mixed state \( I_d/d \). Notice however that Eq. \([21]\) describes a proper CPTP mapping also for values of \( p \) larger than 1 – indeed its Choi state \([1, 2]\) can be easily shown to be positive for any \( p > 0 \) such that \( \frac{p}{d} \sigma_0 + (1 - p)\sigma_1 \geq 0 \).

The map \( \Lambda^d_p \) provides an interpolation between two important quantum channels that have been extensively studied in the literature. Indeed when the flags are orthogonal \( \Lambda^d_p \) reduces to the erasure channel \([20]\). Instead when the flag state coincides, \( \sigma_0 = \sigma_1 \), \( \Lambda^d_p \) is equivalent to the depolarizing channel \([21]\),

\[
\Lambda^d_p[\cdots] = (1 - p)[\cdots] + p \text{Tr}[^{\cdots}] \frac{I_d}{d} .
\]

Most importantly, \( \Lambda^d_p \) is also the un-flagged version of \( \Lambda^d_p \), i.e. the one that we get when, irrespectively from the value of \( \sigma_0 \) and \( \sigma_1 \), we remove the flags states form \([21]\) via partial trace. Therefore invoking the monotonicity argument that links the capacity of a channel with those of its flagged counterpart we can now upper bound the rather elusive quantum capacity of \( \Lambda^d_p \) with the quantum capacity of \( \Lambda^d_p \) which instead, as we shall see in the following section, is relatively easy to characterize at least for some proper choice of the flags states.

IV. THE CAPACITIES OF THE FLAGGED DEPOLARIZING CHANNEL

A fundamental ingredient in studying the capacities of the channel \( \Lambda^d_p \) is the fact that it is covariant under the action of arbitrary unitary transformations \( U \) of \( SU(d) \), i.e.

\[
\Lambda^d_p(U\cdots U^\dagger) = (U \otimes I)\Lambda^d_p[\cdots](U^\dagger \otimes I) ,
\]

the operators \( I \) being the identity on the ancillary space at the output of \( \Lambda^d_p \). From this identity it hence follows that, given two input states of the system which differ from a unitary rotation, assume the same von Neumann entropy
value at the output of the channel $\mathcal{L}_p^d$. In particular this also implies that the output von Neumann entropy associated with a generic input state is a constant $t(p, d, \sigma_0, \sigma_1)$ that explicitly does not depend upon the specific value of $|\psi\rangle$ but only upon the parameters that characterize the map, i.e. $p, \sigma_0, \sigma_1$ and $d$. A simple algebra permits us to explicit determine the value of $t(p, d, \sigma_0, \sigma_1)$ obtaining

$$t(p, d, \sigma_0, \sigma_1) := S(\mathcal{L}_p^d |\psi\rangle \langle \psi|) = S\left( (1-p)|\psi\rangle \langle \psi| \otimes \sigma_0 + p \frac{I_d}{d} \otimes \sigma_1 \right)$$

$$= h\left( \frac{d(1-p)+p}{d} \right) + \frac{p(d-1)}{d} \log(d-1) + \frac{d(1-p)+p}{d} S\left( (1-p)\sigma_0 + \frac{p}{d} \sigma_1 \right) + \frac{p(d-1)}{d} S(\sigma_1),$$

where $h(x) := -x \log x - (1-x) \log(1-x)$ is the binary entropy. By convexity of the von Neumann entropy, it follows that (24) is nothing but the minimum entropy value we can get at the output of the channel $\mathcal{L}_p^d$, i.e.

$$\min_\rho S(\mathcal{L}_p^d |\rho|) = t(p, d, \sigma_0, \sigma_1).$$

As a first application of the above observation we now compute the Holevo capacity $C_1(\mathcal{L}_p^d)$ of the map (21). For this purpose we notice that for any ensemble $\{p_i, \rho_i\}$, one can create a larger ensemble $\{p_i, dU; \mathcal{L}_p^d U \rho_i U^\dagger\}$, where the state $U\rho_i U^\dagger$ is extracted with probability density $p_i dU$, where $dU$ is the Haar measure of $SU(d)$. By concavity of the Holevo quantity it follows that on $\{p_i, dU; \mathcal{L}_p^d U \rho_i U^\dagger\}$ such functional is bound to assume a value that is not smaller than the one it gets on the original ensemble, i.e.

$$\chi(\{p_i; \mathcal{L}_p^d |\rho_i|\}) \leq \chi(\{p_i, dU; \mathcal{L}_p^d[U \rho_i U^\dagger]\}) = S\left( \frac{I_d}{d} \otimes ((1-p)\sigma_0 + p \sigma_1) \right) - \sum_i p_i \int dU S(\mathcal{L}_p^d[U \rho_i U^\dagger])$$

$$= \log d + S((1-p)\sigma_0 + p \sigma_1) - \sum_i p_i S(\mathcal{L}_p^d |\rho_i|),$$

where in the first identity we used the depolarizing identity

$$\int dU \ U\rho U^\dagger = \frac{I_d}{d},$$

and the fact that

$$\mathcal{L}_p^d \left[ \frac{I_d}{d} \right] = \frac{I_d}{d} \otimes ((1-p)\sigma_0 + p \sigma_1),$$

while in the second one we employed (23) to remove any functional dependence upon $U$. We can now invoke (25) to put an upper bound on $\chi(\{p_i, dU; \mathcal{L}_p^d[U \rho_i U^\dagger]\})$ by replacing all the $S(\mathcal{L}_p^d |\rho_i|)$ terms with the constant $t(p, d, \sigma_0, \sigma_1)$. The resulting quantity no longer depends on the input of the channel and provide an achievable maximum for the Holevo information of the channel yielding the identity

$$C_1(\mathcal{L}_p^d) = \log d + S((1-p)\sigma_0 + p \sigma_1) - t(p, d, \sigma_0, \sigma_1),$$

(the achievability being granted e.g. by ensembles of the form $\{dU; |\psi\rangle \langle \psi|U^\dagger\}$, with $|\psi\rangle$ arbitrarily chosen).

Next we focus on the entanglement assisted capacity of $\mathcal{L}_p^d$. For this purpose we use the fact that the quantum mutual information of a channel as defined in Eq. (35) is concave in $\rho$ [1]. Exploiting this and the covariance of $\mathcal{L}_p^d$ under $SU(d)$ i.e. Eq. (29), we can then write

$$I\left( \frac{I_d}{d}, \mathcal{L}_p^d \right) = I\left( \int U \rho U^\dagger \ dU, \mathcal{L}_p^d \right) \geq \int I(U \rho U^\dagger, \mathcal{L}_p^d) \ dU = I(\rho, \mathcal{L}_p^d),$$

where we used the depolarizing identity [27]. Therefore we can conclude that the state that maximizes the quantum mutual information is $I/d$ and the entanglement assisted capacity is

$$C_E(\mathcal{L}_p^d) = I\left( \frac{I_d}{d}, \mathcal{L}_p^d \right) = S\left( \frac{I_d}{d} \right) + S\left( \mathcal{L}_p^d \left[ \frac{I_d}{d} \right] \right) - S\left( \mathcal{L}_p^d \otimes I [\Phi^d] \langle \Phi^d| \right)$$

$$= 2 \log d + S((1-p)\sigma_0 + p \sigma_1) - t(p, d^2, \sigma_0, \sigma_1),$$
where $|\Phi^d\rangle$ is a purification of $\rho_d^\otimes$ and where we used the fact that

$$\Lambda_p^d \otimes I [|\Phi^d\rangle \langle \Phi^d|] = (1 - p) |\Phi^d\rangle \langle \Phi^d| \otimes \sigma_0 + p \frac{J_d^2}{d^2} \otimes \sigma_1,$$

is formally equivalent to the a pure output state of a channel $\Lambda_p^d$ operating on an input $d^2$ dimensional Hilbert space, so that it entropy is given by the same expression presented in [24] with $d$ replaced by $d^2$, i.e.

$$S\left(\Lambda_p^d \otimes I [|\Phi^d\rangle \langle \Phi^d|]\right) = t(p, d^2, \sigma_0, \sigma_1).$$

(32)

The functional we have to maximize to compute the quantum capacity $Q$ of $\Lambda_p^d$ is the coherent information $J$. In general tackling this issue is not an easy task: the problem however gets simplified if the channel is degradable. To begin with, as we have already anticipated in the previous section, under this circumstance the value of $Q$ coincides with the product state quantum capacity $Q_1$ which does not require regularization with respect to infinite channel uses. Second, in Ref. [22] it was shown that the coherent information of degradable channels is concave in the input state. Applying this to property to $\Lambda_p^d$ allows us to analytically prove that the maximum of $J(\rho, \Lambda_p^d)$ is achieved by taking $\rho$ to be the completely mixed state. The argument goes as follows: assume we select values of $p$, $\sigma_0$, and $\sigma_1$ such that $\Lambda_p^d$ is degradable (the explicit conditions for this to happen will be given in the next section). Now inverting the concavity argument of Ref. [22] we can write

$$J\left(\frac{J_d^2}{d}, \Lambda_p^d\right) = J\left(\int U \rho U^\dagger \, dU, \Lambda_p^d\right) \geq \int J(U \rho U^\dagger, \Lambda_p^d) \, dU = J(\rho, \Lambda_p^d),$$

(34)

where as in Eq. (30) the integral is performed with respect to the Haar measure on the unitary operators $U$ of $SU(d)$ and where we used the depolarizing identity [27] and the covariance property of $\Lambda_p^d$. Accordingly we can write

$$Q(\Lambda_p^d) = Q_1(\Lambda_p^d) = \max_{\rho} J(\rho, \Lambda_p^d) = J\left(\frac{J_d^2}{d}, \Lambda_p^d\right)$$

$$= S\left(\Lambda_p^d \frac{J_d^2}{d}\right) - S\left(\Lambda_p^d \otimes I [|\Phi^d\rangle \langle \Phi^d|]\right)$$

$$= \log d + S((1 - p)\sigma_0 + p\sigma_1) - t(p, d^2, \sigma_0, \sigma_1),$$

(35)

where again we used [23]. It is worth stressing that we can certify the validity of Eq. (35) only for those values of $p$, $\sigma_0$, and $\sigma_1$ which ensures degradability of $\Lambda_p^d$, a condition that which we shall discuss explicitly in the next section.

1. Sufficient conditions for the degradability of $\Lambda_p^d$

Here we analyse the degradability of $\Lambda_p^d$ when $\sigma_1$ is a pure state and $\sigma_0$ is diagonalizable in that basis. For the first case, the channel and its complementary channel can be parametrised by the fidelity between $\sigma_0$ and $\sigma_1$. Let’s choose this parameterization for the flags $\sigma_1 = |e_1\rangle \langle e_1|$ and $\sigma_0 = c^2 |e_1\rangle \langle e_1| + (1 - c^2) |e_1^\perp\rangle \langle e_1^\perp|$. Then the channel can be parametrized by the value of $c$ only, i.e.

$$\Lambda_{p,c}^d(\rho) = (1 - p)\rho \otimes (c^2 |e_1\rangle \langle e_1| + (1 - c^2) |e_1^\perp\rangle \langle e_1^\perp|) + p \frac{J_d^2}{d} \otimes |e_1\rangle \langle e_1|. $$

(36)

To find complementary channel $\Lambda_{p,c}^d$ we should first write the Stinespring [12] form of $\Lambda_{p,c}^d$ as it is discussed in Eq. (11). For this purpose we add extra degree of freedom extending the environment Hilbert space to $\mathcal{H}_E = \mathcal{H}_1 \otimes \mathcal{H}_2 \otimes \mathcal{H}_3 \otimes \mathcal{H}_4 \otimes \mathcal{H}_5$ where $\mathcal{H}_1$, $\mathcal{H}_2$ and $\mathcal{H}_5$ are two dimensional, and $\mathcal{H}_3$ and $\mathcal{H}_4$ are $d$ dimensional Hilbert spaces. Simple algebra can hence be used to verify that the Stinespring representation of the channel can be obtained through the following unitary interaction

$$U_{AE} |\psi\rangle_A |0\rangle_1 |0\rangle_2 |\Phi^d\rangle_{3,4} |0\rangle_5 = \sqrt{1 - p} |\psi\rangle_A |\sigma_0\rangle|1,2 \rangle |\Phi^d\rangle_{3,4} |0\rangle_5 + \sqrt{p} |\Phi^d\rangle_{A,4} |e_1\rangle_1 |e_1\rangle_2 |\psi\rangle_A |1\rangle_5,$$

(37)

where $|0\rangle, |1\rangle$ are two orthogonal states, $|\Phi^d\rangle$ is a maximally entangled state in dimension $d$, and $|\sigma_0\rangle_{1,2}$ is a purifications of $\sigma_0$, and the trace in Eq. (11) is on labels 2,3,4,5 (see Appendix A for details). To find the complementary
We now look for the existence of a degrading CPTP channel \( \tilde{W}_{p,c} \) where

\[
\eta = \frac{1}{\sqrt{d}} \sum_{i=0}^{d-1} \alpha_i |i\rangle \langle i| + p |0\rangle \langle 0| + p |1\rangle \langle 1|
\]

Doing simple algebra reveals that this is the case for all those cases where the following inequality holds,

\[
\eta = \frac{1}{\sqrt{d}} \sum_{i=0}^{d-1} \alpha_i |i\rangle \langle i| + p |0\rangle \langle 0| + p |1\rangle \langle 1|
\]

Under this condition the channel (36) is degradable and its quantum capacity can be computed as in (11), i.e. explicitly

\[
(1 - p) W_{p,c}(\rho \otimes \sigma_{01}) + \frac{p}{d} W_{p,c}(I^d \otimes |e_1\rangle \langle e_1|) = \tilde{\lambda}^d_{p,c}(\rho) .
\]

As a suitable candidate for \( W_{p,c} \) we consider a two-step process which first performs a measurement on system 1 that then triggers an action on A. Specifically, for the measurement we assume an orthogonal projection in the basis \( |e_1\rangle \) and \( |e_2\rangle \). For the action on A instead we assume that if the measurement outcome is \( |e_1\rangle \) we will prepare whatever state was left on A into the fixed state \( |e_1\rangle \langle e_1| = \tilde{\lambda}^d_{q,c} \) with properly selected parameters \( q, c' \). With this choice, the resulting mapping \( W_{p,c} \) on \( \rho_{A,1} \) is hence given by

\[
W_{p,c}(\rho_{A,1}) := \langle e_1 | \text{tr}_A(\rho_{A,1}) | e_1 \rangle | e_1^+ \rangle \langle e_1^+ |_2 \otimes |\Phi^d\rangle \langle \Phi^d|_{3,4} \otimes |0\rangle \langle 0|_5 + \langle e_1^+ | \text{tr}_A(\rho_{A,1}) | e_1^+ \rangle \tilde{\lambda}^d_{q,c} \text{ (tr}_A(\rho_{A,1})) .
\]

With this choice the condition (39) becomes

\[
(1 - p) \left[ c^2 \langle e_1^+ |_2 \otimes |\Phi^d\rangle \langle \Phi^d|_{3,4} \otimes |0\rangle \langle 0|_5 + (1 - c^2) \tilde{\lambda}^d_{q,c} (\rho_A) \right] + p |e_1^+ \rangle \langle e_1^+ |_2 \otimes |\Phi^d\rangle \langle \Phi^d|_{3,4} \otimes |0\rangle \langle 0|_5 = \tilde{\lambda}^d_{p,c} (\rho_A) .
\]

which can be satisfied if it is possible to find \( q, c' \in [0,1] \) such that

\[
q = \frac{p}{1 - p)(1 - c^2) , \quad c' = \frac{c^2(1 - p)}{1 - 2p - c^2 + pc^2} .
\]

Doing simple algebra reveals that this is the case for all those cases where the following inequality holds,

\[
c \leq \sqrt{\frac{1 - 2p}{2 - 2p}} .
\]

Under this condition the channel (36) is degradable and its quantum capacity can be computed as in (11), i.e. explicitly

\[
Q(\tilde{\lambda}^d_{p,c}) = Q(\Lambda^d_{p,c}) = \log d + \eta \left( (1 - p)c^2 + p \right) - \eta \left( (1 - p)c^2 + \frac{p}{d^2} \right) - (d^2 - 1) \eta \left( \frac{p}{d^2} \right) ,
\]

where \( \eta(z) := -z \log(z) \). In Appendix [13] we report a similar, yet less handy, expression for the case where the flag states \( \sigma_0 \) and \( \sigma_1 \) are both pure but non necessarily commuting – see Eq. [137].

V. UPPER BOUNDS ON THE QUANTUM CAPACITY OF THE DEPOLARIZING CHANNEL

The quantum capacity of the depolarizing channel has been extensively studied by several authors [5, 10, 23, 20], yet despite the highly symmetric expression (22), the exact value of \( Q(\Lambda^d_{p}) \) is still unknown.

According to Eq. (20) the quantum capacity of the depolarizing channel \( \Lambda^d_{p} \) can be upper bounded by the capacity of \( \tilde{\lambda}^d_{p,c} \), irrespectively from the choice we make on the parameter \( c \). Intuitively however, as \( c \) gets larger, the bound gets better because channel (21) gets closer to \( \Lambda^d_{p} \). In the previous section we manage to compute the \( Q(\tilde{\lambda}^d_{p,c}) \) for a restricted set of values of \( c \). To get the best upper bound for the quantum capacity of \( \Lambda^d_{p} \) we should choose the maximum value for \( c \) without violating condition (43), therefore we choose

\[
c = c(p) := \frac{1 - 2p}{\sqrt{1 - 2p}} .
\]
Accordingly our best way to upper bound $Q(\Lambda_p^d)$ is provided by the following expression

$$Q(\Lambda_p^d) \leq Q(\Lambda_{p,c(p)}^d) = \log d + \eta \left( \frac{1}{2} \right) - \eta \left( \frac{1}{2} - \left( \frac{d^2 - 1}{d^2} p \right) \right) - (d^2 - 1) \eta \left( \frac{p}{d^2} \right) .$$  \hspace{1cm} (46)

In addition we can obtain another bound by choosing the flags to be pure states as discussed explicitly in Appendix B:

In order test the quality of our finding we now proceed with a comparison with the limits previously proposed in the literature. We start considering first the low noise regime ($p \ll 1$) where (46) gives

$$Q(\Lambda_{p,c(p)}^d) = \log d + \frac{d^2 - 1}{d^2} \left( \log \left( \frac{p}{d^2} \right) - \log e + 1 \right) p + O \left( p^2 \right) ,$$  \hspace{1cm} (47)

which for $d = 2$ yields

$$Q(\Lambda_{p,c(p)}^d) = 1 + \frac{3}{4} (1 - \log e + \log p) p + O \left( p^2 \right) ,$$  \hspace{1cm} (48)

We can compare this with the result in [11] which put the following upper bound for the quantum capacity of two dimensional depolarizing channel in the low noise regime

$$Q(\Lambda_p^d) \leq 1 + \frac{3}{4} (1 - \log e + \log(p)) p + O \left( p^2 \log p \right) .$$  \hspace{1cm} (49)

The first order in (50) is smaller than our bound (51), so at least this special case we do not do particularly well. Things however change when we move out from the $d = 2$, low noise regime. To our knowledge, there are two bounds obtained from the degradable extension of the $d$ dimensional depolarizing channel. The first one is given in Ref. [9] and consists in the following expression

$$Q(\Lambda_p^d) \leq f_{1,d}(p) := \eta \left( \frac{1 + (d - 1)\gamma}{d} \right) + (d - 1) \eta \left( \frac{1 - \gamma}{d} \right) - \eta \left( 1 - \left( \frac{d - 1}{d} \right) \gamma \right) - (d - 1) \eta \left( \frac{\gamma}{d} \right) ,$$  \hspace{1cm} (50)

with $\gamma$ defined as in Eq. 11 and $\gamma = \frac{2d}{\gamma^2 - 1} \left( \frac{1 - p^{d^2 - 1}}{\gamma^2 - 1} \right) - \frac{1}{2} \left( 1 - p^{d^2 - 1} \right)$. The second one was instead obtained by using the fact that $\Lambda_p^d$ is degradable and anti-degradable when $p = \frac{d}{2(d^2 + 1)}$, see [6, 30]. Using this fact, [7, 9] showed we have

$$Q(\Lambda_p^d) \leq f_{2,d}(p) := (1 - \frac{2d}{d + 1}) \log d .$$  \hspace{1cm} (51)

Given that all of these bounds are obtained by degradable extension of depolarizing channel and the convexity of upper bounds [13], we can obtain the following upper bound for the quantum capacity

$$Q(\Lambda_p^d) \leq \text{conv} \left\{ Q(\Lambda_{p,c(p)}^d), f_{1,d}(p), f_{2,d}(p) \right\} ,$$  \hspace{1cm} (52)

FIG. 1: $d = 2$. $Q_1$ is the lower bound from Eq. (57). Conv is the convex hull of all the bounds defined in Eq. (52). Left: low noise regime, the new bound is compared with [10]. Right: high noise regime, comparison with [12].
where conv\{g_1(p), g_2(p), ...\} is defined as the maximal convex function that is less than or equal to all the g_i(p)s. Figure 1 compares the new bound with previous benchmarks for d = 2, [10, 11] for low noise and [12] for high noise, showing that the new bound is better in an intermediate regime. Figure 2 represents all of these three bounds for d = 4, 10.

To be more quantitative, we can study the asymptotic expansion of the capacities of the various extensions for large d. By some algebra one can show that

\[ \Lambda_{p,c}(d) = (1 - 2p) \log d - h(p) + \eta\left(\frac{1}{2}\right) - \eta\left(\frac{1}{2} - p\right) + \eta(1 - p) + O\left(\frac{1}{\log d}\right), \tag{53} \]

\[ f_{1,d}(p) = (1 - 2p) \log d + O\left(\frac{\log d}{d}\right), \tag{54} \]

\[ f_{2,d}(p) = (1 - 2p) \log d + O\left(\frac{\log d}{d}\right), \tag{55} \]

which should be compared with the lower bound of \( Q(\Lambda_p^d) \) one get by taking the value of the single shot coherent information evaluated on the completely mixed state \( I^d/d \), i.e.

\[ Q(\Lambda_p^d) \geq Q_{lower}(\Lambda_p^d) := J(\frac{I^d}{d}, \Lambda_p^d) = \log d - \eta\left(1 - p + \frac{p}{d^2}\right) - (d^2 - 1)\eta\left(\frac{p}{d^2}\right) = (1 - 2p) \log d - h(p) + O\left(\frac{1}{\log d}\right). \tag{56} \]

As we can see our bound is the only one that shows an \( O(1) \) term which is not zero (and negative). Furthermore the gap between our bound and the lower bound scales as

\[ \Delta Q(\Lambda_{p,c}(d)) := Q(\Lambda_{p,c}(d)) - Q_{lower}(\Lambda_p^d) = \eta\left(\frac{1}{2}\right) - \eta\left(\frac{1}{2} - p\right) + \eta(1 - p) + O\left(\frac{1}{\log d}\right). \tag{57} \]

On the contrary the differences between the other upper bounds and the lower bound exhibit a \( O(1) \) gap equal to \( h(p) \) which, as shown in Fig. 3 is larger than \( \frac{1}{\log d} \) for \( p < \frac{1}{2} \) (where the quantum capacity is not zero). In particular it appears that our inequality gives a much better bound for low p, since \( h(p) \) has derivative that diverges as \( -\log p \) when \( p \to 0 \), while \( \Delta Q(\Lambda_{p,c}(d)) \) scales linearly in \( p \).

VI. CONCLUSION

We introduced a specific Flagged Depolarizing channel (FDCH) which is a degradable extension of depolarizing channel for a certain parameter regime. We found this regime and computed different capacities for FDC. As FDC is a degradable extension for this parameter regime, we put an upper bound on the quantum capacity of depolarizing channel. Our result is analytic and works in any dimension, and it is the tightest available analytical upper bound. Unlike other degradable extensions of depolarizing channel [3, 13], the introduced flags are not orthogonal. This technique of adding non orthogonal flags can be used to study the quantum capacity of other channels.

VII. ACKNOWLEDGEMENT

We thank Felix Leditzky, Andreas Winter, and Mark Wilde for helpful feedbacks.

Appendix A: Stinespring representation and complementary channel

Here we show that the mapping
\[
U_{AE} |\psi\rangle_A |0\rangle_1 |0\rangle_2 |\Phi^d\rangle_{3,4} |0\rangle_5 = \sqrt{1-p} |\psi\rangle_A |\sigma_0\rangle_{1,2} |\Phi^d\rangle_{3,4} |0\rangle_5 + \sqrt{p} |\Phi^d\rangle_{A,4} |\sigma_1\rangle_{1,2} |\psi\rangle_3 |1\rangle_5 ,
\]
(A1)
provides a Stinespring representation of the channel \( \Lambda^d_{p,\sigma_0,\sigma_1} \). For this purpose we first notice that \( (A1) \) identifies a unitary transformation because in the domain where we have defined it does preserve the scalar product: indeed introducing the compact notation \( |\psi, e\rangle_{AE} := |\psi\rangle_A |0\rangle_1 |0\rangle_2 |\Phi^d\rangle_{3,4} |0\rangle_5 \) we have
\[
AE \langle \phi, e |U^\dagger_{AE} U_{AE} |\psi, e\rangle_{AE} = (1-p) A \langle \phi |\psi\rangle_A + p A \langle \phi |\phi\rangle_3 = A \langle \phi |\psi\rangle_A = AE \langle \phi, e |\psi, e\rangle_{AE} .
\]
(A2)
Next we notice that by tracing over 2, 3, 4, 5 we get
\[
\text{tr}^{(A1)} [U_{AE} |\psi, e\rangle_{AE} \langle \psi, e |U^\dagger_{AE}] = (1-p) |\psi\rangle_A \otimes |\sigma_0\rangle_{1,2} \otimes |\Phi^d\rangle_{3,4} \otimes |0\rangle_5 + \frac{p}{d} \otimes |\sigma_1\rangle_{1,2} = \Lambda^d_{p,\sigma_0,\sigma_1} (|\psi\rangle_A \langle \psi|) ,
\]
(A3)
for all possible input state \( |\psi\rangle_A \) (here \( \text{tr}^{(A1)} \) indicates that we are taking the partial trace with respect to all degree of freedom of the system but \( A,1 \)).

From the above definition we now show that Eq. (B2) is the complementary channel (2) of \( \Lambda^d_{p,c} \), i.e. that the following identity holds true
\[
\tilde{\Lambda}^d_{p,c} [\rho] = \text{tr}_{A1} [U_{AE} (\rho \otimes |e\rangle_{E}) U^\dagger_{AE}] ,
\]
(A4)
for all input states \( \rho \) (here \( \text{tr}_{A1} \) indicates that the trace is taken on \( A \) and 1). Without loss of generality we can always focus on pure input states. Under this condition the right side of the previous expression yields
\[
U_{AE} (|\psi\rangle_A \otimes |e\rangle_{E}) U^\dagger_{AE} = (1-p) |\psi\rangle_A \otimes |\sigma_0\rangle_{1,2} \otimes |\Phi^d\rangle_{3,4} \otimes |0\rangle_5 + p |\Phi^d\rangle_{A,4} \otimes |e_1\rangle_{1,2} \otimes |\psi\rangle_3 \otimes |1\rangle_5
\]
(A5)
and
\[
+ \sqrt{p(1-p)} |\psi\rangle_A |\Phi^d\rangle_{3,4} \langle \psi|_3 \otimes |\sigma_0\rangle_{1,2} \langle e_1|_1 \otimes |e_1\rangle_2 \otimes |0\rangle_5 + h.c. ,
\]
(A6)
Given that \( |\sigma_0\rangle_{1,2} = c |e_1\rangle_{1,2} + \sqrt{1-c^2} |e_1^\dagger\rangle_{1,2} \) we can take trace over 2, 3, 4 and 5 and get
\[
\tilde{\Lambda}^d_{p,c} (|\psi\rangle_A \langle \psi|) = (1-p) |\sigma_0\rangle_2 \otimes |\Phi^d\rangle_{3,4} \otimes |0\rangle_5 + p |e_1\rangle \langle e_1|_2 \otimes |\psi\rangle_3 \otimes |1\rangle_5
\]
(A8)
and
\[
+ \sqrt{p(1-p)} [c \text{tr}_A (|\psi\rangle_A |\Phi^d\rangle_{3,4} |0\rangle_5 \langle \psi|_3 \langle 1|_5 + h.c.| \otimes |e_1\rangle_2 .
\]
(A9)

Appendix B: Pure flags expansion

The condition for degradability for the pure flags are similar to the case where the flags are mixed but diagonal. In this scenario the channel explicitly writes as
\[
\Lambda^d_{p,c} [\cdots] = (1-p)[\cdots] \otimes |e_0\rangle \langle e_0| + \frac{p}{d} \otimes |e_1\rangle \langle e_1| ,
\]
(B1)
where the parameter \( c \) refers now to the overlap \( c := \langle e_1|e_0\rangle \). Notice that the phase in \( c \) is not important in studying the degradability of \( \Lambda^d_{p,c} \) since the phase in \( c \) can be set to zero by acting with a unitary transformation after the action of the channel \( (B1) \); accordingly in the following we shall assume \( c \) to be real without loss of generality.

To find complementary channel \( \tilde{\Lambda}^d_{p,c} \) we should first write the Stinespring form of this transformation. The Hilbert space of the environment is decomposed as \( \mathcal{H}_E = \mathcal{H}_1 \otimes \mathcal{H}_2 \otimes \mathcal{H}_3 \otimes \mathcal{H}_4 \) where \( \mathcal{H}_1 \) and \( \mathcal{H}_4 \) are two dimensional, and \( \mathcal{H}_2 \) and \( \mathcal{H}_3 \) are \( d \) dimensional Hilbert spaces. The unitary interaction between system and environment acts as following
\[
U_{AE} |\psi\rangle_A |0\rangle_1 |\Phi^d\rangle_{2,3} |0\rangle_4 = \sqrt{1-p} |\psi\rangle_A |e_0\rangle_1 |\Phi^d\rangle_{2,3} |0\rangle_4 + \sqrt{p} |\Phi^d\rangle_{A,3} |e_1\rangle_1 |\psi\rangle_2 |1\rangle_4 ,
\]
(B2)
where \( |0\rangle , |1\rangle \) are two orthogonal states, \( |\Phi^d\rangle \) is a maximally entangled states in dimension \( d \), \( |e\rangle_E = |0\rangle_1 |\Phi^d\rangle_{2,3} |0\rangle_4 \), and the trace in Eq. (1) here is on states 2, 3, 4. Doing simple calculation we can show that this is a Stinespring
representation of $B_1$. To find the complementary channel instead of taking trace over states 2,3,4 we should take trace over states A,1, carrying out the calculation we get

$$
\tilde{\Lambda}'_{d,p,c}(|\psi\rangle\langle\psi|) = (1-p) |\Phi^d\rangle \langle \Phi^d |_{2,3} \otimes |0\rangle \langle 0 |_{4} + p |\psi\rangle \langle \psi |_{2} \otimes I_{d} \otimes |1\rangle \langle 1 |_{4} \\
+ \sqrt{p(1-p)} [c \text{ tr}_{A} (|\psi\rangle \langle \Phi^d |_{2,3} \otimes |0\rangle \langle 0 |_{4} \langle \Phi^d |_{A,3} \langle \psi |_{2} \langle 1 |_{4} ) + h.c.] .
$$

As the form of $\tilde{\Lambda}'_{d,p,c}$ is exactly the same as $\tilde{\Lambda}^d_{p,c}$, the regime where $\Lambda'_{d,p,c}$ is degradable is the same as before, i.e.

$$
c^2 \leq \frac{1 - 2p}{2 - 2p} .
$$

In this regime the quantum capacity of $\Lambda'_{d,p,c}$ can be computed as in Eq. (35), i.e.

$$
Q(\Lambda'_{d,p,c}) = \log d + S((1-p) |e_0\rangle \langle e_0 | + p |e_1\rangle \langle e_1 |) - t(p, d^2, |e_0\rangle, |e_1\rangle) ,
$$

which after some algebra can be casted into the expression

$$
Q(\Lambda'_{d,p,c}) = \log d + \eta \left[ \frac{1}{2} \left(1 - \sqrt{-2(p-1)p \cos(\theta) + 2(p-1) + 1}\right) \right] + \eta \left[ \frac{1}{2} \left(1 + \sqrt{-2(p-1)p \cos(\theta) + 2(p-1) + 1}\right) \right] - \eta \frac{d^2(-p) + d^2 - \sqrt{d^4p^2 - 2d^4p + d^4 - 2d^4p^2 \cos(\theta) + 2d^2p \cos(\theta) + p^2 + p}}{2d^2} \\
- \eta \frac{d^2(-p) + d^2 + \sqrt{d^4p^2 - 2d^4p + d^4 - 2d^4p^2 \cos(\theta) + 2d^2p \cos(\theta) + p^2 + p}}{2d^2} + p \frac{(d^2 - 1)}{d^2} \log \left( \frac{p}{d^2} \right) ,
$$

where $\cos(\theta) = 2c^2 - 1$ and $\eta(z) := -z \log(z)$.
