The temperature and doping dependence of transport coefficients of Yb(Rh$_{1-x}$Co$_x$)$_2$Si$_2$ series of alloys is explained by an asymmetric Anderson model which takes into account the exchange scattering of conduction electrons on Ytterbium ions and the splitting of 4f-states by the crystalline electric field (CEF). The substitution of rhodium by cobalt is described as an increase of chemical pressure which reduces the exchange coupling and the CEF splitting. The scaling analysis and numerical NCA solution of the model show that, at a given temperature, the effective degeneracy of the 4f-state depends on the relative magnitude of the Kondo scale and the CEF splitting. The temperature and doping dependence of the thermopower of Yb(Rh$_{1-x}$Co$_x$)$_2$Si$_2$ series of alloys is explained as an interplay of quantum fluctuations, driven by the exchange scattering, and thermal fluctuations which populate the excited CEF states. The theoretical results obtained in such a way capture all the qualitative features of the experimental data.

I. INTRODUCTION

Recent investigations of electrical, thermal, magnetic, and spectroscopic properties of strongly correlated material Yb(Rh$_{1-x}$Co$_x$)$_2$Si$_2$ revealed a number of interesting, doping-dependent features that have not been fully understood. The high-temperature transport coefficients exhibit typical Kondo behaviour due to the scattering of conduction electrons on Yb ions but the non-monotonic temperature dependence of the data indicates that Kondo effect is modified by the splitting of the 4f state by the crystalline electrical field (CEF) into several multiplets. The substitution of rhodium by cobalt reduces the Kondo scale and changes the temperature dependence of transport coefficients in a qualitative way (see, e.g., Fig. 1) but the relationship between the doping-induced change of the Kondo scale and the CEF splitting has not been established.

The neutron scattering data show that the 4f-state of YbRh$_2$Si$_2$ is split by the CEF into four doublets and that the first excited level is separated from the ground state by an energy $\Delta_1 \approx 200$ K. In YbCo$_2$Si$_2$, the data show the same level scheme but $\Delta_1 \lesssim 50$ K. Magnetic and thermodynamic measurements on Yb(Rh$_{1-x}$Co$_x$)$_2$Si$_2$ alloys provide an indirect evidence that the structure of the CEF excitations is unchanged by doping but that $\Delta_1$ decreases as $x$ increases. Thus, an increase of cobalt concentration reduces not just the Kondo coupling but the CEF splitting as well; this should be taken into account, when analysing the thermoelectric response of these materials.

Our paper explains the thermopower of Yb(Rh$_{1-x}$Co$_x$)$_2$Si$_2$ series of alloys using a highly asymmetric Anderson model with several f-like multiplets. The calculations take into account the reduction of the exchange coupling and the CEF splitting due to the substitution of rhodium by cobalt. In what follows, we discuss the experimental results in Sec. II, describe the model in Sec. III, provide a qualitative solution obtained by a poor man’s scaling in Sec. IV, and discuss the numerical NCA solution of the model in Sec. V. The theoretical results are compared with the experimental data in Sec. VI and Sec. VII summarises the results.

II. EXPERIMENT

The temperature dependence of the thermopower of Yb(Rh$_{1-x}$Co$_x$)$_2$Si$_2$ alloys, $S(T)$, is shown in Fig. 1 for various concentration of cobalt ions. At low doping, $x < 0.195$, the thermopower exhibits a deep minimum at temperature $T_{\text{min}} \approx 100$ K, where $S(T_{\text{min}}) = -60 \, \mu V/K$. Above $T_{\text{min}}$, the thermopower increases logarithmically
and, for \( x > 0 \), it changes sign above room temperature. An increase of \( x \) makes the minimum less deep but doesn’t change much the value of \( T_{\text{min}} \). The thermopower of a similar shape is often found in Kondo systems with a large Kondo scale or in valence fluctuating materials.

At higher doping, \( x > 0.27 \), the thermopower acquires a double-well shape, i.e., in addition to the high-temperature minimum, around \( T_{\text{min}} \approx 100 \) K, it develops a low-temperature one at \( T_0 \leq 10 \) K. For temperatures between \( T_0 \) and \( T_{\text{min}} \), we find a maximum of \( S(T) \) at temperature \( T_{\text{max}} \), where \( S(T_{\text{max}}) \) is negative for \( x < 0.68 \) and positive for \( x > 0.68 \). The data show that an increase of \( x \) pushes \( T_{\text{max}} \) and \( T_0 \) to lower values; it also reduces temperature at which \( S(T) \) changes sign. Contrary to that, \( T_{\text{min}} \) doesn’t change much with doping.

The electrical resistivity of \( \text{Yb(Rh}_{1-x}\text{Co}_x)\text{Si}_2 \) alloy exhibits a maximum at temperature \( \rho_{\text{max}} \), which decreases as the concentration of cobalt increases. For large enough \( x \), a secondary maximum appears at a higher temperature which is not much different from \( T_{\text{min}} \). For \( T \geq T_{\text{max}}^{\rho} \), the conduction electrons’ mean free path is very short (it is of the order of the lattice spacing), so that the transport properties can be discussed assuming incoherent scattering of conduction electrons on Yb ions. Since we have \( T_{\rho}^{\text{max}} < T_0 \) for all \( x \), the non-monotonic behaviour of \( S(T) \) in \( \text{Yb(Rh}_{1-x}\text{Co}_x)\text{Si}_2 \) can be described by an impurity model. For a periodic array of Yb ions, such a description breaks down at \( T \ll T_{\text{max}}^{\rho} \) due to the onset of coherence. At such low temperatures, the resistivity and thermopower should follow the Fermi liquid laws.

III. THE MODEL

To model \( \text{Yb(Rh}_{1-x}\text{Co}_x)\text{Si}_2 \) alloys we take one Yb ion per unit cell and assume that the scattering of conduction holes on a given Yb ion is independent of other Yterbiums, except through the modification of the chemical potential. In other words, we use an effective impurity model which treats the \( 4f \) states as scattering resonances rather than Bloch states but it allows for the charge transfer between the conduction and \( f \)-states. The chemical potential, \( \mu \), is adjusted at every temperature and doping, so as to maintain the overall charge neutrality of the compound. That is, for \( n_c \) conduction holes and \( n_f \) Yb holes per site, the total charge \( n = n_c + n_f \) is always conserved. The fluctuations of Yb ions between the low-energy \( \text{4f}^{13} \) and the high-energy \( \text{4f}^{14} \) configuration broaden the \( 4f \)-states into resonances of half-width \( \Gamma = \pi V^2 N(\mu) \), where \( V \) is the hybridization matrix element and \( N(\mu) \) is the conduction electrons density of states at the Fermi level.

In the large-\( U \) limit, where the two-hole configuration of Yb ions can be neglected, we arrive at an effective single-impurity Anderson model in which the single-hole configuration is represented by \( N - 1 \) excited CEF states separated from the ground state by energies \( \Delta_i = E_{f_i} - E_0^f (i = 1, \ldots, N - 1) \). Here, \( E_0^f \) and \( E_{f_i} \) are the energies of the ground and excited states, respectively. The total degeneracy of \( 4f \)-states is \( N = \sum_{i=0}^{N-1} N_i \), where the individual degeneracies of the CEF states, \( N_i \), are determined by the point group symmetry of the crystal. In the hole picture, the Kondo effect due to the \( \text{4f}^{13} - \text{4f}^{14} \) fluctuations is described by the Hamiltonian

\[
H_A = H_{\text{band}} + H_{\text{imp}} + H_{\text{mix}} .
\]

\( H_{\text{band}} \) describes the single-hole excitations in the conduction band with a semicircular density of states centred at \( E_0^c \) and of half-width \( W \), which we take as the unit of energy. The origin of the energy axis is set to \( \mu \). The unrenormalized CEF excitations of \( 4f \) ions are described by \( H_{\text{imp}} \); their spectral functions are given by a set of delta functions at energies \( E_{f_i} > 0 \). The transfer of holes between the \( 4f \) ions and conduction band is described by \( H_{\text{mix}} \), which depends on the coupling constant \( g_0 = \Gamma / \pi E_{f_i}^0 \). This coupling broadens the spectral functions of \( 4f \) excitations into narrow resonances.

The qualitative features of the model depend in an essential way on the coupling constant \( g \), the lowest energy of the \( 4f \)-hole \( E_{f_i}^0 \), and the CEF splitting \( \Delta_1 \). In Yb intermetallics, pressure or chemical pressure shift the \( 4f \)-states away from the chemical potential, without changing much their width \( \Gamma \). Thus, the cobalt doping increases \( E_{f_i}^0 \), which reduces the coupling constant and the Kondo scale. The data on \( \text{Yb(Rh}_{1-x}\text{Co}_x)\text{Si}_2 \) alloys show also that cobalt doping reduces the CEF splitting. This facilitates the thermal occupation of excited states and changes the effective degeneracy of the \( 4f \)-states at a given temperature.

In what follows, we first solve the model by the poor man’s scaling and find its qualitative features in various parts of the parameter space. Then, we solve the model in the non-crossing approximation (NCA) and study the effects of temperature and doping on transport coefficients. The input parameters for numerical calculations are \( \Gamma, E_{f_i}^0 (g_0 = \Gamma / \pi E_{f_i}^0), \Delta_i, N_i \), and the total number of electrons \( n_f + n_c \). For Yb-based compounds, we take \( N = 8 \), \( n_f \leq 1 \), and assume \( \Gamma, \Delta_1 \ll E_{f_i}^0 < W \), i.e., \( g_0 \ll 1 \).

IV. THE SCALING SOLUTION

For given input parameters, the scaling equations are obtained by reducing the band width from \( W \) to \( W - \delta W \) and renormalizing the coupling constant from \( g \) to \( g + \delta g \), while keeping the form of the Hamiltonian unchanged. Considering, for simplicity, a \( m \)-fold degenerate CEF ground state separated from a \( M \)-fold degenerate excited state by energy \( \Delta \), we obtain the scaling equation

\[
(T_K/W)^{m/N} (T_K + \Delta/W)^{M/N} = (T_K^0/W)^{2/N} .
\]

\( \Delta = 1 \).
where $T_K$ is the scaling invariant of the model at hand, $N = m + M$, and $T_K^N = W e^{-1/2g_0}$ is the scaling invariant of a 2-fold degenerate model with the same bare coupling $g_0$ and bandwidth $W_0$. The Kondo scale of the model is provided by the low energy cut-off at which the renormalized coupling diverges. The scaling shows that $T_K$ depends exponentially on the coupling constant and algebraically on the CEF splitting.

The properties of the system are determined by the renormalized coupling, $g(W,T_K,\Delta)$, which is obtained by replacing $g_0$ by $g$ in Eq. (2). Then, for a given $T_K$ and $\Delta$, we define the scaling trajectory $g(T)$ by making the replacement $W \rightarrow T$. Along the scaling trajectory, the transport coefficients are obtained from the lowest order perturbation theory, in which the bare exchange coupling is replaced by the renormalized $g(T)$. The results obtained in such a way are equivalent to an infinite-order perturbation theory which keeps all the parquet diagram. Depending on the relative magnitude of $T_K$ and $\Delta$, the transport coefficients generated by scaling theory exhibit qualitatively different features.

If the initial parameters are such that $T_K$ is larger or comparable to $T_0$, where $T_0 = \Delta/\Lambda$ and $\Lambda \simeq 3 - 5$, the quantum fluctuations render the CEF splitting irrelevant and the system behaves as $N$-fold degenerate one. In that case, the approximate solution of Eq. (2) can be written as

$$T_K^N = \left(\frac{T_K^0}{W}\right)^{\frac{\pi}{4}} \cdot$$

where $T_K^N$ is the Kondo scale of $N$-fold degenerate f-state coupled to conduction states of bandwidth $2W$. Since $T_K^0/W < 1$ and $N$ is large, $T_K^N$ is greatly enhanced with respect to $T_K^0$. For $T > T_0$, the system is in the local moment (LM) regime with large magnetic entropy. As temperature is reduced, the scaling breaks down at $T \simeq T_0$, where $g(T)$ diverges. Here, the magnetic entropy is removed by a crossover to a non-degenerate Fermi liquid (FL) regime, but the details of the crossover cannot be obtained by scaling.

For $T/T_K^N < 1$, the lowest order perturbation theory in terms of the renormalized coupling gives the electrical resistivity, $\rho = \rho[g(t)]$, as universal function of reduced temperature $t = T/T_K^N$. The resistivity obtained in such a way is a monotonic function of temperature: it is negligibly small for $t \gg 1$ and it is close to the unitarity limit for $t \approx 1$. (The unitarity limit of the Anderson model, given by $\rho(T = 0)$, is known exactly from the phase shift analysis and the Friedel sum rule. The high-temperature thermopower obtained in the same way has a positive slope in the LM regime, where $t > 1$, and a negative one in the FL regime, where $t < 1$. (The scaling theory breaks down for $t < 1$ but since $S(T)$ has to vanish at $T = 0$, its low-temperature slope must be negative.) Thus, for $T_K^N > T_0$, the resistivity exhibits a single (negative) minimum at temperature $T_{\text{min}}$, indicating the crossover from a LM to FL state. A decrease of the coupling constant, for given $N$, reduces $T_K^N$ and shifts $T_{\text{min}}$ to lower temperatures.

In the opposite case, such that $T_K \ll \Delta$, the approximate solution of Eq. (2) can be written as

$$T_K^N = \left(\frac{T_K^0}{W}\right)^{N/m},$$

or

$$T_K^N = \left(\frac{W}{\Delta}\right)^{M/2} T_K^0 W.$$
For $T \leq T_\Delta$, thermal depopulation of excited CEF states gives rise to the crossover into the low-temperature LM regime. Here, a single $f$-hole has only two channels available for scattering and the system is close to half-filling, and the ensuing thermopower is small. (At half filling exactly, $S(T) = 0$.) The break-down of the $N$-fold degenerate LM regime is indicated by a minimum of $S(T)$ at $T_{\text{min}} < T_\Delta$.

In Yb compounds, the crossover from the $N$-fold to the 2-fold (or 4-fold) degenerate LM regime is characterized by the thermopower with a negative slope. Once the low-temperature LM regime is stabilised, i.e., temperature is such that $T_K \ll T < T_{\text{min}}$, the thermopower becomes a universal function of $T/T_K$ with a positive slope. Eventually, for $T \approx T_K$, the system makes a crossover in the FL regime, where $S(T) \approx -T/T_K$. Thus, the poor man’s scaling of the Anderson model with the CEF splitting yields the thermopower with two minima: the high-temperature one, indicating the collapse of the $N$-fold degenerate LM regime and the low-temperature one, indicating the collapse of the 2-fold degenerate LM regime, and the crossover into the FL regime.

The scaling theory describes rather accurately the properties of the system in the LM regimes. However, it cannot describe the crossovers or the low-temperature FL regime. Under chemical pressure, the coupling constant and the CEF splitting of Yb(Rh$_{1-x}$Co$_x$)$_2$Si$_2$ change simultaneously, making the scaling trajectory subject to two competing effects. The ensuing shifts of the thermopower minima are difficult to infer from scaling and in order to analyse the experimental data, a more accurate solution has to be used. The solution of the model provided by the NCA calculations is presented next.

V. THE NUMERICAL NCA SOLUTION

The single-particle spectral functions of the $f$-holes and the transport coefficients of the Anderson model, obtained by solving numerically the NCA equations, have been discussed in detail in Refs.\[6,8\]. Here, we consider the modifications due to a simultaneous change of the coupling constant and the CEF splitting. These results allow us to discuss the behaviour of Yb(Rh$_{1-x}$Co$_x$)$_2$Si$_2$ series of alloys for various concentration of cobalt ions.

We present the results for the ground state doublet at energy $E_f^0$, an excited quartet at $E_f^0 + \Delta_1$, and an additional excited doublet at $E_f^0 + \Delta_2$. All the energies are measured with respect to $\mu$. We choose $\Gamma = 0.12$ eV, $W = 4$ eV, and $n_{\text{t0}} = 5.63$ electrons per ion, i.e., we take (on average) 0.74 holes in each one of 8 ‘effective’ hybridized channels. The behaviour of the spectral function is illustrated at various temperatures for $E_f^0 = 1.0$ eV, $\Delta_1 = 0.06$ eV, and $\Delta_2 = 1.06$ eV. The temperature and doping dependence of the thermopower are obtained by performing the calculations for several additional values of $E_f^0$ and $\Delta_1$.

![FIG. 2: f-electron spectral function $A(\omega)$, calculated by the NCA, plotted as a function frequency for several temperatures, as indicated in the figure. The data show the results for an Yb ground state doublet at $E_f^0 = 1.0$ eV, an excited quartet at $E_f^0 + \Delta_1$, and a doublet at $E_f^0 + \Delta_2$, where $\Delta_1 = 0.06$ eV and $\Delta_2 = 1.06$ eV. The hybridisation strength $\Gamma = 0.12$ eV and the conduction band halfwidth is 4 eV. Inset: the low-frequency part of the spectral functions.](image)

### A. Spectral function

The spectral function, $A(\omega)$, of an Yb 4$f$-hole is shown in Fig.2 as a function of frequency and for several temperatures. This spectral function describes the hole-like excitations and exhibits at low temperatures a Kondo resonance centred slightly below the chemical potential. In the NCA calculations, the Kondo scale of the model is provided by the distance of the centre of the resonance from the chemical potential. At low temperatures and for the model with the CEF splitting, this distance is exponentially reduced with respect to the Kondo scale of an 8-fold degenerate model with the same coupling constant. The spectral function exhibits additional low-energy resonances which are shifted by $\pm \Delta_1$ from the chemical potential. These resonances are due to the exchange scattering of conduction electrons on the excited CEF quartet. The weak resonance at about $\omega \approx 0.95$ eV is due to the single particle excitations and its position is determined by $E_f^0$. (The small downward shift with respect to the input value is caused by enforcing the charge neutrality condition.) The weak resonance at $\omega \approx -1.1$ eV is also a many-body effect due to the highest CEF doublet. The inset in the upper panel of Fig. 2 shows the temperature dependence of the low-energy spectral weight. The low-energy peaks due to the CEF excitations are well resolved for $T \leq \Delta_1/3$ but for $T > \Delta_1$ only a single Kondo resonance remains (blue curve). This resonance characterizes an 8-fold degenerate $f$-hole and if we take its distance from the chemical potential as an estimate of the Kondo scale, the values are consistent with the results obtained by the the NCA for an octet. Thus, the spectral function indicates clearly the high-temperature crossover from an 8-fold degenerate to a 2-fold degenerate LM regime and, eventually,
The temperature dependence of $S(T)$ is shown for several values of $E_f^0$, as indicated in the figure. The other parameters are the same as in Fig. 2. The reduction of $E_f^0$ increases $T_K$, so that the low-temperature minimum of $S(T)$ (indicated by the dashed arrows) moves to higher temperatures. The effect on the high-temperature minimum (indicated by the arrows) is just the opposite: the break-down of the high degenerate LM regime occurs at slightly lower temperatures.

the low-temperature crossover from the LM to the FL regime.

B. Thermopower

The same crossovers are revealed by the temperature dependence of the thermopower, as shown in Fig. 3 for several positions of the ground state doublet and with other parameters the same as in Fig. 2. The reduction of $E_f^0$ increases $T_K$, so that the low-temperature minimum of $S(T)$ (indicated by the arrows) moves to higher temperatures. However, we cannot reach that regime by our NCA solution. For weak coupling, the temperature at which $S(T)$ changes sign provides an estimate of $T_K$. This temperature agrees with the Kondo scale inferred from the maximum of the spectral function. For larger coupling, the low-temperature thermopower doesn’t change sign and we obtain an order of magnitude estimate the Kondo scale of the effective doublet by using of $T_K \sim T_0$. However, for $T < T_{min}$, the thermopower changes sign at high temperatures, such that $T < T_K$, the thermopower should follow the Fermi liquid law, $S(T) \sim -T/T_K$. However, we cannot reach that regime by our NCA solution. For weak coupling, the temperature at which $S(T)$ changes sign provides an estimate of $T_K$. This temperature agrees with the Kondo scale inferred from the maximum of the spectral function. For larger coupling, the low-temperature thermopower doesn’t change sign and we obtain an order of magnitude estimate the Kondo scale of the effective doublet by using of $T_K \sim T_0$.

If $E_f$ is reduced sufficiently, the exchange coupling becomes such that $T_K^N \sim T_0$. The CEF splitting is found in the systems with large Kondo scale. For a given CEF splitting, a reduction of $E_f$ (an increase of the coupling constant) increases $T_0$ and reduces $T_{min}$, so that the separation between the thermopower minima decreases and the double-well shape of $S(T)$ becomes less pronounced. As shown in Ref. [6], for small enough $E_f$, the thermopower minima coalesce and, eventually, a single broad minimum emerges.

The non-monotonic behaviour of $S(T)$ revealed by the numerical solution of the NCA equations is explained by the scaling theory discussed in the previous section. Since the parameters in the NCA calculations yield $T_K \ll T_K^N \ll T_\Delta$, the system has more than one LM regime and the thermopower shown in Figs. 3 and 4 exhibits two minima. At very high temperatures, where all the states are thermally occupied, the system is fully-degenerate, so that the CEF splitting can be neglected and $S(T)$ is a logarithmic function. For $T < T_\Delta$, the excited CEF states depopulate and the effective degeneracy of the f-level starts decreasing. The thermopower minimum at $T_{min} \sim T_\Delta \gg T_K^N$ indicates the collapse of the highly-degenerate LM regime and the crossover to the low-temperature LM regime. The shift of $T_{min}$ with $E_f$, which can be seen in Fig. 3, is also explained by scaling. For a given CEF splitting, an increase of the exchange coupling enhances the Kondo scale, so that the quantum fluctuations diminish the crystal field effects and make the $f$-state appear fully-degenerate at lower temperature. For larger exchange coupling (at constant $\Delta$), the collapse of the $N$-fold degenerate LM state occurs at lower temperature.

In the crossover region, $T < T_{min}$, the thermopower increases until the low-temperature LM state is stabilised, as indicated by the maximum of $S(T)$ at $T_{max}$. The value of $S(T)$ around $T_{max}$ is negative for small $E_f$ (large coupling) and positive for large enough $E_f$ (small coupling). For $T < T_{max}$, the thermopower behaves as expected of a 2-fold degenerate $f$-hole: it decreases logarithmically towards the low-temperature minimum at $T_0$. This minimum, signifies the collapse of the 2-fold degenerate LM state and the crossover into the FL regime; it is visible in Fig. 3 for $E_f^0 \leq 1.0$, while for $E_f^0 > 1.0$, our numerical procedure becomes unstable before we can reach $T_0$. At lowest temperatures, such that $T \ll T_K$, the thermopower minimas can be minimum. For $T < T_{min}$, the thermopower changes sign at high temperatures (indicated by the arrows) and the CEF splitting is found in the systems with large Kondo scale. For a given CEF splitting, a reduction of $E_f$ (an increase of the coupling constant) increases $T_0$ and reduces $T_{min}$, so that the separation between the thermopower minima decreases and the double-well shape of $S(T)$ becomes less pronounced. As shown in Ref. [6], for small enough $E_f$, the thermopower minima coalesce and, eventually, a single broad minimum emerges.

The non-monotonic behaviour of $S(T)$ revealed by the numerical solution of the NCA equations is explained by the scaling theory discussed in the previous section. Since the parameters in the NCA calculations yield $T_K \ll T_K^N \ll T_\Delta$, the system has more than one LM regime and the thermopower shown in Figs. 3 and 4 exhibits two minima. At very high temperatures, where all the states are thermally occupied, the system is fully-degenerate, so that the CEF splitting can be neglected and $S(T)$ is a logarithmic function. For $T < T_\Delta$, the excited CEF states depopulate and the effective degeneracy of the f-level starts decreasing. The thermopower minimum at $T_{min} \sim T_\Delta \gg T_K^N$ indicates the collapse of the highly-degenerate LM regime and the crossover to the low-temperature LM regime. The shift of $T_{min}$ with $E_f$, which can be seen in Fig. 3, is also explained by scaling. For a given CEF splitting, an increase of the exchange coupling enhances the Kondo scale, so that the quantum fluctuations diminish the crystal field effects and make the f-state appear fully-degenerate at lower temperature. For larger exchange coupling (at constant $\Delta$), the collapse of the $N$-fold degenerate LM state occurs at lower temperature.

In the crossover region, $T < T_{min}$, the thermopower increases until the low-temperature LM state is stabilised, as indicated by the maximum of $S(T)$ at $T_{max}$. The value of $S(T)$ around $T_{max}$ is negative for small $E_f$ (large coupling) and positive for large enough $E_f$ (small coupling). For $T < T_{max}$, the thermopower changes sign at high temperatures, such that $T < T_K$, the thermopower should follow the Fermi liquid law, $S(T) \sim -T/T_K$. However, we cannot reach that regime by our NCA solution. For weak coupling, the temperature at which $S(T)$ changes sign provides an estimate of $T_K$. This temperature agrees with the Kondo scale inferred from the maximum of the spectral function. For larger coupling, the low-temperature thermopower doesn’t change sign and we obtain an order of magnitude estimate the Kondo scale of the effective doublet by using of $T_K \sim T_0$.

If $E_f$ is reduced sufficiently, the exchange coupling becomes such that $T_K^N \sim T_\Delta$, and quantum fluctuations render the CEF splitting irrelevant, i.e., the system becomes effectively $N$-fold degenerate. In that case, the NCA calculations yield the thermopower with a single negative minimum and with an $N$-dependent shape. For large degeneracy, $N \gg 1$, the thermopower is always negative and its high-temperature slope is very small; the minimum of $S(T)$ is not very pronounced and the value of $T_{min}$ is unrelated to $T_K^N$. When degeneracy is reduced, $N \leq 6$, the thermopower changes sign at high enough temperatures and the minimum is better pronounced. For $N=2$, temperature at which $S(T)$ changes sign or temperature at which $S(T)$ has minimum can be simply related to the Kondo scale of the model.

The variation of $S(T)$ due to the change of the CEF splitting is presented in Fig. 4. The data show that a decrease of $\Delta$, with other parameters being fixed, shifts $T_{min}$ to lower and $T_0$ to higher values. This is consistent
with the scaling analysis which shows that the reduction of $\Delta$ has a two-fold effect: i) it reduces temperature at which the population of the excited CEF states changes, thereby decreasing $T_{\text{min}}$, ii) it enhances the Kondo scale of the effective doublet, so that $T_0$ increases. (For an effective doublet, $T_0$ is proportional to $T_K$.) On the other hand, an increase of $E_f$, with other parameters being fixed, has the opposite effect. It reduces the exchange coupling and shifts $T_K$ and $T_0$ to lower values. But the effect of quantum fluctuations is now also reduced, so that higher temperature is needed in order to populate the excited CEF states, i.e., $T_{\text{min}}$ increases.

If an application of chemical pressure reduces simultaneously the CEF splitting and the exchange coupling (by increasing $E_f$), the position of $T_{\text{min}}$ doesn’t change much, while $T_0$ is shifted to lower temperatures. (Compare the data obtained for $E_f=1.0, \Delta=0.06$ (black diamonds) and $E_f=1.1, \Delta=0.05$ (red circles), showing that in both cases $T_{\text{min}}$ is nearly the same, while $T_0$ is shifted a lot.

VI. COMPARISON OF THE THEORY AND EXPERIMENT

The solution of the single impurity Anderson model presented in the previous sections captures all the essential features of the thermopower of Yb(Rh$_{1-x}$Co$_x$)$_2$Si$_2$ intermetallic compounds. As mentioned already, the substitution of rhodium by cobalt increases chemical pressure which has a two-fold effect: i) the 4$f$ level moves further away from the chemical potential so that the exchange coupling and the Kondo scale are reduced; ii) the CEF splitting decreases, which reduces the temperature at which thermal fluctuations change the effective degeneracy of the 4$f$ states. Since the Kondo scale depends exponential on the exchange coupling, while the CEF splitting is assumed to be linear in cobalt concentration, the ratio $T_K/\Delta$ is a highly non-linear function of doping. As a consequence, the cobalt substitution has a large impact on the properties of the system: an increase of cobalt concentration brings us from the regime where $T_K/\Delta \simeq 1$ and $S(T)$ has a single minimum to the regime where $T_K/\Delta \ll 1$, and $S(T)$ has two minima.

At high cobalt concentration, $1 \geq x \geq 0.68$, the experimental data are described by the model with the input parameters such that $T_K \ll T_K^N \ll \Delta$. The corresponding thermopower exhibits a negative minimum at temperature $T_0 < 10$ K, in accord with the experiment. This low-temperature minimum indicates the crossover from a non-degenerate Fermi liquid to a 2-fold degenerate LM with Kondo scale $T_K$. As temperature increases above $T_0$, i.e., $T > T_K$, the thermopower becomes less negative and, for $x \simeq 1$ it even becomes positive. Note, the model describing the compound with $x \simeq 1$ has the highest value of $E_f$ (the lowest coupling) and the lowest value of $\Delta$. A further increase of temperature brings $S(T)$ to its maximum, where $S(T)$ is positive when $x \simeq 1$ and negative when $x < 1$. This maximum signifies the collapse of the 2-fold degenerate regime and the onset of a broad crossover to the high-temperature regime, where the excited CF states are occupied. The lower the cobalt concentration, the higher the values of $T_0$ and temperature at which $S(T)$ changes sign. (The sign-change occurs somewhere between $T_0$ and $T_{\max}$.) The change of $T_0$, and $T_{\max}$ induced by the cobalt doping agrees with the theoretical results obtained for smaller $E_f$, i.e., for larger $T_K$.

The crossover region terminates at temperature $T_{\text{min}}$, where $S(T)$ has a deep (negative) minimum. For $T > T_{\text{min}}$, the $f$-state is effectively $N$-fold degenerate and the Kondo scale is $T_K^N$. Here, the slope of the thermopower is positive, so that $S(T)$ can change sign at high enough temperature. Unlike the minimum at $T_0$, which is related to $T_K$, the minimum at $T_{\text{min}}$ is caused by an interplay of quantum and thermal fluctuations and it cannot be explained by taking only $T_K^N$ or $\Delta$ into account. Since quantum fluctuations (Kondo effect) and thermal fluctuations (population of the excited CEF states) shift $T_{\text{min}}$ in the opposite directions, a reduction of cobalt concentration (a simultaneous increase of $T_K^N$ and $\Delta$) doesn’t necessarily lead to the change of $T_{\text{min}}$. This feature, seen in Fig. 4(b) agrees with the experimental data which show (see Fig. 4(a)) that cobalt doping changes the width of the crossover region, $T_{\text{min}} - T_{\max}$ by shifting $T_{\max}$ but not $T_{\text{min}}$. (Compare the data set with $E_f=1.1, \Delta=0.05$ (red circles) and the data set $E_f=1.1, \Delta=0.05$ (black diamonds) which show that $T_0$ and $T_{\max}$ increase, while $T_{\text{min}}$ doesn’t change as we reduce $E_f$ and increase $\Delta$.)

At intermediate concentrations, $0.68 > x > 0.195$, the experimental data are explained by the model in which the parameters are such that the exchange coupling and the CEF splitting are further increased with respect to the $x \simeq 1$ case. The enhanced quantum fluctuations increase $T_0$ and $T_{\max}$, and make the thermopower at $T_{\text{min}}$
more negative than for higher cobalt concentration. We now have $T_K < T_K^N$ and $T_K^N \approx T_K$. For low enough $x$ (smaller $E_f$ and larger $\Delta$), the value of $T_{\text{min}}$ is pushed up, the maximum of $S(T)$ is suppressed, and the double-well shape of $S(T)$ is transformed into a single minimum with a shoulder on the low-temperature side.

For $x < 0.195$, the coupling constant is assumed to be so large that quantum fluctuations dominate over the thermal fluctuations and the CF splittings cease to play any role. The $f$-state behaves as an effective octet with Kondo scale $T_K^N$ and in order to remove a huge magnetic entropy at low temperatures, the system makes a crossover from an $N$-fold degenerate LM state to a non-degenerate FL ground state. The thermopower exhibits a single minimum but, since $N$ is large, $T_{\text{min}}$ and $T_K^N$ are not simply related. An increase of the exchange coupling, at constant $N$, enhances the Kondo scale and broadens the minimum of $S(T)$; it also reduces the high-temperature slope of $S(T)$, so as to make the minimum of $S(T)$ less pronounced. For $T \gg T_{\text{min}}$, the thermopower changes sign, except at lowest cobalt concentrations, where $S(T)$ always remains negative. Behaviour of this type is seen not just in Yb(Rh$_{1-x}$Co$_x$)$_2$Si$_2$ for low cobalt concentration but also in other Yb systems with large Kondo scale.

VII. CONCLUSIONS AND SUMMARY

The temperature and doping dependence of transport coefficients of Yb(Rh$_{1-x}$Co$_x$)$_2$Si$_2$ series of alloys is explained by an asymmetric Anderson model which takes into account the exchange scattering of conduction electrons on Ytterbium ions and the splitting of the 4$f$-state by the CEF. The substitution of rhodium by cobalt is treated as an increase of chemical pressure which reduces the exchange coupling and the CEF splitting. The model neglects all the details of the band structure, so we do not aim at a quantitative description of the experimental results. However, on a qualitative level, the interplay of the Kondo effect and the CEF splitting captures all the main features of the experimental data on Yb(Rh$_{1-x}$Co$_x$)$_2$Si$_2$ intermetallic compounds.

The scaling analysis and numerical solutions of the NCA equations show that the effective degeneracy of the 4$f$-state at a given temperature depends on the relative importance of quantum fluctuations, driven by the exchange scattering, and thermal fluctuations which populate the excited CEF states. The properties of the system crucially depend on the ratio $T_K/\Delta$, where $T_K$ is an exponential function of the exchange coupling. Since the CEF splitting and the exchange coupling are linear in cobalt concentration, the ratio $T_K/\Delta$ is a highly non-linear function of doping. Plotting, in analogy with the Doniach diagram, $T_K$ and $\Delta$ versus chemical pressure yields a phase diagram in which the $T_K \geq \Delta$ region is separated from the $T_K \ll \Delta$ region. The temperature dependence of the response function in these two regions is completely different: in the former, the system makes a single crossover from a highly degenerate LM state to a FL state, while in the later, there are two crossovers. The first one, from the highly degenerate to the 2-fold degenerate LM regime and the second one, from the LM to the FL regime. Thus, the evolution of thermopower across the Yb(Rh$_{1-x}$Co$_x$)$_2$Si$_2$ series of alloys can be understood as an interplay of quantum and thermal fluctuations.
