.....
We investigate double Λ hyperfragment formation from the statistical decay of double Λ compound nuclei produced in the Ξ^- absorption at rest in light nuclei, ^{12}C , ^{14}N and ^{16}O . We examine the target and the $\Lambda\Lambda$ bond energy dependence of the double Λ hyperfragment formation probabilities, especially of those double hypernuclei observed in experiments. For the ^{12}C (^{14}N) target, the formation probabilities of ${}_{\Lambda\Lambda}^6\text{He}$ and ${}_{\Lambda\Lambda}^{10}\text{Be}$ (${}_{\Lambda\Lambda}^{13}\text{B}$) are found to be reasonably large as they are observed in the KEK-E373 (KEK-E176) experiment. By comparison, for ^{16}O target, the formation probability of ${}_{\Lambda\Lambda}^{11}\text{Be}$ is calculated to be small with $\Delta B_{\Lambda\Lambda}$ consistent with the Nagara event. We also evaluate the formation probability of ${}_{\Lambda\Lambda}^5\text{H}$ from a Ξ^- - ${}^6\text{He}$ bound state, ${}_{\Xi}^7\text{H}$.

1. Introduction

Formation of double Λ hypernuclei (D Λ HN) from Ξ^- absorption in nuclei is of importance in several aspects. The Ξ^- absorption at rest in nuclei is the most efficient way to produce D Λ HN, and uniquely identified D Λ HN [1–5] provide strong constraints on the $\Lambda\Lambda$ interaction [6, 7]. The strength and density dependence of the $\Lambda\Lambda$ interaction are the keys to solve the hyperon puzzle in neutron star physics. Until now, four D Λ HN formation events have been uniquely identified, and more will be found in the J-PARC-E07 experiment, where 10^4 Ξ^- absorption events in nuclei are expected to be observed. Let us comment on these points in order.

The baryon-baryon interaction has been one of the central subjects in nuclear physics. Compared with the nucleon-nucleon interaction, hyperon-nucleon scattering data are much more scarce and single Λ hypernuclear data are also used to constrain the ΛN interaction. For the $\Lambda\Lambda$ interaction, there are theoretical predictions in the meson exchange model [8], the quark cluster model [9], and the lattice QCD calculations [10]. Experimentally, by comparison, it is not possible to perform scattering experiments, and hence the binding energies of D Λ HN [1–5] and the correlation function data from high-energy nuclear collisions [11, 12] have been utilized to experimentally constrain the $\Lambda\Lambda$ interaction. While

[†]Report number: YITP-19-105

the correlation function technique is recently applied to get knowledge on several hadron-hadron interactions [11], we need further theoretical and experimental studies to constrain interactions precisely [12]. At present, the strongest constraint on the $\Lambda\Lambda$ interaction is provided by the $\Lambda\Lambda$ bond energy of the DAHN, ${}_{\Lambda\Lambda}^6\text{He}$, observed in the Nagara event [3]. The $\Lambda\Lambda$ bond energy represents the strength of the $\Lambda\Lambda$ interaction, and is defined as $\Delta B_{\Lambda\Lambda} \equiv S_{\Lambda\Lambda}({}_{\Lambda\Lambda}^AZ) - 2S_{\Lambda}({}^{A-1}_{\Lambda}Z)$, where $S_{\Lambda\Lambda}$ and S_{Λ} are the separation (binding) energies of $\Lambda\Lambda$ and Λ . The bond energy of ${}_{\Lambda\Lambda}^6\text{He}$ is found to be $\Delta B_{\Lambda\Lambda}({}_{\Lambda\Lambda}^6\text{He}) = 0.67 \pm 0.12$ MeV [4]. This bond energy can be fitted by a $\Lambda\Lambda$ interaction with the low-energy scattering parameters of $(a_0, r_{\text{eff}}) = (-0.44 \text{ fm}, 10.1 \text{ fm})$ [6], where a_0 and r_{eff} are the scattering length and the effective range, respectively.

The $\Lambda\Lambda$ interaction plays a crucial role also in neutron star physics. With most of the well-known attractive ΛN two-body interactions, Λ hyperon mixing is calculated to take place in neutron star matter at $(2 - 4)\rho_0$ and the equation of state (EOS) is softened [13]. Consequently it is hard to support massive neutron stars with masses around two solar mass [14]. In order to solve this problem, known as the hyperon puzzle, several mechanisms have been proposed so far. One of the natural ways is to introduce repulsive three-baryon interactions [15, 16]. For example, it is possible to support massive neutron stars by introducing repulsive three-body contact couplings in RMF models [16]. It should be noted that the three-baryon repulsion needs to operate also among $\Lambda\Lambda N$ and $\Lambda\Lambda\Lambda$. Otherwise Λ matter becomes more stable than nuclear matter with hyperon mixing at high densities. The $\Lambda\Lambda N$ three-baryon interaction will cause effective density-dependent $\Lambda\Lambda$ and ΛN interactions in nuclear matter. If we can observe and uniquely identify many DAHN in a wide mass region, it would be possible to deduce the density dependence of the $\Lambda\Lambda$ interaction and the underlying $\Lambda\Lambda N$ three-baryon interaction.

The most efficient reaction to form DAHN is the Ξ^- absorption at rest in nuclei. DAHN formation proceeds in the following steps. First Ξ^- particles are produced in the (K^-, K^+) reactions on nuclei or protons [1–5] or \bar{p} -nucleus collisions [17]. The produced Ξ^- particle is absorbed in a nucleus, and converted to two Λ particles via the $\Xi^- p \rightarrow \Lambda\Lambda$ reaction in the nucleus. If two Λ s are trapped in the nucleus in the preequilibrium stage, a double Λ compound nucleus (DAC) is formed [18]. The compound nucleus deexcite by emitting nucleons, Λ s, α s and other clusters. When these two Λ particles occasionally stay in the same fragment with an excitation energy below the particle emission threshold, a DAHN is formed. When the sequential weak decay of the DAHN is observed, one can identify that a $S = -2$ nucleus is formed. It is also expected to produce and detect DAHN in heavy-ion collisions [19], while there is no clear evidence of DAHN formation in these reactions yet.

Until now, several experiments have been performed to find DAHN, and four of them have been uniquely identified from Ξ^- absorption in nuclei as summarized in Table 1 [1–4]; ${}_{\Lambda\Lambda}^{10}\text{Be}$ from $\Xi^- + {}^{12}\text{C}$ reaction at CERN [1], ${}_{\Lambda\Lambda}^{13}\text{B}$ from $\Xi^- + {}^{14}\text{N}$ in KEK-E176 experiment [2], ${}_{\Lambda\Lambda}^6\text{He}$ from $\Xi^- + {}^{12}\text{C}$ (Nagara event) [3] and ${}_{\Lambda\Lambda}^{10}\text{Be}^*$ from $\Xi^- + {}^{12}\text{C}$ (Demachi-Yanagi event) [4] in KEK-E373 experiment. Another report on ${}_{\Lambda\Lambda}^6\text{He}$ [20] was questioned [21] and found to be not consistent with the Nagara event [3, 4]. It should be noted that the identifications of the above four DAHN rely on the consistency between the events. For example, $B_{\Lambda\Lambda}$ values of ${}_{\Lambda\Lambda}^{10}\text{Be}$ in Refs. [1] and [4] can be consistent by assuming the channel of ${}_{\Lambda\Lambda}^{10}\text{Be} \rightarrow {}^9_{\Lambda}\text{Be}^* + p + \pi^-$ in the weak decay in the event of Ref. [1] and the formation of the excited state ${}_{\Lambda\Lambda}^{10}\text{Be}^*$ in the Demachi-Yanagi event [4]. In order to further observe DAHN, the J-PARC-E07 experiment

Table 1 Uniquely identified double Λ hypernuclear formation events [1–4]. We also show the possible formation channels in the Mino event, a new event observed in the J-PARC E07 experiment [5].

Experiment	Reaction	$\Delta B_{\Lambda\Lambda}$ (MeV)	Ref.
CERN	$\Xi^- + {}^{12}\text{C} \rightarrow {}_{\Lambda\Lambda}^{10}\text{Be} + d + n$	1.3 ± 0.4	[1]
KEK-E176	$\Xi^- + {}^{14}\text{N} \rightarrow {}_{\Lambda\Lambda}^{13}\text{B} + p + n$	0.6 ± 0.8	[2]
Nagara	$\Xi^- + {}^{12}\text{C} \rightarrow {}_{\Lambda\Lambda}^6\text{He} + \alpha + t$	0.67 ± 0.17	[3, 4]
Demachi-Yanagi	$\Xi^- + {}^{12}\text{C} \rightarrow {}_{\Lambda\Lambda}^{10}\text{Be}^* + d + n$	-1.52 ± 0.15	[4]
Mino	$\Xi^- + {}^{16}\text{O} \rightarrow {}_{\Lambda\Lambda}^{10}\text{Be} + \alpha + t$	1.63 ± 0.14	[5]
	$\Xi^- + {}^{16}\text{O} \rightarrow {}_{\Lambda\Lambda}^{11}\text{Be} + \alpha + d$	1.87 ± 0.37	
	$\Xi^- + {}^{16}\text{O} \rightarrow {}_{\Lambda\Lambda}^{12}\text{Be}^* + \alpha + p$	-2.7 ± 1.0	

has been carried out. While the analysis is still on-going, a new DAHN formation event is discovered recently, ${}_{\Lambda\Lambda}\text{Be}$ from $\Xi^- + {}^{16}\text{O}$ (Mino event) [5]. We summarize the uniquely identified DAHN events in Table 1. We also show the candidate fragmentation reactions in the Mino event.

Since further events are expected to be observed from the J-PARC-E07 and future experiments, it would be possible to perform statistical analysis of fragment formation events from Ξ^- absorption at rest in light nuclei. Statistical decay of DAC was studied by using a canonical fragmentation model [22], a sequential binary statistical decay model [23], and a microcanonical fragmentation model [24]. We also note that the Ξ^- absorption reaction in ${}^{12}\text{C}$ was analyzed by using the direct reaction model in Ref. [25]. In Ref. [23], the Ξ^- absorption reaction in ${}^{12}\text{C}$ was analyzed in a combined framework of a transport model and a statistical decay model of hypernuclei. The formation probability of the DAC (${}_{\Lambda\Lambda}^{13}\text{B}^*$) was evaluated to be around 30% in the preequilibrium stage by using the antisymmetrized molecular dynamics (AMD) transport model calculation [23], and the total DAHN formation probability was found to be around 18% after the statistical decay. This analysis was performed before the discovery of the Nagara event [3], and a strongly attractive $\Lambda\Lambda$ interaction was adopted, $\Delta B_{\Lambda\Lambda}({}_{\Lambda\Lambda}^{13}\text{B}) = 4.9$ MeV, as suggested by the KEK-E176 experiment [2]. After the Nagara event, the KEK-E176 event was reinterpreted and the $\Lambda\Lambda$ bond energy is now considered to be $\Delta B_{\Lambda\Lambda}({}_{\Lambda\Lambda}^{13}\text{B}) = 0.6 \pm 0.8$ MeV. With these updated less attractive $\Lambda\Lambda$ interaction, it would be possible to predict the DAHN formation probabilities in a more reliable manner.

In this article, we discuss the formation of DAHN from the statistical decay of DAC formed via the Ξ^- absorption at rest in nuclei. Specifically, we concentrate on the target nuclei ${}^{12}\text{C}$, ${}^{14}\text{N}$ and ${}^{16}\text{O}$. These are the main light component of emulsion, and some DAHN have been reported to be formed. We mainly discuss the formation probabilities ${}_{\Lambda\Lambda}^6\text{He}$ and ${}_{\Lambda\Lambda}^{10}\text{Be}$ from $\Xi^- + {}^{12}\text{C}$, ${}_{\Lambda\Lambda}^{13}\text{B}$ from $\Xi^- + {}^{14}\text{N}$, and ${}_{\Lambda\Lambda}^{11}\text{Be}$ from $\Xi^- + {}^{16}\text{O}$. We also discuss the dependence of the formation probabilities on the $\Lambda\Lambda$ bond energy, and the decay of Ξ hypernucleus formed in the ${}^7\text{Li}(K^-, K^+)$ reaction.

This paper is organized as follows. In Sec. 2, we provide a general idea of statistical decay of compound hypernuclei. In Sec. 3, we evaluate DAHN formation probabilities from

Ξ absorption reaction at rest in ^{12}C , ^{14}N and ^{16}O . In Sec. 4, we discuss ${}_{\Lambda\Lambda}^5\text{H}$ formation probability from $\Xi^- - {}^6\text{He}$ bound state at various values of the Ξ^- binding energy. Summary and discussion are given in Sec. 5.

2. Statistical decay of double Λ compound nuclei and hypernuclear binding energies

In this paper, the statistical decay of DAC is calculated by using a sequential binary statistical decay model (SDM) [26]. In SDM, an excited nucleus 1 is assumed to decay to nuclei 2 and 3 with the decay rate of

$$\Gamma_{1\rightarrow 23}dE_2dE_3 = \frac{\rho_2(E_2, J_2)\rho_3(E_3, J_3)}{2\pi\rho_1(E_1, J_1)} \sum_{L, J_{23}} T_L dE_2 dE_3, \quad (1)$$

where E_i and J_i denote the excitation energy and the angular momentum of the i -th nucleus. We adopt the back-shifted Fermi gas model to evaluate the level density $\rho_i(E_i, J_i)$ [27]. The factor $T_L = \Theta(L_c - L)$ is the transmission coefficient of the partial wave L in the fusion reaction $2 + 3 \rightarrow 1$ with the incident energy corresponding to the excitation energies and the Q -value. We assume the strong absorption in the inverse fusion process $2 + 3 \rightarrow 1$, and take the form $T_L = \Theta(L_c - L)$ with L_c being the maximum orbital angular momentum of the fusion. Statistical decays are assumed to be binary and to proceed until all the fragments are in their ground states. The SDM has been found to work well also for hypernuclear formation reactions when combined with the transport models describing the preequilibrium stage [23, 28, 29].

The essential inputs of SDM is the binding energies of nuclei, which would be formed during the sequential decay processes. While the binding energies of normal nuclei are well known, information on single and double hypernuclear binding energies is limited. Then we have constructed the mass table based on the following assumptions. First, all existing normal nuclei plus Λ and $\Lambda\Lambda$ are assumed to form single and double hypernuclei, respectively. Normal nuclei include those whose ground states are resonance and unstable to particle emission. We also consider dineutron (nn) and ${}^2\text{He}$ (pp) as resonance nuclei, and their energies are assumed to be 100 keV above the threshold, in order to mimic three-body decays. Second, for single hypernuclei, we adopt the separation energy if measured. We use the separation energy data summarized by Bando et al. (BMZ) [30] and by Hashimoto and Tamura (HT) [31]. We add 0.5 MeV to the separation energies measured in (π^+ , K^+) experiments [31] to take account of the recalibration as shown in Ref. [32]. If not measured, we adopt the Λ separation energy S_Λ , parameterized as a function of the mass number and fitted to the observed separation energies,

$$S_\Lambda = \frac{c_0(A-1)}{A} \frac{1 - c_1x}{1 + c_2x + c_3x^2}, \quad (2)$$

where A denotes the hypernuclear mass number and $x = 1/(A-1)^{2/3}$. By fitting to the BMZ and HT data, we determined the parameters of $c_0 = 30.18$ MeV, $c_1 = 1.52$, $c_2 = 3.17$ and $c_3 = 4.38$. Results of the fit is shown in Fig. 1. Thirdly, for DAHN, the $\Lambda\Lambda$ bond energy is given as a linear function of the mass number. We compare the results of the three models, $\Delta B_{\Lambda\Lambda} = 4.9$ MeV (model A), $\Delta B_{\Lambda\Lambda} = 0.67$ MeV (model B), and $\Delta B_{\Lambda\Lambda}(A=6) = 0.67$ MeV and $\Delta B_{\Lambda\Lambda}(A=11) = 1.87$ MeV (model C). These model parameters are determined by the

old rejected value of $\Delta B_{\Lambda\Lambda}$ from E176 experiment [33] (model A), the Nagara event (model B), and by the Nagara and Mino events (model C).

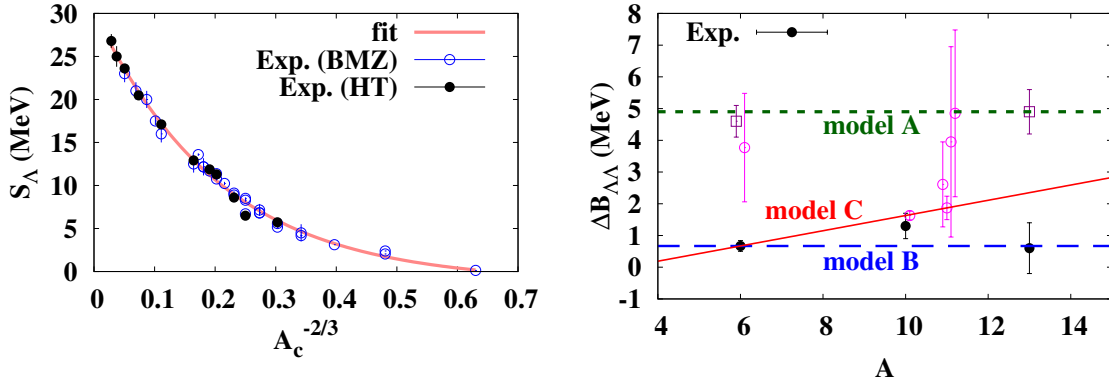

Fig. 1 Left: Separation energy of single hypernuclei. Data summarized in [30] (open circles) and [31] (filled circles) are shown by symbols, and the results of fit is shown by the solid curve. Right: $\Lambda\Lambda$ bond energy of DAHN. Filled circles show the results of uniquely identified ground state $\Lambda\Lambda$ bond energy $\Delta B_{\Lambda\Lambda}$. Dotted, dashed and solid lines show $\Delta B_{\Lambda\Lambda}$ in the models A, B and C, respectively. Open circles and squares show experimental data of $\Delta B_{\Lambda\Lambda}$ without unique identifications and rejected values, respectively.

3. Double hypernuclear formation from Ξ^- absorption in nuclei

We now discuss DAHN formation from Ξ^- absorption reaction at rest in ^{12}C , ^{14}N and ^{16}O . We assume that Ξ^- is absorbed from the $3D$ atomic orbit, so the Ξ^- binding energy is $B = \mu\alpha^2 Z^2 / 2n^2 = 0.126, 0.174$ and 0.230 MeV for ^{12}C , ^{14}N and ^{16}O targets, respectively, where μ is the reduced mass, Z is the atomic number of the target, and $n = 3$ for the $3D$ orbit. A part of the released energy in the conversion process, $M_{\Xi^-} + M_p - 2M_\Lambda = 28.62$ MeV, is used by the separation energy of the proton, 15.96, 7.55 and 12.13 MeV, and thus the energies from the threshold, $^{11}\text{B} + \Lambda\Lambda$, $^{13}\text{C} + \Lambda\Lambda$ and $^{15}\text{N} + \Lambda\Lambda$, are obtained as 12.66, 21.07 and 16.49 MeV, for ^{12}C , ^{14}N and ^{16}O targets, respectively. These energies are summarized in Table 2.

Open channels including DAHN from the Ξ^- absorption reactions are shown in Fig. 2. Many channels including 2-, 3- and 4-body can be populated in the final state. We have performed the statistical decay model calculation from the DAC until all the fragments are deexcited to the ground state. In order to handle variety of decay path, the decay channel, excitation energies and angular momenta of daughter fragments are chosen in the Monte-Carlo method.

In Table 3, we summarize the formation probabilities of DAHN in the SDM calculation from the DAC, $^{13}_{\Lambda\Lambda}\text{B}^*(\Xi^- + ^{12}\text{C})$, $^{15}_{\Lambda\Lambda}\text{C}^*(\Xi^- + ^{14}\text{N})$, and $^{17}_{\Lambda\Lambda}\text{N}^*(\Xi^- + ^{16}\text{O})$. The total DAHN formation probability in SDM is calculated to be (25 – 80)%. If we assume that the DAC formation probability of 30% is common in the three targets, the total DAHN formation probability is (7.5 – 24)%, which is larger than the lower limit of the 2Λ trapping probability (double and twin hypernuclear formation), 4.8% for light nuclei, evaluated by the KEK-E176

Table 2 Relevant energies in stopped Ξ^- absorption reaction at rest in ^{12}C , ^{14}N and ^{16}O . We show the target binding energies (B_T), the proton separation energies (S_p) and the energy from the $\Lambda\Lambda$ emission threshold (E_{th}). We also show the case of the ^6He target, a core nucleus of $^7_{\Xi}\text{H}$, which may be formed in the $^7\text{Li}(K^-, K^+)$ reaction.

Target	B_T (MeV)	S_p (MeV)	E_{th} (MeV)	B_{Ξ} (MeV)
^{12}C	92.165	15.957	12.569 - B_{Ξ}	0.126
^{14}N	76.047	7.551	21.065 - B_{Ξ}	0.174
^{16}O	127.624	12.127	16.489 - B_{Ξ}	0.230
^6He	29.268	23.482	5.137 - B_{Ξ}	0-4

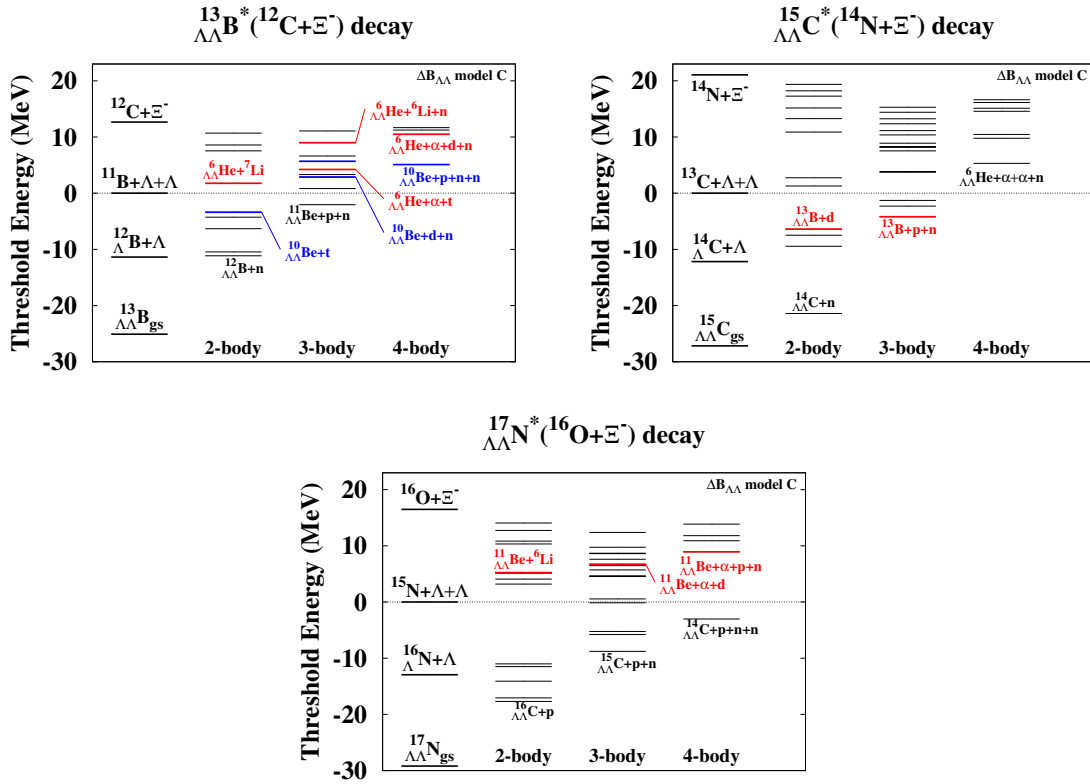

Fig. 2 Open channels including DAHN from Ξ^- absorption in ^{12}C , ^{14}N and ^{16}O .

collaboration [33, 34]. By comparison, the calculated DAHN formation probability is larger than the 2Λ trapping probability captured by light nuclei, $5.0 \pm 1.7\%$ [35]. The small 2Λ trapping probability data may suggest small bond energies as in the Model B.

3.1. Ξ^- absorption in ^{12}C

First we discuss the Ξ^- absorption in ^{12}C , where $^6_{\Lambda\Lambda}\text{He}$ [3] and $^{10}_{\Lambda\Lambda}\text{Be}$ [1, 4] were observed. In Fig. 3, we show the DAHN mass distribution obtained in the SDM calculation of the DAC, $^{13}_{\Lambda\Lambda}\text{B}^*$, assumed to be formed in the Ξ^- absorption in ^{12}C . We find that DAHN with

Table 3 Formation probabilities of DAHN in the statistical decay model from the DAC, ${}_{\Lambda\Lambda}^{13}\text{B}^*(\Xi^- + {}^{12}\text{C})$, ${}_{\Lambda\Lambda}^{15}\text{C}^*(\Xi^- + {}^{14}\text{N})$, and ${}_{\Lambda\Lambda}^{17}\text{N}^*(\Xi^- + {}^{16}\text{O})$. The probabilities are given in %. The "-" symbols show that the DAHN are either unbound, energetically not accessible, or not populated in the Monte-Carlo sampling of the decay paths in the SDM calculation.

$A = 11$ is most frequently formed; (18.9 – 27.1)% for ${}_{\Lambda\Lambda}^{11}\text{Be}$ and (4.3 – 8.7)% for ${}_{\Lambda\Lambda}^{11}\text{B}$. Next frequently formed DAHN is ${}_{\Lambda\Lambda}^{10}\text{Be}$ with the probability of (5.5 – 18.7)%. While the $\Delta B_{\Lambda\Lambda}$ model dependence is not significant for heavier ($A \geq 11$) hypernuclei, small $\Delta B_{\Lambda\Lambda}$ in models B and C suppress formation probabilities of lighter hypernuclei. For example, the formation probability of ${}_{\Lambda\Lambda}^6\text{He}$ is calculated to be 4.3% in model A, while it becomes 1.6% and 1.3% in models B and C, respectively.

In SDM, the formation probability strongly depends on the Q -value and the number of fragments in the final state as shown in Fig. 4. Since the statistical binary decay favors

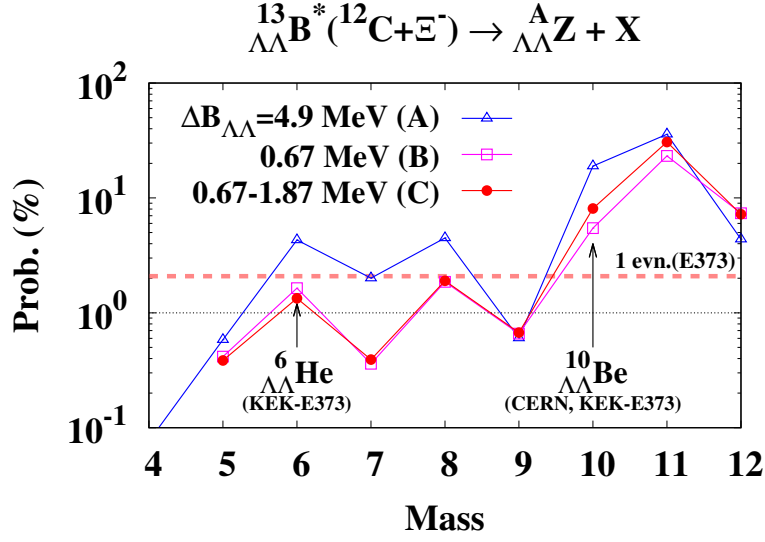

Fig. 3 DAHN mass distribution obtained in the statistical decay model starting from the DAC (${}_{\Lambda\Lambda}^{13}\text{B}^*$) assumed to be formed from the Ξ^- absorption at rest from the $3D$ atomic orbit in ${}^{12}\text{C}$. Results of the model A (triangles), B (squares) and C (circles) for the $\Lambda\Lambda$ bond energy $\Delta B_{\Lambda\Lambda}$ are compared.

Fig. 4 Threshold energy dependence of the event probabilities obtained in SDM from ${}_{\Lambda\Lambda}^{13}\text{B}^* (\Xi^- + {}^{12}\text{C})$. Filled circles, squares and triangle show the event probability in SDM as a function of the threshold energy in 2-body, 3-body and 4-body channels, respectively. Open circles and squares show the channels including ${}_{\Lambda\Lambda}^6\text{He}$ and ${}_{\Lambda\Lambda}^{10}\text{Be}$, respectively.

Table 4 Event probabilities of hypernuclear formation events including ${}_{\Lambda\Lambda}^6\text{He}$ and ${}_{\Lambda\Lambda}^{10}\text{Be}$ from the DAC (${}_{\Lambda\Lambda}^{13}\text{B}^*$) assumed to be formed in the Ξ^- absorption reaction in ${}^{12}\text{C}$. The probabilities are given in %.

decays into excited state having large level densities, two-body decays with large Q -values do not necessarily exhaust the probabilities. The formation and decay of ${}_{\Lambda\Lambda}^6\text{He}$ in the Nagara event [3] have been uniquely identified to take place as

In the formation of ${}_{\Lambda\Lambda}^{10}\text{Be}$ [1], the following sequence was found not to be inconsistent with the Nagara event [36, 37],

These fragmentation branches have relatively large Q -values, 8.4 and 9.8 MeV in the $\Delta B_{\Lambda\Lambda}$ model C, for channels (3) and (4), respectively. As a result, the event probability of the decay channel (3) (the decay channel (4)) in SDM is calculated to be 2.6, 1.0 and 0.9 % (8.8, 3.5 and 5.0 %) in models A, B and C, respectively.

We shall now evaluate the expected number of events in the experiment. In the KEK-E373 experiment, about 10^3 events of Ξ^- absorption in emulsion nuclei are analyzed [4]. About half of the Ξ^- absorption events are those with light nuclei, ${}^{12}\text{C}$, ${}^{14}\text{N}$ and ${}^{16}\text{O}$; therefore it would be reasonable to assume that about 160 events of Ξ^- absorption in ${}^{12}\text{C}$ are analyzed. The formation probability of DAC, ${}_{\Lambda\Lambda}^{13}\text{B}^*$, is about 30% in AMD [23]. Thus the number of decay in a given channel may be given as $160 \times 0.3 \times \text{Br}$ with Br being the branching ratio (event probability). For the fragmentation channel (3) (for the formation of ${}_{\Lambda\Lambda}^6\text{He}$), the estimated number of events in the E373 experiment is 1.2, 0.5 and 0.4 (2.1, 0.8 and 0.6) in models A, B and C, respectively. Since these numbers are close to unity, it is not unreasonable that the KEK-E373 experiment observed one event in the channel of Eq. (3). Since the $\Delta B_{\Lambda\Lambda}$ models B and C are more realistic, we can judge that the KEK-E373 experiment was reasonably lucky provided that the detection efficiency of ${}_{\Lambda\Lambda}^6\text{He}$ is high enough. As for the fragmentation channel (4) (for the formation of ${}_{\Lambda\Lambda}^{10}\text{Be}$), the estimated number of events in the E373 experiment is 4.2, 1.7 and 2.4 (14.1, 6.0 and 8.2) in models A, B and C, respectively. The observation of ${}_{\Lambda\Lambda}^{10}\text{Be}$ in E373 experiment was reasonable, as long as the detection efficiency of the sequential weak decay is not small.

3.2. Ξ^- absorption in ^{14}N

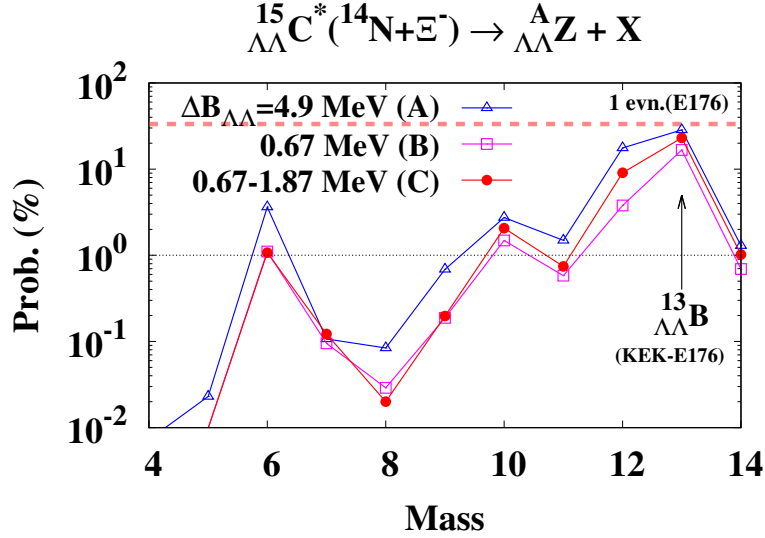

Fig. 5 Double Λ hyperfragment mass distribution in SDM from $^{15}\text{C}^*$ ($\Xi^- + ^{14}\text{N}$).

Next we proceed to discuss the Ξ^- absorption in ^{14}N , where $^{13}_{\Lambda\Lambda}\text{B}$ was observed [2]. In Fig. 5, we show the DAHN mass distribution in SDM calculation of $^{15}\text{C}^*$ from $\Xi^- + ^{14}\text{N}$. As in the case of $\Xi^- + ^{12}\text{C}$, two nucleon evaporation processes are favored, and DAHN with $A = 13$ is most frequently formed; (11.2 – 18.5)% for $^{13}_{\Lambda\Lambda}\text{B}$ and (5.4 – 10.0)% for $^{13}_{\Lambda\Lambda}\text{C}$. We also find $^{12}_{\Lambda\Lambda}\text{B}$ ((3.4 – 16.4)%), $^{10}_{\Lambda\Lambda}\text{Be}$ ((1.4 – 2.6)%), and $^6_{\Lambda\Lambda}\text{He}$ ((1.1 – 3.6)%) are also frequently formed. Since the proton separation energy is smaller and the initial $^{15}_{\Lambda\Lambda}\text{C}^*$ energy is larger for ^{14}N , the $\Delta B_{\Lambda\Lambda}$ model dependence is smaller than other target nuclei.

In the DAHN formation event in E176 [2], the following sequence is found to be consistent with the Nagara event [37],

As shown in Fig. 6, this decay channel is found to have the largest event probability; 17.9, 10.4 and 14.6% (18.5, 11.2 and 15.5%) for the event probability of this channel (formation probability of $^{13}_{\Lambda\Lambda}\text{B}$) in models A, B and C, respectively. In the KEK-E176 experiment, the number of events was estimated to be $77.6 \pm 5.1^{+0.0}_{-12.2}$ for Ξ^- absorption at rest in emulsion [34], and 31.1 ± 4.8 for absorption events on light nuclei [33]. Then we may roughly estimate the number of Ξ^- absorption events on ^{14}N around 10. With the DAC formation probability of around 30 %, the expected number of events in the fragmentation channel in (5) (formation of $^{13}_{\Lambda\Lambda}\text{B}$) is 0.5, 0.3 and 0.4 (0.6, 0.3 and 0.5) in models A, B and C, respectively. We can judge that the KEK-E176 experiment was also reasonably lucky provided that the detection efficiency of sequential weak decay of $^{13}_{\Lambda\Lambda}\text{B}$ is high.

3.3. Ξ^- absorption in ^{16}O

We now discuss the Ξ^- absorption in ^{16}O , where $_{\Lambda\Lambda}\text{Be}$ was reported to be observed [5]. In Fig. 7, we show the DAHN mass distribution in SDM calculation of $^{17}_{\Lambda\Lambda}\text{N}^*$ from $\Xi^- + ^{16}\text{O}$.

Fig. 6 Threshold energy dependence of the event probabilities in SDM from ${}^{15}_{\Lambda\Lambda}C^*$ ($\Xi^- + {}^{14}\text{N}$). Open circles show the channels including ${}^{13}_{\Lambda\Lambda}\text{B}$.

Fig. 7 Double Λ hyperfragment mass distribution in SDM from ${}^{17}_{\Lambda\Lambda}N^*$ ($\Xi^- + {}^{16}\text{O}$).

The most frequently formed DAHN is ${}^{14}_{\Lambda\Lambda}\text{C}$, which is a bound state of ${}^{12}\text{C} + \Lambda + \Lambda$, and the formation probability in SDM is 59.3, 38.5 and 52.8% in models A, B and C, respectively. The next frequently formed one is ${}^{15}_{\Lambda\Lambda}\text{C}$, which is formed via the two nucleon evaporation from ${}^{17}_{\Lambda\Lambda}N^*$. We also find that formation of DAHN with $A = 7$ and 8 is strongly suppressed in the $\Delta B_{\Lambda\Lambda}$ models B and C.

In the J-PARC E07 experiment, it is expected to detect 100 DAHN formation events among 10^4 stopped Ξ^- events. As of November, 2018, 920 Ξ^- absorption events are analyzed [38], and 8 and 6(+2) double and twin hypernuclear formation events are detected. Among them,

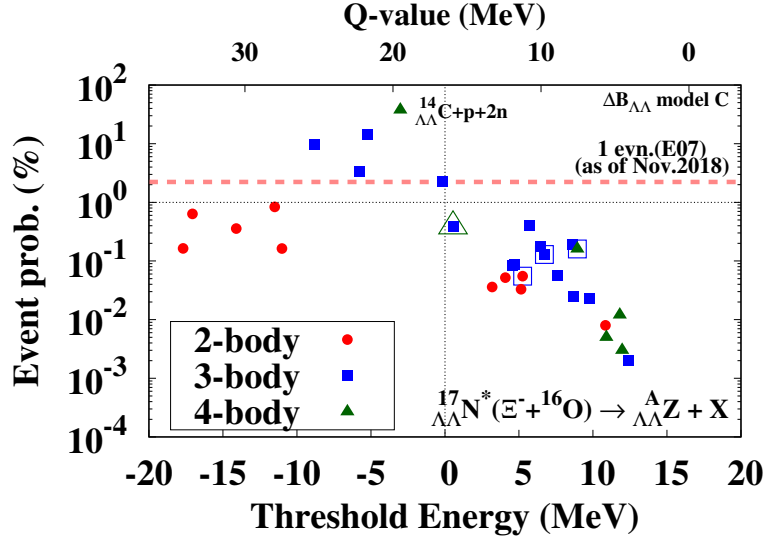

Fig. 8 Threshold energy dependence of the event probabilities in SDM from ${}_{\Lambda\Lambda}^{17}\text{N}^*$ ($\Xi^- + {}^{16}\text{O}$). Open circles, squares and triangles show the channels including ${}_{\Lambda\Lambda}^{10}\text{Be}$, ${}_{\Lambda\Lambda}^{11}\text{Be}$ and ${}_{\Lambda\Lambda}^{12}\text{Be}$, respectively.

Table 5 Event probabilities of hypernuclear formation events including ${}_{\Lambda\Lambda}\text{Be}$ from ${}_{\Lambda\Lambda}^{17}\text{N}^*$ ($\Xi^- + {}^{16}\text{O}$). The probabilities are given in %.

Channel	Prob. (%)		
	A	B	C
$\Delta B_{\Lambda\Lambda}$ model			
${}_{\Lambda\Lambda}^{10}\text{Be} + {}^7\text{Li}$	0.07	0.04	0.03
${}_{\Lambda\Lambda}^{10}\text{Be} + \alpha + t$	0.3	0.04	0.06
${}_{\Lambda\Lambda}^{11}\text{Be} + {}^6\text{Li}$	0.08	0.07	0.06
${}_{\Lambda\Lambda}^{11}\text{Be} + \alpha + d$	0.3	0.09	0.1
${}_{\Lambda\Lambda}^{11}\text{Be} + \alpha + p + n$	0.7	0.01	0.2
${}_{\Lambda\Lambda}^{12}\text{Be} + \alpha + p$	0.6	0.3	0.4

there is one event (Mino event) where the formed DΛHN is identified to be ${}_{\Lambda\Lambda}\text{Be}$ [5]. The event was interpreted as one of the following three candidates,

$$\Xi^- + {}^{16}\text{O} \rightarrow {}_{\Lambda\Lambda}^{10}\text{Be} + \alpha + t \quad (\Delta B_{\Lambda\Lambda} = 1.63 \pm 0.14 \text{ MeV}), \quad (6)$$

$$\Xi^- + {}^{16}\text{O} \rightarrow {}_{\Lambda\Lambda}^{11}\text{Be} + \alpha + d \quad (\Delta B_{\Lambda\Lambda} = 1.87 \pm 0.37 \text{ MeV}), \quad (7)$$

$$\Xi^- + {}^{16}\text{O} \rightarrow {}_{\Lambda\Lambda}^{12}\text{Be}^* + \alpha + p \quad (\Delta B_{\Lambda\Lambda} = -2.7 \pm 1.0 \text{ MeV}). \quad (8)$$

Experimentally, the second candidate (${}_{\Lambda\Lambda}^{11}\text{Be}$ formation) is considered to be most probable, and the ${}_{\Lambda\Lambda}^{11}\text{Be}$ formation probability is reasonably large (1.1%) in SDM with model A, as shown in Table 3. By comparison, ${}_{\Lambda\Lambda}^{11}\text{Be}$ formation is less probable, 0.2 and 0.3%, in the models B and C, respectively. By assuming the number of the Ξ^- absorption events in ${}^{16}\text{O}$ to be around 150 and DAC formation probability of 30%, the expected number in the

second candidate is 0.14, 0.04 and 0.06 for models A, B and C, respectively. In SDM, the third candidate (${}_{\Lambda\Lambda}^{12}\text{Be}^*$ formation) is more probable, the expected number is 0.25, 0.15 and 0.17 for models A, B and C, respectively.

4. Double hypernuclear formation from Ξ^- nucleus

In addition to Ξ^- absorption in nuclei, conversion of Ξ *nuclei* would also make DΛHN. The (K^-, K^+) reactions on nuclear target populate certain Ξ hypernuclear states, which become doorway states to DΛHN. Especially, the ${}^7\text{Li}(K^-, K^+)$ reaction may produce the neutron rich Ξ hypernucleus ${}_{\Xi}^7\text{H} = \Xi^- + {}^6\text{He}$, if exists. Kumagai-Fuse and Akaishi proposed that the branching ratio of ${}_{\Xi}^7\text{H}$ conversion to form ${}_{\Lambda\Lambda}^5\text{H}$ is surprisingly large to be around 90% [39]. The first reason of this large branching ratio is the limited decay channels,

$${}_{\Xi}^7\text{H} \rightarrow {}_{\Lambda\Lambda}^5\text{H} + n + n, {}_{\Lambda}^4\text{H} + \Lambda + n + n, {}_{\Lambda}^4\text{H}^* + \Lambda + n + n, {}^3\text{H} + \Lambda + \Lambda + n + n. \quad (9)$$

if the separation energy of Ξ in ${}_{\Xi}^7\text{H}$ is around 2 MeV or more. In the left panel of Fig. 9, we show the decay channels from ${}_{\Xi}^7\text{H}$. There are two channels, ${}_{\Lambda}^3\text{H} + \Lambda + 3n$ and ${}^2\text{H} + 2\Lambda + 3n$, 1.7 and 1.6 MeV below the $\Xi^- + {}^6\text{He}$ threshold, respectively. If the binding energy of Ξ in ${}_{\Xi}^7\text{H}$ is larger than 1.7 MeV, ${}_{\Xi}^7\text{H}$ does not decay to these channels. The second reason of the large branching ratio is in the small Q -values. Since a large part of the released energy in $p\Xi^- \rightarrow \Lambda\Lambda$ (~ 28.6 MeV) is exhausted in breaking the α cluster in ${}_{\Xi}^7\text{H}$, the threshold energy of $\Xi^- + {}^6\text{He}$ is only 5.1 MeV above the $\Lambda\Lambda$ emitting threshold (${}^5\text{H} + \Lambda + \Lambda$ threshold). This energy difference is much smaller than in the case of Ξ^- absorption in ${}^{12}\text{C}$ (12.7 MeV), ${}^{14}\text{N}$ (21.1 MeV) and ${}^{16}\text{O}$ (16.5 MeV). Furthermore, the binding energy of Ξ^- suppresses the Q -values. The Q -values in the channels shown in Eq. (9) are estimated as $\sim 11, 7, 6$ and 5 MeV, respectively [39]. These Q -values are small and the corresponding "temperatures" are small. Hence the three-body decays would be favored than four-body or five-body decays. As a result, the decay process will be dominated by the ${}_{\Lambda\Lambda}^5\text{H} + 2n$ channel having the largest Q -value and three-bodies in the final state. In Ref. [39], approximate but explicit calculations were performed for the decay process of ${}_{\Xi}^7\text{H}$, and a large branching ratio decaying to ${}_{\Lambda\Lambda}^5\text{H}$ is obtained. Based on this estimate of high branching ratio to form ${}_{\Lambda\Lambda}^5\text{H}$, Fujioka *et al.* proposed a new experiment at J-PARC (P75) [40]. Since the branching ratio is crucial to determine the feasibility of the experiment, it is valuable to evaluate the branching ratio in different approaches.

We shall now discuss the branching ratio of the ${}_{\Lambda\Lambda}^7\text{H}$ decay to ${}_{\Lambda\Lambda}^5\text{H} + 2n$ in SDM described in Sec. 2 and used in Sec. 3 as it is. The $\Delta B_{\Lambda\Lambda}$ model C is applied as an example. There are several differences from Ref. [39]. First, the matrix elements are evaluated statistically as given in Eq. (1), and excited states in the bound as well as unbound energy regions are also taken into account. Second, several other channels are included. As discussed in Sec. 2, nuclei with ground states being resonances are included. These nuclei include ${}^5\text{H}$, ${}_{\Lambda}^5\text{H}$, ${}_{\Lambda}^6\text{H}$ and ${}_{\Lambda\Lambda}^6\text{H}$. By including decay channels containing these nuclei, ${}_{\Lambda\Lambda}^7\text{H}^*$ can decay in sequential binary decay chains, for example ${}_{\Lambda\Lambda}^7\text{H}^* \rightarrow {}_{\Lambda\Lambda}^6\text{H} + n \rightarrow {}_{\Lambda\Lambda}^5\text{H} + n + n$ and ${}_{\Lambda\Lambda}^7\text{H}^* \rightarrow {}_{\Lambda}^6\text{H}^* + \Lambda \rightarrow {}_{\Lambda}^5\text{H} + \Lambda + n \rightarrow {}_{\Lambda}^4\text{H} + \Lambda + n + n$. The third point is the binding energy differences. We adopt the measured and fitted S_{Λ} for single hypernuclei, and the model C is used for $\Delta B_{\Lambda\Lambda}$. The threshold energies of decay channels in the present treatment are shown in the right panel of Fig. 9.

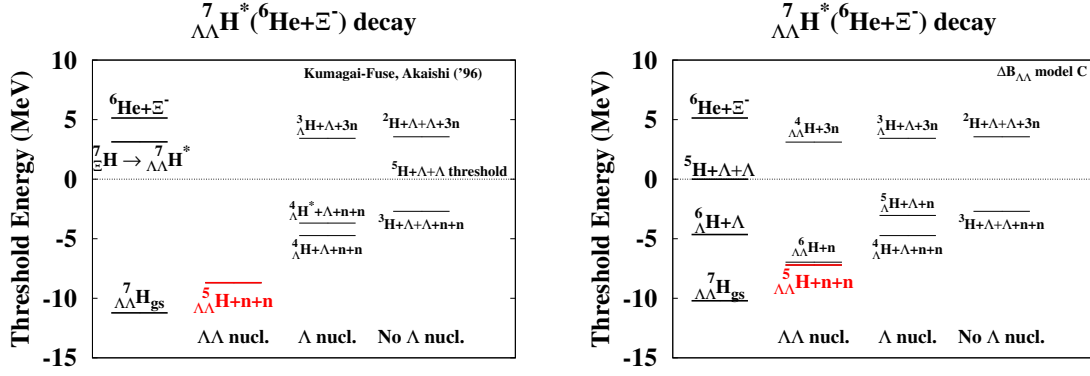

Fig. 9 Open channels including DAHN from ${}^7_{\Xi}H^*$, in Ref. [39] (left) and in the model C (right).

Fig. 10 Branching ratios of ${}^7_{\Lambda\Lambda}H \rightarrow {}^5_{\Lambda\Lambda}H + n + n$ (circles) and ${}^7_{\Lambda\Lambda}H \rightarrow {}^4_{\Lambda}H + \Lambda + n + n$ (triangles) in SDM as functions of the binding energy of Ξ^- in ${}^7_{\Xi}H$. Solid (dotted) lines show the results in the $\Delta B_{\Lambda\Lambda}$ model C with (without) dineutron emission. Dashed lines show the results without considering particle unstable nuclei in the decay processes and with the channels and binding energies used in [39].

In Fig. 10, we show the branching ratios of ${}^7_{\Lambda\Lambda}H \rightarrow {}^5_{\Lambda\Lambda}H + n + n$ ($\text{Br}({}^5_{\Lambda\Lambda}H)$) and ${}^7_{\Lambda\Lambda}H \rightarrow {}^4_{\Lambda}H + \Lambda + n + n$ ($\text{Br}({}^4_{\Lambda}H)$) obtained in the SDM calculation using the $\Delta B_{\Lambda\Lambda}$ model C as functions of the binding energy of Ξ^- in ${}^7_{\Xi}H$ (solid curves). The Ξ^- binding energy in ${}^{15}_{\Xi}C$ was evaluated from the twin hypernuclear formation in the Kiso event, $\Xi^- + {}^{14}N \rightarrow {}^{15}_{\Xi}C \rightarrow {}^{10}_{\Lambda}Be^{(*)} + {}^5_{\Lambda}He$, as $B_{\Xi} = 3.87 \pm 0.21$ MeV or 1.03 ± 0.18 MeV [37, 41]. These two values are for decays to the ground state and the excited state of ${}^{10}_{\Lambda}Be$. The binding energy would be smaller in ${}^7_{\Xi}H$, so the binding energy region of $0 \leq B_{\Xi} \leq 4$ MeV would be enough.

The branching ratio $\text{Br}({}_{\Lambda\Lambda}^5\text{H})$ increases with increasing B_{Ξ} , as expected, and takes values between 43.6% ($B_{\Xi} = 0$) and 57.8% ($B_{\Xi} = 4$ MeV) in the B_{Ξ} region of interest. These values are smaller than those in Ref. [39], but still a large branching ratio around 50% seems to be probable in SDM.

Let us discuss the difference of the branching ratio in the present study and in Ref. [39]. We show the SDM results without dineutron emission by dotted lines in Fig. 10. The model C is used for $\Delta B_{\Lambda\Lambda}$. In this case, ${}_{\Lambda}^6\text{H}(B({}_{\Lambda}^6\text{H}) = 10.44$ MeV) is assumed to decay into ${}_{\Lambda}^4\text{H}(B({}_{\Lambda}^4\text{H}) = 10.52$ MeV) in the final state, while the one neutron emission into ${}_{\Lambda}^5\text{H}(B({}_{\Lambda}^5\text{H}) = 8.83$ MeV) is not allowed energetically. The branching ratio to form ${}_{\Lambda\Lambda}^5\text{H}$ takes $\text{Br}({}_{\Lambda\Lambda}^5\text{H}) = 42.3\%$ ($B_{\Xi} = 0$) and 52.0% ($B_{\Xi} = 4$ MeV). These values are slightly smaller than those with dineutron emission. This is because the direct three-body decay of ${}_{\Lambda\Lambda}^7\text{H}^*$ into ${}_{\Lambda\Lambda}^5\text{H} + 2n$ simulated by dineutron emission is suppressed, while the effect of dineutron emission is not significant and hypernuclear formation is dominated by binary decay sequences such as ${}_{\Lambda\Lambda}^7\text{H}^* \rightarrow {}_{\Lambda\Lambda}^6\text{H}^{(*)} + n \rightarrow {}_{\Lambda\Lambda}^5\text{H} + 2n$ and ${}_{\Lambda\Lambda}^7\text{H}^* \rightarrow {}_{\Lambda}^6\text{H}^{(*)} + \Lambda \rightarrow {}_{\Lambda}^5\text{H} + \Lambda + n$. Since the Q -values are small, it is reasonable to expect that two-body (binary) decays are expected to be favored than three-body or four-body decays. We also show the branching ratios in SDM with the $\Delta B_{\Lambda\Lambda}$ values and channels used in Ref. [39] by dashed lines in Fig. 10. Here we adopt $\Delta B_{\Lambda\Lambda} = 1.92$ MeV and ignore unstable hypernuclei with respect to particle decay, ${}_{\Lambda}^5\text{H}$, ${}_{\Lambda}^6\text{H}$ and ${}_{\Lambda\Lambda}^6\text{H}$, in the decay processes. The branching ratio to ${}_{\Lambda\Lambda}^5\text{H}$ takes larger values than those with particle unstable nuclei, and takes values of $\text{Br}({}_{\Lambda\Lambda}^5\text{H}) = 46.7\%$ ($B_{\Xi} = 0$) and 67.8% ($B_{\Xi} = 4$ MeV). These values are still smaller than those in Ref. [39]. Therefore the larger branching ratio around 90% in Ref. [39] is found to be a result of an explicit evaluation of the transition width in a specific model treatment in addition to the kinematical reasons such as the limited number of decay channels and ignoring particle unstable states during the decay processes. For a more serious estimate, we need calculations with updated Ξ^-N and $\Lambda\Lambda$ interactions and experimental confirmation of the three-body decay width in the same theoretical treatment.

It should be noted that the formation of DAC and its statistical decay may be a less reliable picture of hypernuclear formation for lighter nuclear targets. For example, while AMD+SDM roughly explains the ${}_{\Lambda}^4\text{H}$ formation probability from the K^- absorption reaction at rest in ${}^{12}\text{C}$ and ${}^{16}\text{O}$, the combined framework underestimates [29] the probability for ${}^7\text{Li}$ and ${}^9\text{Be}$ targets [42]. These light target nuclei, ${}^7\text{Li}$ and ${}^9\text{Be}$, have cluster structure in the ground states and easily dissociate to fragments after the conversion process of $K^-N \rightarrow \pi\Lambda$. Then DAHN formation may take place without going through DAC.

5. Summary and discussion

We have investigated the double Λ hypernuclear (DAHN) formation from the double Λ compound nuclei (DAC), ${}_{\Lambda\Lambda}^{13}\text{B}^*$, ${}_{\Lambda\Lambda}^{15}\text{C}^*$, ${}_{\Lambda\Lambda}^{17}\text{N}^*$ and ${}_{\Lambda\Lambda}^7\text{H}^*$ in the statistical decay model (SDM). The first three compound nuclei would be formed in the Ξ^- absorption at rest in light nuclear target in the emulsion, $\Xi^- + {}^{12}\text{C} \rightarrow {}_{\Lambda\Lambda}^{13}\text{B}^*$, $\Xi^- + {}^{14}\text{N} \rightarrow {}_{\Lambda\Lambda}^{15}\text{C}^*$, and $\Xi^- + {}^{16}\text{O} \rightarrow {}_{\Lambda\Lambda}^{17}\text{N}^*$, and the last one would be formed from the Ξ -hypernuclei, ${}^7\text{Li}(K^-, K^+)_{\Xi}^7\text{H}_{\text{gs}}$ followed by ${}^7_{\Xi}\text{H}_{\text{gs}} \rightarrow {}_{\Lambda\Lambda}^7\text{H}^*$. SDM has been demonstrated to work well in describing fragment formation processes, especially when combined with the transport model calculation to populate the compound nuclei and the excitation energies. In the antisymmetrized molecular dynamics (AMD) calculations of Ξ^- absorption in ${}^{12}\text{C}$, the formed DAC are dominated by ${}_{\Lambda\Lambda}^{13}\text{B}^*$ and its probability

is around 30%. Assuming that this mechanism also applies to the Ξ^- absorption in other target nuclei, we have evaluated the formation probabilities of DAHN. We have also applied the same SDM to evaluate the branching ratio of the Ξ hypernucleus ${}^7_{\Xi}\text{H}$ to form ${}^5_{\Lambda\Lambda}\text{H}$.

We have examined the target and the $\Lambda\Lambda$ bond energy ($\Delta B_{\Lambda\Lambda}$) dependence of the DAHN formation probabilities, and the event probabilities are also examined for the channels in which DAHN have been observed in experiments. The bond energy is given as $\Delta B_{\Lambda\Lambda} = 4.9$ MeV (model A), $\Delta B_{\Lambda\Lambda} = 0.67$ MeV (model B), and $\Delta B_{\Lambda\Lambda}(A = 6) = 0.67$ MeV and $\Delta B_{\Lambda\Lambda}(A = 11) = 1.87$ MeV (model C). In models A and B, $\Delta B_{\Lambda\Lambda}$ is assumed to be independent of the hypernuclei, and in the model C, $\Delta B_{\Lambda\Lambda}$ is assumed to be a linear function of the DAHN mass number. Models B and C are consistent with the Nagara event result.

In the Ξ^- absorption in ${}^{12}\text{C}$, ${}^6_{\Lambda\Lambda}\text{He}$ and ${}^{10}_{\Lambda\Lambda}\text{Be}$ are observed in the fragmentation channel of $\Xi^- + {}^{12}\text{C} \rightarrow {}^6_{\Lambda\Lambda}\text{He} + \alpha + t$ and $\Xi^- + {}^{12}\text{C} \rightarrow {}^{10}_{\Lambda\Lambda}\text{Be} + d + n$, respectively. In SDM, these channels are found to have relatively large probabilities, and the expected numbers of events are consistent with unity within a factor of three. For ${}^{14}\text{N}$ target, ${}^{13}_{\Lambda\Lambda}\text{B}$ is observed in the channel $\Xi^- + {}^{14}\text{N} \rightarrow {}^{13}_{\Lambda\Lambda}\text{B} + p + n$. The SDM calculation shows that this channel has the largest event probability among other fragmentation channels, and the expected number of events is (0.3 – 0.4) in $\Delta B_{\Lambda\Lambda}$ models B and C. For ${}^{16}\text{O}$ target, ${}_{\Lambda\Lambda}\text{Be}$ is observed. The mass number and channels are not uniquely identified, but the experimentally most probable channel is $\Xi^- + {}^{16}\text{O} \rightarrow {}^{11}_{\Lambda\Lambda}\text{Be} + \alpha + d$. This channel is found to have small event probability of (0.2 – 0.3)% and the expected number of events is (0.04 – 0.06) in $\Delta B_{\Lambda\Lambda}$ models B and C. If the observation was not accidental, we may need other mechanisms than the statistical decay of DAC.

The $\Delta B_{\Lambda\Lambda}$ model dependence of the DAHN formation probabilities is not significant in the main decay channels, where a few nucleons are evaporated; two nucleon emission for ${}^{12}\text{C}$ and ${}^{14}\text{N}$ targets and three nucleon emission for ${}^{16}\text{O}$, as shown in Figs. 3, 5 and 7. One nucleon emission to excited levels is favored in each step of the statistical binary decay because of the large level densities in the daughter nuclei, $\rho \propto A^{-5/3} e^{2\sqrt{aE^*}}$ with a being the level density parameter, $a \simeq A/8$ MeV $^{-1}$ [27]. Since the mass number dependence of $\Delta B_{\Lambda\Lambda}$ is assumed to be small, the $\Delta B_{\Lambda\Lambda}$ difference results in the shift of the excitation energies of the parent and daughter nuclei simultaneously and does not affect the decay width of one nucleon emission strongly. By comparison, lighter DAHN formation depends more strongly on $\Delta B_{\Lambda\Lambda}$. Since the initial energy is fixed in Ξ^- absorption in nuclei, the Q -value difference of around 4 MeV in emitting light DAHN is significant in the total released energy of (10 – 30) MeV in the fragmentation.

We have also discussed the branching ratio to form ${}^5_{\Lambda\Lambda}\text{H}$ from a Ξ hypernucleus ${}^7_{\Xi}\text{H}$, which can be formed in the ${}^7\text{Li}(K^-, K^+)$ reaction and is assumed to be converted to a DAC, ${}^7_{\Lambda\Lambda}\text{H}^*$. It was proposed that the branching ratio would be around 90% [39]. In SDM calculations, the branching ratio is found to be (40 – 60)% in the Ξ binding energy range of (0 – 4) MeV. This branching ratio is still large but lower than that in Ref. [39]. The difference seems to come from the method to evaluate the decay width; explicit few-body calculations in [39] and the statistical assumptions in the present work.

The theoretical framework adopted in the present work may be too much simplified to describe realistic DAHN formation processes, and we need improvements in the theoretical frameworks for more quantitative estimates of the formation probabilities of DAHN from Ξ^-

absorption reactions at rest and Ξ hypernuclei. First, the initial DAC formation probabilities need to be evaluated with updated $\Delta B_{\Lambda\Lambda}$ values consistent with the Nagara event and for ^{14}C , ^{14}N and ^{16}O target nuclei in a consistent way. We have adopted the formation probability of DAC in the initial preequilibrium stage of around 30%, based on the antisymmetrized molecular dynamics (AMD) calculation of Ξ^- absorption at rest in ^{12}C [23]. This probability is obtained with a strongly attractive $\Lambda\Lambda$ interaction, which gives the $\Lambda\Lambda$ bond energy $\Delta B_{\Lambda\Lambda} = 4.9$ MeV in $^{13}_{\Lambda\Lambda}\text{B}$, and ^{14}N and ^{16}O targets were not considered. Second, we need more care to discuss hypernuclear formation in reactions on light nuclear targets such as ^7Li and ^9Be . When the ground state of the target has a developed cluster structure, direct reaction processes are found to be more important than in reactions on C, N and O targets [29]. This may also apply to the decay of light Ξ^- nucleus such as $^7_{\Xi}\text{H}$ as discussed in Sec. 4. Thirdly, we may need other quantum effects or multifragmentation mechanisms to understand the DAHN formation consistently with the twin hypernuclear formation, where two single Λ hypernuclei are formed. The twin hypernuclear formation probability is known to be comparable to that of DAHN, but SDM predicts much lower probability of twin hypernuclear formation. In Ref. [23], quantum fluctuation effects are considered and are found to promote twin hypernuclear formation, but the twin hypernuclear formation probability is still underestimated. One of the possible mechanisms for producing twin single hypernuclei efficiently is to go through the resonance states of two single hypernuclei around the threshold energy of Ξ^- and target nuclei [25]. This mechanism seems plausible, since resonance states tend to appear around the threshold, and there are several twin hypernuclear channels around the Ξ^- -target threshold. Another candidate mechanism is the multifragmentation, simultaneous decay to three or more fragments. The excitation energy of $E^* = (30 - 50)$ MeV corresponds to the temperature of $T \simeq \sqrt{E^*/a} \sim 5$ MeV and multifragmentation may be relevant at this temperature. Actually, canonical and microcanonical statistical fragmentation models are applied to hypernuclear formation in Refs. [22, 24]. Thus it is desired to examine DAHN formation probabilities in multifragmentation models.

Acknowledgments

The authors would like to thank Hiroyuki Fujioka, Tomokazu Fukuda and Emiko Hiyama for giving us motivation for this work, Hirokazu Tamura, Toshiyuki Gogami, for telling us the recalibration results in SKS data, and Jørgen Randrup for useful discussions and careful reading of our manuscript. This work is supported in part by the Grants-in-Aid for Scientific Research from JSPS (Nos. 19H05151 and 19H01898), and by the Yukawa International Program for Quark-hadron Sciences (YIPQS).
