The dynamic evolution of a highly underexpanded transient supersonic jet at the exit of a pulse detonation engine is investigated via high-resolution time-resolved schlieren and numerical simulations. Experimental evidence is provided for the presence of a second triple shock configuration along with a shocklet between the reflected shock and the slipstream, which has no analogue in a steady-state underexpanded jet. A pseudo-steady model is developed, which allows for the determination of the post-shock flow condition for a transient propagating oblique shock. This model is applied to the numerical simulations to reveal the mechanism leading to the formation of the second triple point. Accordingly, the formation of the triple point is initiated by the transient motion of the reflected shock, which is induced by the convection of the vortex ring. While the vortex ring embedded shock move essentially as a translating strong oblique shock, the reflected shock is rotating towards its steady state position. This results in a pressure discontinuity that must be resolved by the formation of a shocklet.

I. INTRODUCTION

Supersonic transient underexpanded compressible jets can be found in many applications such as rocket propulsion, shock tubes, pulse detonation engines, etc. The transient supersonic jet is also of interest in the field of safety and security management, e.g., in case of an accidental release of a gas from a high-pressure reservoir or volcanic blasts. The characterization of such a flow field has been the subject of research in some detail for many years. The first stage of the jet evolution is the well known shock-diffraction phenomenon, which has been investigated numerically, experimentally and analytically by many researchers [1–4]. The next stage is the dynamic evolution of a highly transient supersonic trailing jet behind the leading shock, which has also received significant attention [5–11]. However, both the numerical and experimental study of the flow at this stage is inherently challenging [12, 13] due to the short timescales and large dynamic ranges involved. The last stage of the transient supersonic jet evolution is simply the steady underexpanded jet, which has been extensively investigated in the last decades [14].

While the structures in a transient underexpanded jet evolve in time, many of the salient flow features are analogous to those observed in the more classical steady underexpanded jet. An expansion fan originating from the nozzle exit accounts for the mismatch in pressure between the jet and the surroundings. The expansion fan reflects as compression waves from the sonic lines. These compression waves converge to an oblique shock wave, which reflects as a shock wave at the jet centerline (see illustration in figure 7(b)). This reflected shock again reflects at the sonic line and results in new expansion waves. A series of reflected shock and expansion waves result in the characteristic shock cell structure or “shock diamonds” of underexpanded jets. Highly underexpanded jets are characterized by a strong Mach disk as a result of a Mach reflection at the jet centerline. As the pressure ratio decreases, the Mach disk becomes smaller. It was originally thought that for weak underexpanded jets there are no Mach reflections, but only regular reflections. However, it was shown that a regular reflection of a shock from an axis of symmetry is impossible, and therefore all reflections at the centerline of an axisymmetric jet must be Mach reflections [15]. The flow downstream of the Mach disk becomes subsonic, while the flow downstream of the oblique shocks remains supersonic. A mismatch in temperature, entropy, and velocity occurs between the boundary of these two regions. A shear layer produced by the slipstream between the low-speed core and high speed annulus results in vortical structures, which persist across multiple shock cells [16]. In the steady state jet these aforementioned structures are well understood, however during the initial development of a transient jet their temporal evolution is far more complex, yet has received less attention.

To introduce the flow structures relevant to the discussion to follow, a time series of schlieren images capturing key points in the early-stage evolution of a transient supersonic jet are presented in figure 1, for a shock wave with a Mach number of $Ms = 1.76$ exiting from a circular tube. These images are separated by a uniform time interval of $50 \mu s$; the time τ given above the images is non-dimensionalised $\tau = (t * Ms * a_0)/D$, where t is the time after the shock wave leaves the tube exit, D is the tube exit diameter and a_0 is the speed of sound ahead of the leading shock. The corresponding experimental setup is discussed in chapter II.

The first stage of the jet evolution, the shock diffraction, is shown in figure 1(a). This image captures the moment immediately after the shock wave exits the tube. Towards the radial edge the shock wave has already undergone a three-dimensional diffraction as indicated by the partially curved shock; both diffracted and undisturbed leading shocks are clearly visible. The exhaust flow of the tube expands through a pseudo-steady Prandtl-Meyer expansion fan (PM) centered at the tube exit’s sharp corner. The leading characteristic (LC) of these waves marks the separation point (SP) between the undisturbed leading shock and the diffracted shock. The same flow features have been observed first by Skews [1] at a plane-walled convex corner for a diffracting shock wave. The information about the area expansion travels along the LC toward the jet centerline leading to a fully curved leading shock wave (figure 1(b)). Since the pressure at the tail of the PM expansion waves is lower than the pressure transmitted back by the leading shock wave, a second shock arises to match the two phases. Friedman [17] has shown that this second shock occurs due to the over-expansion caused by the increase of the volume, which does not arise in one-dimensional studies. Figure 1(b) captures the moment as this second shock is just being formed at the outer region of the jet next to the barrel shock. The upper and lower second shock waves, highlighted in figure 1(b) propagate toward the jet centerline to form a single shock wave. As these shocks coalesce, a single curved shock wave is formed (figure 1(c)). The curved shock wave transforms to a disk-shaped shock wave shortly after, as can be seen in figure 1(d). This is the origin of the well known Mach disk of a steady underexpanded jet.

Besides the Mach disk, several other features are visible in figure 1 that have been reported in the literature. The leading shock sets the gas inside the tube in motion by compressing the flow while propagating through the tube. Following the leading shock, a highly transient jet establishes itself at the outlet of the tube. Elder Jr and De Haas [18] initiated the studies of transient supersonic jets of an open-end shock tube using spark schlieren measurements. They reveal the presence of a vortex ring in the trailing jet for Mach numbers $Ms = 1.12$ and 1.32 , which grows non-linearly with time and distance. In a systematic study Brouillette and Hebert [19] found three different types of flow fields of the trailing jet depending on the leading shock Mach number. Accordingly, there is a shock-free vortex ring characterized by a very thin core for $Ms < 1.43$. For higher Mach numbers the vortex ring contains an embedded

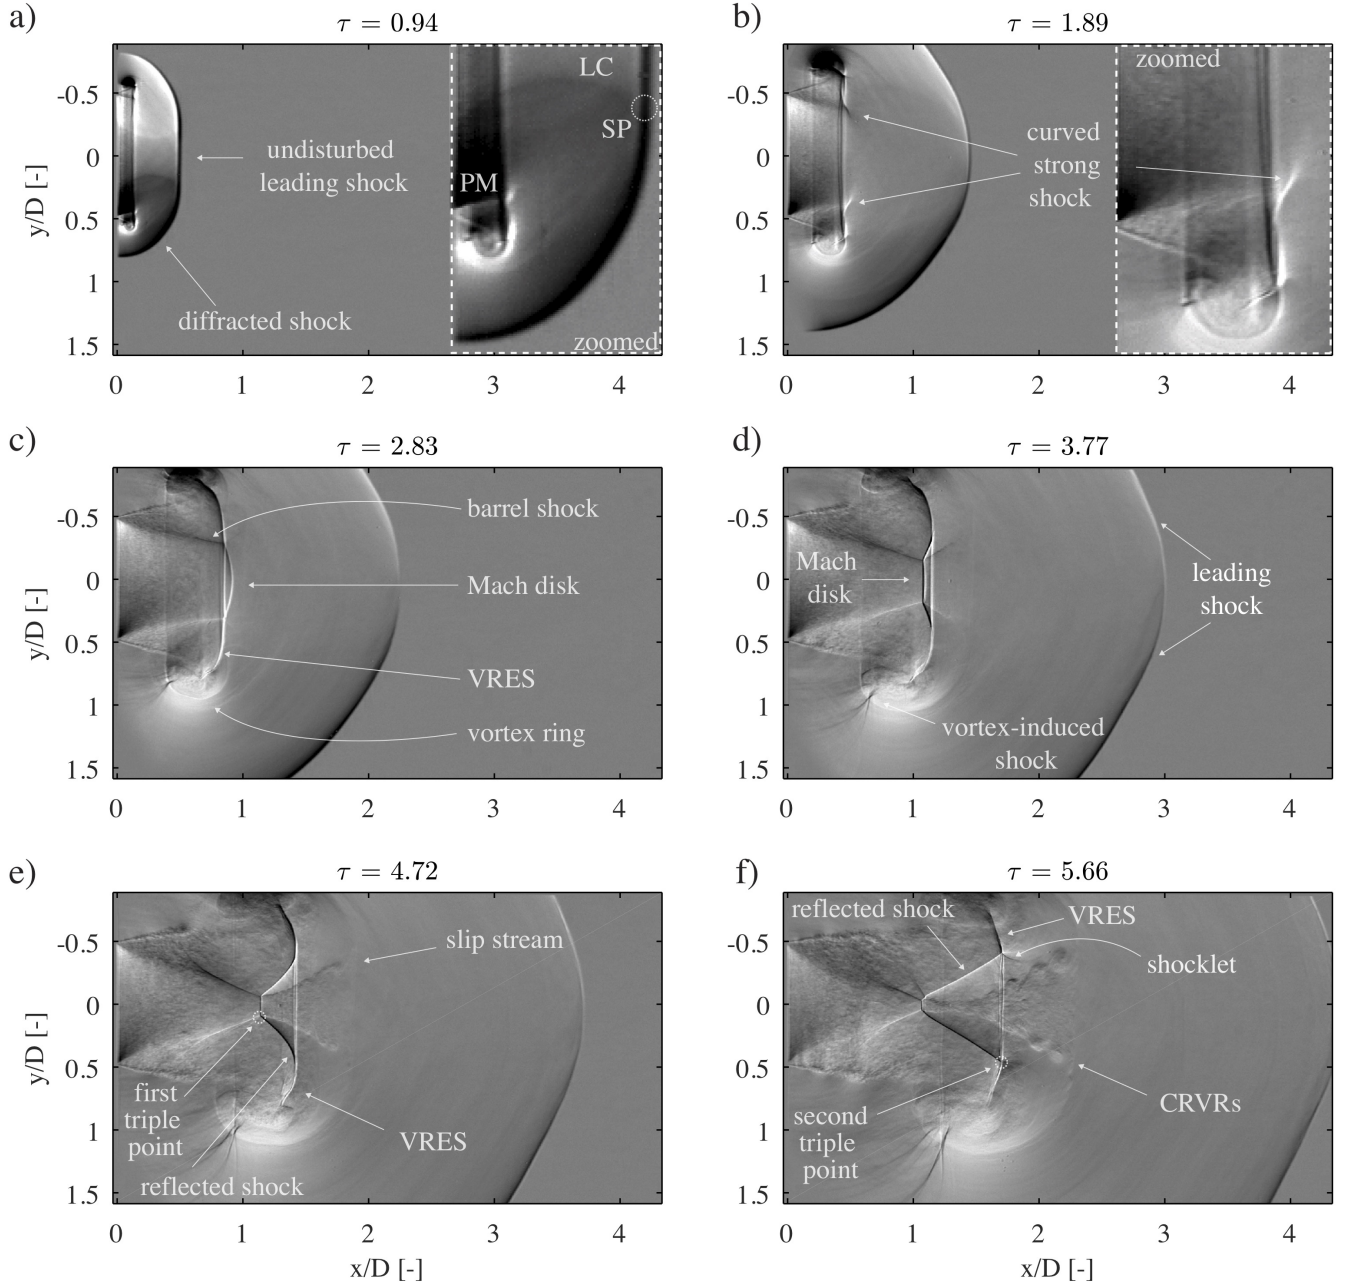

FIG. 1: A time series of six $\frac{\partial \rho}{\partial y}$ schlieren images showing the detailed evolution of the exhaust flow at its early stage for $Ms = 1.76$. The x and y-coordinates are normalized by the tube diameter, D . The origin of the axis corresponds to the point on the tube centerline at the tube exit. The time displayed above each image corresponds to the time elapsed since the shock wave has passed the pressure probe next to the exhaust tube outlet.

shock, the so-called vortex-ring-embedded shock (VRES) (also visible in figure 1(c)). Brouillette and Hebert [19] found the occurrence of counter-rotating vortex rings (CRVRs) for $Ms > 1.6$ (figure 1(d)). The primary vortex ring can also contain an additional shock wave, the so-called vortex-induced shock as indicated in figure 1(d). These flow features can be seen more clearly in figure 2, where an overview of the dominant flow features at $\tau = 6.13$ is given.

Besides the shock waves associated with the vortex ring, the trailing jet can also contain a number of additional shock systems. Ishii et al. [7] exhibited the presence of a Mach disk and a triple shock configuration in the trailing jet for high-Mach number leading shock flow. Figure 1(d) shows the corresponding shock system, which consist of the barrel shock, the reflected shock and the Mach disk. The reflection of the barrel shock from the jet centerline as an axis of symmetry must be a Mach reflection in the same manner as for a steady underexpanded jet [15]. The corresponding

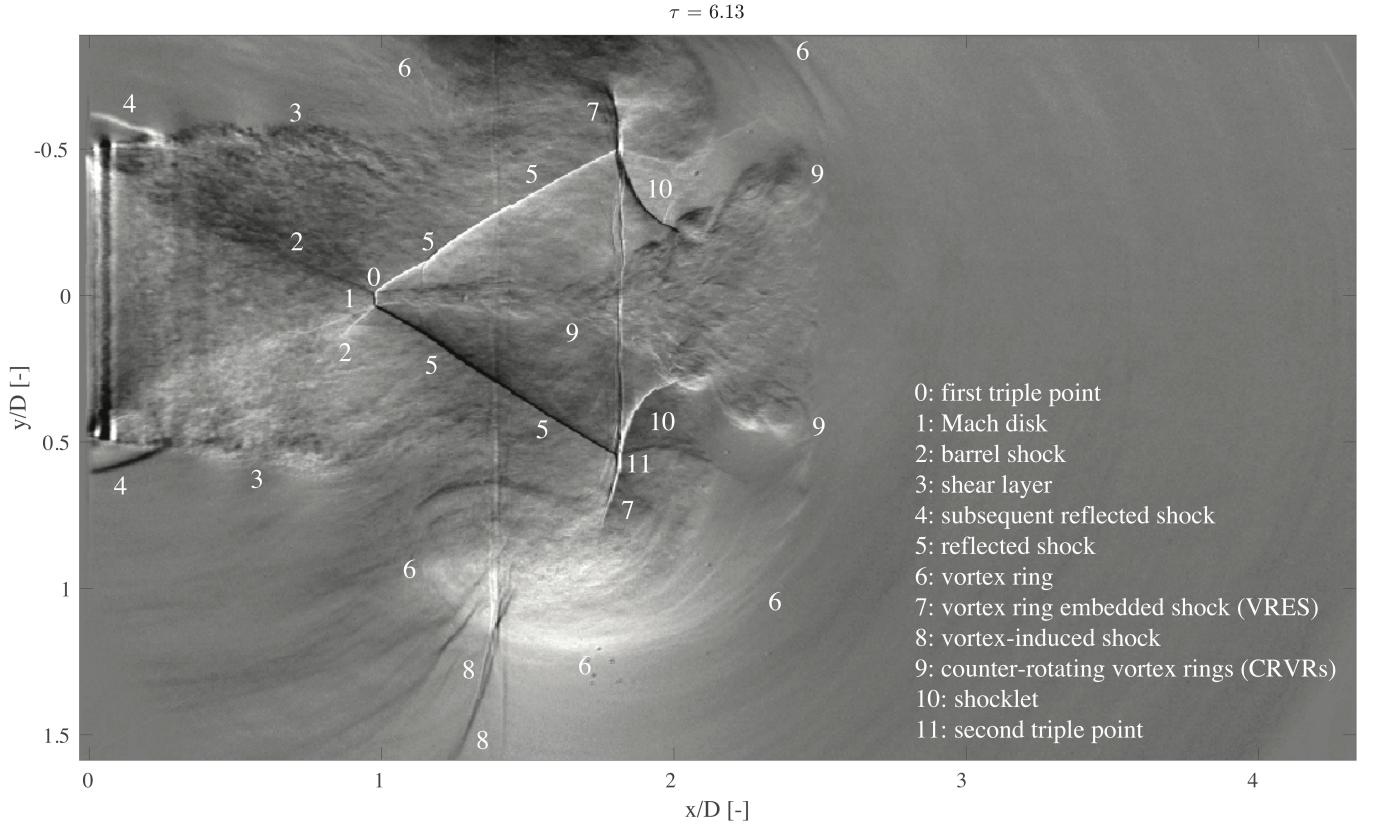

FIG. 2: Overview of the main flow features at $\tau = 6.13$.

slipstream downstream of the triple point can be recognized in figure 1(e). Unlike the steady underexpanded jet the slipstream is inclined towards the jet boundary in radial direction. A number of CRVRs are apparent in figure 1(f). These vortices are generated by Kelvin-Helmholtz (KH)-instabilities of the shear layers along the slipstream [7]. Dora et al. [8] showed that the evolution of CRVRs is driven by the same physical mechanism as for the Mach reflection. They claim that the shear layer along the slip stream grows spatially due to the eddy pairing. In accordance to that, the close-up views in figure 3 reveal a number of eddies along the slipstream growing both in size and strength. Moreover, the image sequence shows clear evidence for the pairing process confirming the observations of Dora et al. [8]. As shown by Kleine et al. [20], the CRVRs wraps around the vortex ring at a later time. In a recent study, Zhang et al. [21] demonstrated that the interaction of the CRVRs with the vortex ring increases the instability of the primary vortex ring.

The features observed in figure 1(a)-(e) have been described in the previous studies of Dora et al. [8], Kleine et al. [20] and Zhang et al. [21]. There is however an additional feature in figure 1(f) that has received far less attention: a transient shocklet formed at the intersection of the reflected shock and the VRES resulting in a second triple point. This feature has no analogue in steady-state jets, yet has received little consideration in past research on transient jets. Thus, this paper presents an experimental and numerical investigation of the shock evolution in a highly underexpanded jet. The paper is laid out as follows. A general description of the facility, as well as the schlieren methodology is given in sections II A and II B, respectively. Section II C presents the numerical methodologies and the setup for the conducted simulations. Section III A considers the formation and evolution of the second triple point and its associated shock structure. Section III B provides a proposed mechanism for the formation of the second triple point by applying a developed model for determination of post shock flow condition.

II. METHODOLOGY

A. Experimental Facility and Instrumentation

In the current study a PDE is used to generate a shock wave. A PDE is, in its simplest form, a tube filled with a combustible mixture. Two different reactive waves can be generated using a PDE: a supersonically propagating combustion front, which is known as a detonation wave, and a subsonically propagating front, which is referred to as a deflagration wave. A schematic of the PDE and its instrumentation is presented in figure 4. The PDE consists of two sections, the Deflagration-to-Detonation Transition (DDT) section and the exhaust tube. Hydrogen is injected through eight circumferentially distributed fuel lines at the rear end of the tube. Air is injected directly upstream of the DDT section. Once the tube is filled with a combustible mixture a spark plug is used to initiate combustion. Orifices installed in the DDT section accelerate the flame. By varying the mixture volume and equivalence ratio the operation mode of the PDE can be adjusted. In the current study we are interested in the transient supersonic jet of a shock-induced flow and therefore, we want to minimize the impact of combustion on the exhaust flow. Hence, the tube is only partially filled with a lean mixture prior to ignition to allow for the shock wave to decouple from the reaction front. The decoupling ensures a time gap between the arrival of the shock wave and combustion products at the tube exit.

The key governing parameter for the shock-induced flow is the Mach number of the shock wave propagating through the tube. To achieve comparability between the experimental and the numerical results we matched the respective Mach numbers of the leading shock waves at the tube exits, ensuring a similar flow field at the initial stage of the transient starting jet. The leading-shock Mach number for the schlieren and numerical results discussed in section III A is $Ms = 2.15$.

Piezoelectric pressure sensors (PCB112A05) are used to measure the leading shock wave velocity using the time of flight model. Three pressure sensors are flush-mounted in the DDT section and five in the exhaust tube. The last pressure sensor is mounted 4D upstream the tube end. The combustion front is tracked inside the tube by using ion probes flush-mounted in the opposite side to the pressure probes within the exhaust tube. These sensors are used to ensure the decoupling of the leading shock wave from the combustion front. For measurements of total pressure at the tube exit a piezoresistive Kulite XCE-062 transducer is placed at $x/D = -0.3$ on the jet centerline, as shown in figure 4(c). A frequency response correction of the signal is applied by using a Kulite KSC-2 signal conditioner [22]. Two type-K thermocouples measure the temperature of air and hydrogen. The pressure in both the hydrogen and air supply lines is measured using Festo pressure transducers (SPTW-P10R). The mass flows of air and hydrogen are measured using Coriolis mass flow meters and are controlled using proportional valves. The data from ionization and pressure probes are collected on 11 channels using a National Instruments MXI-Express DAQ system at 1 MHz sampling rate.

B. Schlieren Diagnostic

The flow at the open end of the PDE is investigated using time-resolved high-resolution schlieren measurements. Figure 4(b) presents a schematic illustration of the schlieren setup. A standard z-type configuration is used with two 6-inch parabolic f/8 mirrors for collimating and refocusing of light. A pulsed LED is used as a light source as suggested by Willert *et al.* [23]. A very high-intensity light pulse at a very short time span is generated using an

FIG. 4: Sketch of the experimental setup showing (a) the pulse detonation engine, pressure sensors, and ion probes, (b) the schlieren setup and (c) the total pressure probe.

overdriven-operated LED. An exposure time of $1 \mu\text{s}$ has shown to be the best trade off between smearing of high-speed flow features and image contrast. The schlieren images are captured at up to 80 kHz with a Photron SA-Z camera. In the Cartesian coordinate system the x-coordinate corresponds to the jet axis and the y and z-coordinate to the radial directions. A razor blade aligned perpendicular and parallel to either the x or y-coordinate is used. The resultant images correspond to path integrated density gradients in the x-direction $\frac{\partial \rho}{\partial x}$ and y-direction $\frac{\partial \rho}{\partial y}$, respectively.

C. Numerical Simulations

1. Finite Volume Discretizations

The present numerical simulations are based on the three dimensional Euler equations for an ideal gas, and the one-dimensional reactive Euler equations for an ideal gas mixture. In describing the respective numerical discretizations used, we will employ the following notation below: ρ is the density, \mathbf{v} the flow velocity vector, p the pressure, \mathbf{Y} the species vector, E the total energy, \mathbf{I} the identity matrix and γ the isentropic exponent of the mixture.

The three-dimensional Euler equations read

$$\begin{aligned} \frac{\partial}{\partial t} \rho + \nabla \cdot (\rho \mathbf{v}) &= 0 \\ \frac{\partial}{\partial t} (\rho \mathbf{v}) + \nabla \cdot (\rho \mathbf{v} \otimes \mathbf{v} + p \mathbf{I}) &= 0 \\ \frac{\partial}{\partial t} (\rho E) + \nabla \cdot ((\rho E + p) \mathbf{v}) &= 0 \end{aligned} \quad (1)$$

and we assume the equation of states for perfect gases

$$\rho E = \frac{p}{\gamma - 1} + \frac{1}{2} \rho \mathbf{v} \cdot \mathbf{v} \quad (2)$$

with $\gamma = 1.4$. To compute the numerical solution to (1) we use an explicit Godunov-type second order finite volume scheme with an exact Riemann solver. The inter-cell fluxes are computed by a MUSCL reconstruction step on the

conservative variables $(\rho, \rho \mathbf{v}, \rho E)$ and the slopes used in this step are limited by the van-Leer limiter to control artificial oscillations at discontinuities (see, e.g., [24] for a textbook reference). Multidimensionality is handled using Strang-splitting for the spatial derivatives in (1) and this leads in total to a second order accurate scheme in regions of smooth solution behaviour and to first order non-oscillatory approximations near discontinuities and extrema. This scheme is augmented by the cut-cell approach for the representation of solid wall boundary conditions introduced by Klein et al. [25] and Gokhale et al. [26] which is compatible with directional operator splitting. The cylindrical boundary of the combustion tube is represented as a level set and is embedded in a regular Cartesian grid. We also make use of block-structured adaptive mesh refinement techniques (Berger & Olinger [27]) to locally refine the grid in regions of interest, such as shock waves or cut-cells.

The one-dimensional reactive gas flow simulations in the detonation tube are based on the one-dimensional form of (1) with chemical reactions described by balance laws for the chemical species,

$$\frac{\partial}{\partial t}(\rho \mathbf{Y}) + \nabla \cdot (\rho u \mathbf{Y}) = -\rho \dot{\mathbf{Y}}. \quad (3)$$

Furthermore, the energy equation of state is modified to account for a mixture of gases, i.e.,

$$\rho E = \rho \int_{T_0}^T c_v(\tau, \mathbf{Y}) d\tau + \rho Q_0(\mathbf{Y}) + \frac{1}{2} \rho u^2, \quad (4)$$

where $c_v(\tau, \mathbf{Y})$ is the specific heat capacity at constant value and the formation enthalpy at $T = T_0$ is $Q_0(\mathbf{Y})$. In this study these functions, just as the reaction rate functions $\dot{\mathbf{Y}}(T, p, \mathbf{Y})$ are provided by an H2-O2 reaction mechanism for high pressure combustion following Burke et al. [28].

The numerical scheme used here is described in [29]. It differs from the inert gas 3D solver explained above by (i) the use of Strang splitting for the implementation of the chemical reaction terms, and (ii) the use of the HLLE approximate Riemann solver as a numerical flux function. The HLLE solver is the version of the general HLL scheme of Harten et al. [30] with the numerical signal speeds determined according to Einfeldt [31]. This flux function provides added robustness and efficiency relative to the exact Riemann solver. Its advantages for detonation wave applications have been discussed by Berndt [32].

2. Initial Data and Boundary Conditions for the Approximate Representation of the Experiment

The combustion tube in the experiment is only partially filled with the combustible mixture but its fill fraction and equivalence ratio along the tube is not known. Although we are given measured pressure data over time at the tube outlet in addition to the Mach number for the leading shock wave, a complete description of the thermodynamic quantities is not experimentally available. To approximate inflow boundary conditions into the 3D simulation domain at the outlet of the combustion tube, we perform a series of one-dimensional simulations of H2-O2 detonations and compared the results with the measurements. Varying the equivalence ratio of the combustible mixture and the fill fraction of the tube we found a one-dimensional solution within the tube that matches the Mach number of the leading shock as well as the total pressure over time (figure 5) rather accurately.

Even if the flow states in the combustion tube can be well approximated by cross-sectional averages of the conserved quantities, thereby allowing for a one-dimensional approximation, the flow states next to the tube exit are always affected non-trivially by multidimensional effects. To properly capture these, the three-dimensional simulations cover the entire length of the PDE in addition to a large flow domain beyond the tube exit. Initial conditions within the tube are given by the solution from the one-dimensional computation at a point in time right after the combustible mixture is entirely consumed, but before the leading shock wave has reached the tube exit. Outside the combustion tube we initially assume air at rest at atmospheric conditions.

FIG. 5: Total pressure over time for $Ms = 2.15$ at $x/D = -0.3$.

III. THE EARLY-STAGE EVOLUTION OF THE TRANSIENT SUPERSONIC JET

In the following the formation and evolution of the second triple point and its associated shock structure are discussed based on both experimental and numerical results. Finally a proposed mechanism for the second triple point is presented.

A. Formation and evolution of the shocklet

In figure 2 we noted the presence of a second triple point at the intersection of the reflected shock and the vortex ring. Unlike the first triple point and its associated system of shocks, this second triple point is not observed in a steady underexpanded jet. While the shocks associated with this second triple point are visible in some published work, as of yet there has been no discussion of the mechanism by which it forms. The triple point is formed at the intersection of the reflected shock, the VRES, and a new transient shock structure which, due to its transient nature, we will refer to as a shocklet. The shocklet and its associated triple point are only present for a short time during the early evolution of the transient jet.

Figure 6 presents a series of numerical and experimental snapshots spanning this early evolution period. Experimental schlieren images are compared with numerical schlieren images produced by path integration through the three-dimensional simulation data. The numerical schlieren images display grey scales of the quantity

$$S(x, y) = \int_{z_0}^{z_1} \frac{\partial \rho}{\partial x}(x, y, z) dz.$$

In addition, a planar representation of the early evolution of the underexpanded jet is given in figure 6 by contour plots of the Mach number at $z = 0$. Subsonic and supersonic region of the jet cross section are color-coded with blue and red colors, respectively. There is excellent agreement between the numerical and experimental schlieren results during this early evolution of the jet. Figure 6(a)-(c) shows the leading shock wave and a triple point configuration consisting of the barrel shock, the Mach disk and the reflected shock. Up to this time ($\tau \leq 4.08$) the reflected shock and the VRES are simply the same shock wave, and the size and position of the shock are primarily dictated by the strong vortex in which it is embedded. As the vortex propagates further downstream, the upstream boundary condition for the shock is instead dictated by the Mach reflection arising from the incident shocks generated at the lip. At larger radial positions however, the shock is still very much a function of the velocity field induced by the vortex ring. At $\tau = 5.43$, while the shock still forms a contiguous surface, the angle set by the triple point is significantly different to that required in the vortex ring. This disparity increases as the vortex ring propagates further from the nozzle, and while the shock surface remains contiguous, by $\tau = 6.79$ a sharp kink forms on this surface, separating the the VRES from the reflected shock (figure 6(g)-(i)). As the vortex ring moves further downstream at $\tau = 8.15$, the kink becomes a triple point, and a second triple shock configuration occurs (figures 6(j)-(m)). The shocklet is clearly visible between the reflected shock and the CRVRs in both experimental and numerical data as shown in figures 6(j)-(m).

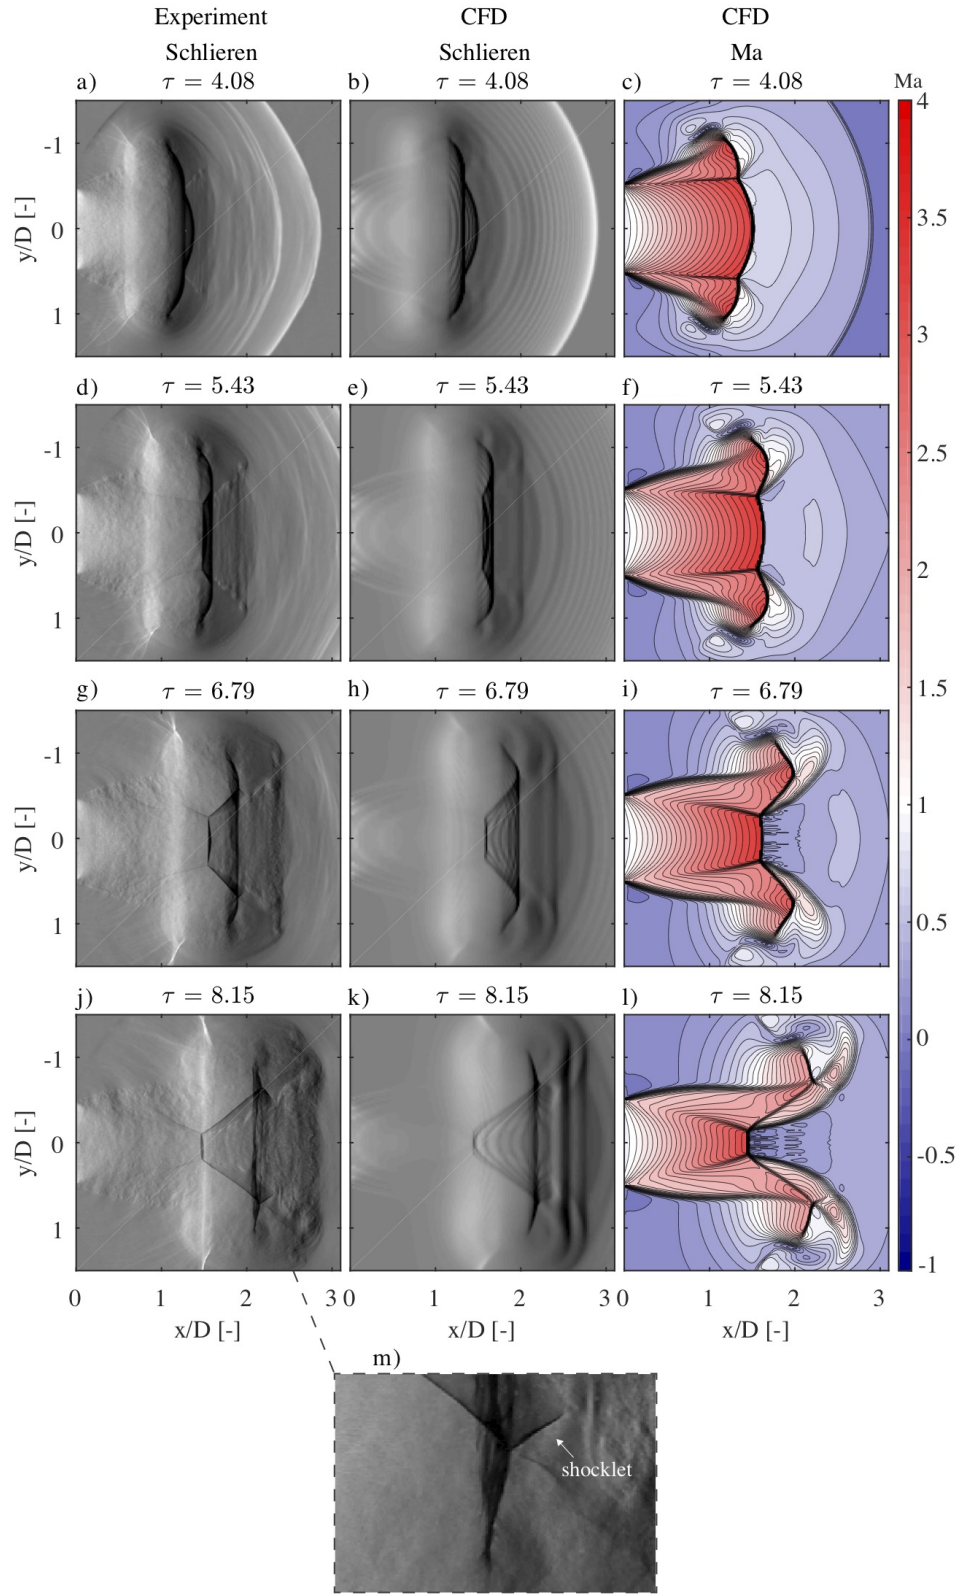

FIG. 6: Formation of the shocklet based on experimental $\frac{\partial \rho}{\partial x}$ schlieren images for $Ms = 2.15$ (left column) numerical $\frac{\partial \rho}{\partial x}$ schlieren images (center), and Mach number contour plots at $z = 0$ (right column).

a) transient underexpanded jet

b) steady underexpanded jet

FIG. 7: Schematic illustration of the jet structure for the transient and steady underexpanded jet.

To facilitate a clearer description of the formation of the shocklet, figure 7 presents a schematic comparison between the structures in the transient jet and those in its steady-state counterpart. The illustration in figure 7(a) corresponds approximately to the flow state shown in figures 6(j)-(m). A triple point configuration as a result of a Mach reflection can be observed for both steady and transient jet. This shock system consists of the barrel shock, the Mach disk, the reflected shock and the triple point (T_1). In case of the steady underexpanded jet, the reflected shock of the primary shock system reflects as expansion waves from the sonic line (figure 7(b)). However, for the transient jet the sonic line is significantly distorted by the presence of the vortex ring, and a simple reflection does not occur. Instead, a second triple shock configuration occurs, as illustrated in figure 7(a). This shock system consists of the reflected shock, the VRES and the shocklet, intersecting at a second triple point T_2 .

The subsequent evolution of the second shock system is shown in Figure 8 based on a time series of five schlieren images. No further tilting of the reflected shock toward the jet center line can be observed; the initial angle of the reflected shock has reached an approximate steady state. In contrast, the vortex ring and its embedded shock (VRES) move further downstream, with the VRES decreasing continuously in size. Therefore, the triple point T_2 translates downstream and radially outwards (figure 8(a)-(e)). As the vortex ring convects further, the sonic line shifts inwards, and a portion of the reflected shock must become propagative; this upstream-propagating wave rapidly decays into an acoustic wave, in a manner analogous to the shock leakage process of jet screech [33]. The conversion of this part of the reflected shock into an upstream-propagating wave effectively terminates the second triple point (figure 8(e)).

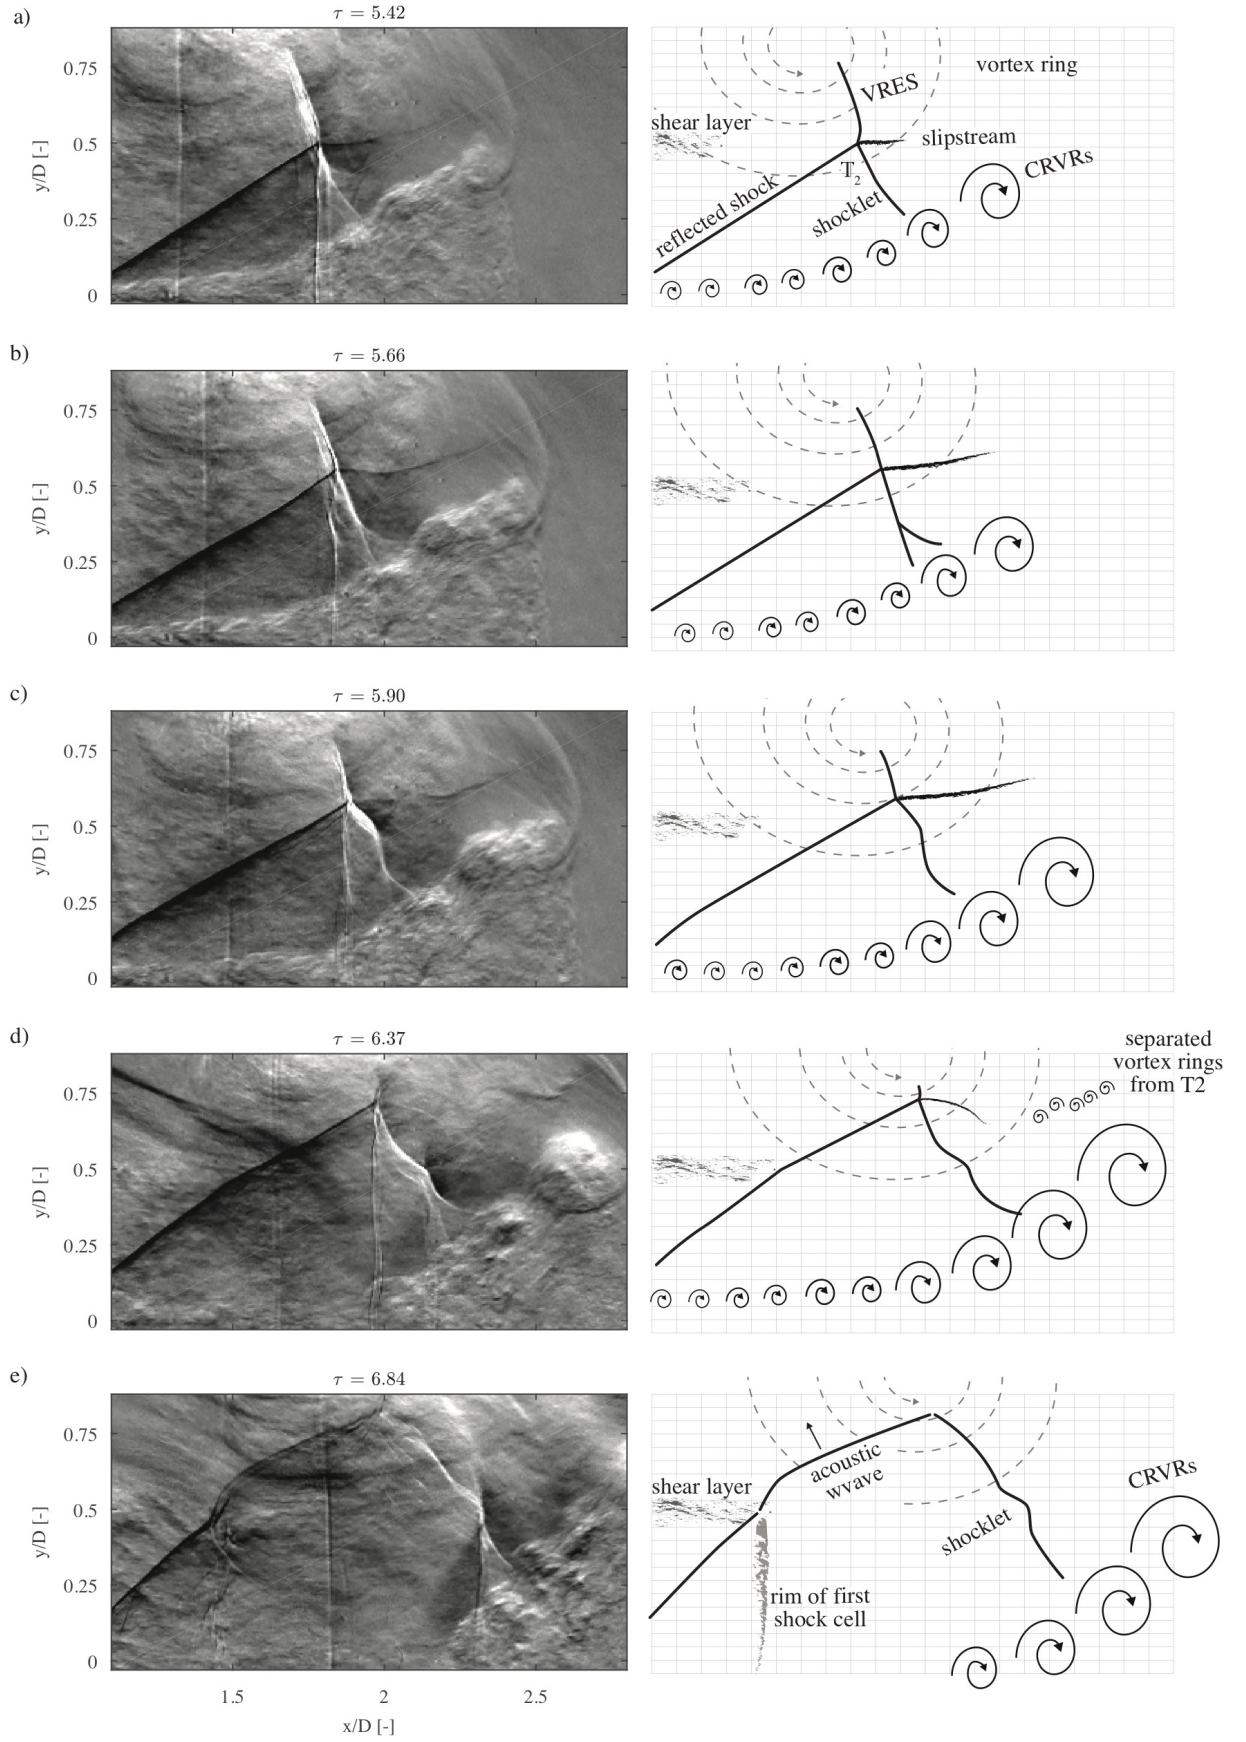

FIG. 8: $\frac{\partial \rho}{\partial y}$ schlieren images for $Ms = 1.76$ showing the evolution of the second triple point configuration.

FIG. 9: Sequence of pressure contours determined from numerical simulations for a Riemann problem with $Ms = 1.71$. The yellow dashed line indicate the formation of a pressure gradient that potentially leads to the formation of the shocklet.

While the second triple shock configuration and its corresponding slipline terminate, small vortex rings along the slipline separate from the triple point (T2), as shown in figure 8(d). Finally, the impingement point of the reflected shock upon the jet shear layer appears as a wavy line in the schlieren image, representing the rim of the first shock cell. Also evident in figure 8 is an interaction between the primary and second triple point configuration. The upper bound of the shocklet is the triple point, its lower bound is the sonic line associated with the internal shear layer generated by the first triple point. The shocklet undergoes deformation via interaction with the CRVRs generated along the primary slipline, (Figure 8(b)-(d)) and the interaction produces lambda-shocks close to the CRVRs (figures 8(b)). Both, the experimental and numerical data show a second triple point configuration.

B. A proposed mechanism for the formation of the second triple point

The formation of the second triple point in the transient jet has no equivalent in the steady jet, as visualized in figure 7. Thus, the explanation for its formation must lie inherently in the dynamics of a transient jet. The convection of the vortex ring and its associated shock structure is one such process, and the temporal variation in upstream flow conditions within the tube is another. In order to separate these processes, the numerical simulations were repeated with a constant inflow condition at the tube exit. Also, a different shock Mach number of $Ms = 1.71$ is chosen, to rule out the impact of the shock strength. The inflow conditions for the numerical simulations corresponds to the solution of the Riemann problem for a planar shock wave propagating at a constant speed corresponding to $Ms = 1.71$. The results are shown in figure 9, where the formation of the second triple point is clearly visible. Hence, this suggests that the transient interaction between the first triple point and the vortex ring are the likely explanation for the formation of the second triple point.

The consideration of the time-series of pressure distributions shown in figure 9 demonstrates that unlike the steady jet counterpart, the reflected shock is non-stationary for a time before the formation of the second triple point. The reflected shock elongates and rotates, as the vortex ring and its embedded shock move further downstream. As the reflected shock tilts toward the jet centerline, a strong pressure gradient parallel to the shock develops along its downstream face. This region of negative pressure gradient, from the jet core to the jet shear layer, is marked as $-\nabla p$ in figure 9. Unlike for a steady jet, this region of negative pressure gradient grows in size and strength with time for a transient jet. We suggest that it is the motion of the reflected shock, which results in a pressure gradient downstream of the reflected shock, that in turn leads to the formation of the shocklet and the second triple point. In the following we develop a model to evaluate this hypothesis.

1. Transient oblique shock model (TOS)

To test the hypothesis that it is the unsteady motion of the reflected shock that gives rise to the formation of the triple point, we develop a model for the effect of this motion. The model delivers the post-shock flow conditions for a transient, rotating oblique shock wave based on the pre-shock flow conditions and the shock motion. The underlying

FIG. 10: Schematic illustration of the transient oblique shock (TOS) model

assumption of the approach is that the moving shock wave can be treated as a quasi-steady problem by converting the flow velocity into a reference frame that moves with the shock.

A schematic illustration of the problem is presented in figure 10(a). In a time period of $\Delta t = t_2 - t_1$ a shock wave moves from $\overline{C_1D_1}$ to $\overline{C_2D_2}$. The objective of the model is to determine the post-shock condition for a particle upstream of the shock wave at x , which will be processed by the shock wave after a certain time. The particle in x at t_1 has already passed the shock wave at t_2 , since the flow velocity v is higher than the corresponding shock velocity S .

A simple approach is used to estimate the shock velocity S . The intersection of v with $\overline{C_1D_1}$ is marked as a point I_1 in figure 10. A perpendicular line from I_1 to $\overline{C_2D_2}$ intersect with $\overline{C_2D_2}$ at a point I_2 . The shock velocity $S(x)$ is approximated simply by the displacement of the shock $\overline{I_1I_2}$ over the time interval by $S = \frac{\overline{I_1I_2}}{\Delta t}$.

The determination of post-shock properties for an oblique shock is an elementary gas-dynamics problem, solved by the simple application of the Rankine-Hugoniot equations. The problem here however involves a shock that is both translating and rotating. The proposed model is thus essentially an attempt to produce an appropriate co-ordinate transformation to allow the application of quasi-steady 1-D conservation equations to a rotating shock. Therefore, the Mach number in the absolute reference $M_1 = \frac{v}{a}$ must be converted into a reference frame that moves with the shock. Taking the shock velocity into account, the Mach number in the shock reference frame is simply $M_1^s = \frac{v-S}{a}$. To apply the Rankine-Hugoniot equations for an oblique shock, the normal component of M_1^s is determined by considering the shock angle in the shock reference frame β^s . As shown in figure 10, β^* is the cross angle between $\overline{C_1D_1}$ and M_1^s . Assuming an infinitesimal $|\overline{I_1I_2}|$, the mean value of β and β^* is taken as the shock angle β^s . Hence, the normal Mach number in shock reference Mn_1^s can be determined as $Mn_1^s = M_1^s \sin \beta^s$. Finally, the post-shock conditions are evaluated by applying the normal component of the Mach number in the Rankine-Hugoniot equations:

$$M_2^2 = \frac{1 + \frac{\gamma-1}{2}(M_1^s \sin \beta^s)^2}{\gamma(M_1^s \sin \beta^s)^2 - \frac{\gamma-1}{2}}, \quad (5)$$

$$\frac{p_2}{p_1} = 1 + \frac{2\gamma}{\gamma+1}((M_1^s \sin \beta^s)^2 - 1), \quad (6)$$

$$\frac{\rho_2}{\rho_1} = \frac{(\gamma+1)(M_1^s \sin \beta^s)^2}{1 + (\gamma-1)(M_1^s \sin \beta^s)^2}, \quad (7)$$

FIG. 11: (a) Pressure distribution at $\tau = 2.66$ as derived from the numerical simulations at constant inflow conditions with $M_s = 1.71$. T_1 and O represents the first triple point and the tail of the VRES. The TOS model is applied for x_1 , x_2 and x_3 . The result of the TOS analysis is given in table I. (b) Pressure distribution at $\tau = 3.15$ shows a uniform pressure distribution downstream of the reflected shock.

$$\frac{T_2}{T_1} = \frac{p_2}{p_1} \frac{\rho_1}{\rho_2}. \quad (8)$$

Here, p , ρ , T are the pressure, density, and temperature, respectively. In the following section, this model is used to demonstrate the formation mechanism of the second triple point.

2. Formation mechanism of the triple point based on the TOS model

As previously stated, the formation of the secondary triple point must be linked to the transient evolution of the jet, as only the first triple point appears in steady-state underexpanded jets. The secondary triple point is made up of the reflected shock from the first triple point, the VRES, and the shocklet, as shown in figure 7(a). Of these, the first two have been discussed in the literature at some length; the shocklet is the component that has therefore gone undescribed. To establish why the shocklet forms, we apply the TOS model to the motion of the reflected shock, with a starting point well before the shocklet is observed. Initial observations suggest that the pressure gradient parallel to the downstream face of the reflected shock is likely linked to the shocklet's formation, thus we seek to test whether this pressure gradient is a result of the motion of the shock.

The application of the TOS model involves analysis of a series of discrete points parallel to the upstream face of the reflected shock (x_1 to x_n), as per figure 11. We use the early stages of evolution before the formation of the shocklet to test the validity of the model. Thus we start our analysis at 2.66, where the reflected shock and VRES are essentially a single contiguous shock wave (from T_1 to O in figure 11(a)). Three discrete points x_1 to x_3 are selected just upstream of the reflected shock for the TOS analysis. The changes in flow properties during passage through the shock wave are considered for particles originating at these points using the TOS model. To this end, the motion of the reflected shock is tracked for two snapshots ($\tau = 2.66$ and $\tau = 2.90$). A small time period of $\Delta\tau = 0.24$ is chosen for the TOS analysis, as an infinitesimal shock displacement is the underlying assumption of the model. The results of the TOS analysis are presented as several input and output parameters in table I. Here the input parameters, M_1 , p_1 , α are the Mach number, pressure and flow angle, respectively, extracted directly from the numerical results. The output parameters of

TABLE I: TOS results for $\tau = 2.66$ shown in figure 11(a).

the TOS analysis, Mn_1^s , M_1^s , β^s and p_2 are the normal Mach number in shock reference, the Mach number in shock reference, the shock angle and the pressure downstream of the reflected shock, respectively.

Figure 11(b) presents the pressure distribution based on the numerical simulation, shortly after the distribution in figure 11(a). This time interval $\Delta\tau = 0.48$ allows for the particle upstream of the reflected shock at $\tau = 2.66$ to be processed by the shock wave at $\tau = 3.15$. For the TOS analysis the calculated pressure downstream of the shock wave is given as p_2 in table I. The results show a constant value of 1.2 bar for x_1 , x_2 and x_3 , i.e., a uniform pressure distribution. In accordance, the results from the numerical simulations confirm a uniform pressure distribution downstream of the reflected shock in figure 11(b). Hence, the predicted uniform pressure distribution downstream of the reflected shock based on the TOS analysis agrees qualitatively very well with the CFD results. This agreement sustains for the entire conducted analysis, as pointed out in the reminder of this section. Hence, the TOS model is considered as valid.

The pressure gradient is of course readily available from the numerical simulation; the purpose of the model is to determine the source of this gradient. According to equation 6, the pressure downstream of a moving shock, p_2 , is a function of Mn_1^s and p_1 . While p_1 is fixed by the upstream flow conditions, Mn_1^s can be highly affected by the displacement of the shock wave due to the shock propagation velocity S . Figure 12 illustrates the impact of the shock displacement on S , which is given as a TOS output parameter. While an orthogonal shock displacement results in an uniform S distribution (figure 12(a)), a rotational shock displacement leads into a gradient in S along the shock wave (figure 12(b)). Here we seek to test whether the rotation of the shock is sufficient to explain the strength of the gradient observed in the data.

Evolution of the pressure distribution downstream of the reflected shock

The pressure distribution downstream of the reflected shock is uniform up to $\tau = 3.15$ (figure 11(b)), since the motion of the reflected shock at this time point is primarily translation rather than rotation; this translational motion is indicated by the constant S distribution in table I. However, as the vortex ring and its embedded shock translate further downstream ($t > 2.66$), and pass the Mach disk (figure 13(a)), the inner part of the reflected shock begins to tilt. The TOS model is applied to 4 discrete points upstream of the tilted part of the reflected shock, as shown in figure 13(a). The results of the TOS analysis for x_1 to x_4 are shown in table II. The model suggests a decreasing downstream pressure p_2 from $x_1 \rightarrow x_4$. Figure 13(b) exhibits the pressure field obtained from the numerical simulation a short time later, at $\tau = 4.36$. In accordance with the results of the TOS analysis, a non-uniform pressure distribution can be observed downstream of the reflected shock.

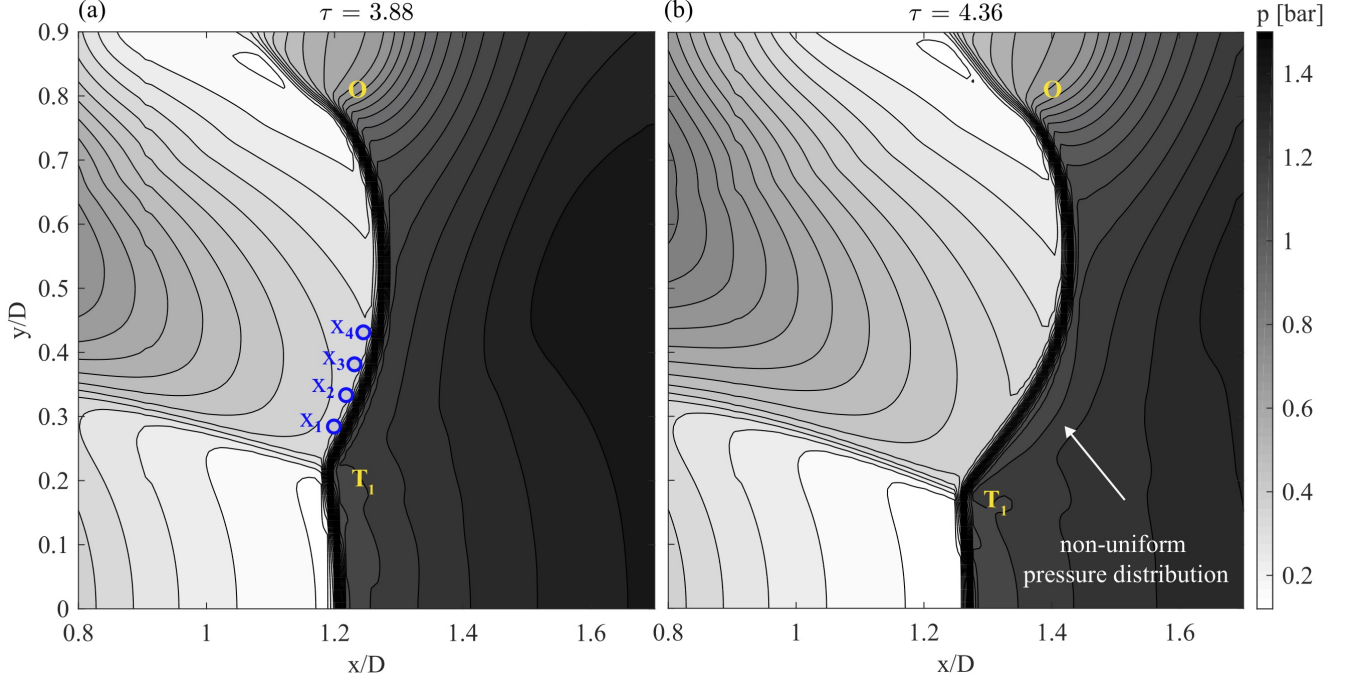

FIG. 13: (a) Pressure distribution at $\tau = 3.88$ as derived from the numerical simulations at constant inflow conditions with $M_s = 1.71$. T_1 and O represents the first triple point and the tail of the VRES.. The TOS model is applied for x_1 to x_4 . The result of the TOS analysis is given in table II. (b) Numerical pressure distribution at $\tau = 4.36$, showing a pressure gradient on the downstream face of the reflected shock.

TABLE II: TOS results for $\tau = 3.88$, shown in figure 13(a).

	input			output						
	M_1	$p_1[\text{bar}]$	α	M_{n1}^s	M_1^s	β^s	$S[m/s]$	$\frac{p_2}{p_1}$	$p_2[\text{bar}]$	
x_1	2.33	0.37	-1.3	1.81	1.97	66.6	123	3.65	1.35	
x_2	2.36	0.36	0.2	1.77	1.97	64.3	134	3.51	1.27	
x_3	2.40	0.35	2.4	1.73	1.97	61	149	3.33	1.16	
x_4	2.44	0.33	4.2	1.69	1.99	58.3	161	3.18	1.06	

The aforementioned results indicate that the pressure gradient observed in the simulation data can be caused purely by the rotation of the oblique shock. The next step is to determine a more exact mechanism. Therefore, we consider next the spatial distribution of the flow between the jet core and the jet shear layer ($x_1 \rightarrow x_4$ in figure 13(a)). According to table II there is a declining pressure ratio $\frac{p_2}{p_1}$ from $x_1 \rightarrow x_4$, as $\frac{p_2}{p_1}(x_1) > \frac{p_2}{p_1}(x_2) > \frac{p_2}{p_1}(x_3) > \frac{p_2}{p_1}(x_4)$, which results in a pressure gradient downstream of the shock wave. According to equation 6, the pressure ratio $\frac{p_2}{p_1}$ is a function of M_1^s and $\sin \beta^s$. The term $\sin \beta^s$ can be linearized to β^s under the small-angle approximation. Therefore, in the context of the model, the negative pressure ratio from $x_1 \rightarrow x_4$ can be ascribed to either decreasing M_1^s , decreasing β^s , or both. While M_1^s remains almost uniform from $x_1 \rightarrow x_4$, a significant decrease for β^s is evident, as shown in table II. Consequently, if the mechanism leading to the distribution of M_1^s and β^s is known, the formation of the non-uniform pressure region downstream of the reflected shock can likewise be determined.

To elucidate the mechanism responsible for the distribution of M_1^s and β^s , we consider the displacement of the reflected shock; the corresponding shock propagation velocity S is given in table II. The significant increase of the shock velocity from $x_1 \rightarrow x_4$ indicates a strong tilting motion of the shock wave. The increase in the shock velocity S leads inherently to a decrease in the relative Mach number in shock reference M_1^s , as $M_1^s = M_1 - \frac{S}{a(x)}$. This correlation can also be recognized visually from figure 10, which illustrates a tilting shock wave. As shown in table II, the approaching Mach number M_1 increases from $x_1 \rightarrow x_4$, which has the opposite effect on M_1^s , as can be seen from the equation

TABLE III: TOS results for $\tau = 4.60$, shown in figure 14(a).

	input			output						
	M_1	$p_1[\text{bar}]$	α	$M_{n_1}^s$	M_1^s	β^s	$S[m/s]$	$\frac{p_2}{p_1}$	$p_2[\text{bar}]$	
x_1	2.23	0.42	-7.9	1.74	2.04	58.5	70	3.35	1.40	
x_2	2.29	0.41	-4.3	1.68	2.07	54.1	81	3.13	1.27	
x_3	2.37	0.37	-1.0	1.64	2.14	49.9	91	2.95	1.09	
x_4	2.4	0.35	0.4	1.61	2.17	48.1	95	2.87	1.02	
x_5	2.57	0.29	5.1	1.96	2.00	78.1	169	4.31	1.24	
x_6	2.63	0.27	7.1	1.97	2.04	75.3	177	4.36	1.16	
x_7	2.73	0.23	10.2	2.06	2.07	83.5	185	4.79	1.12	

above. However, the uniform distribution of M_1^s over $x_1 \rightarrow x_4$ indicates, that the increase of S compensates for the increase of M_1 . Consequently, the uniform distribution of M_1^s is caused by the pronounced increase of S , i.e., due to the strong tilting of the reflected shock. Moreover, the tilting motion of the reflected shock also affects the shock angle β . The rotation of the shock results in an inherent reduction of the shock angle ($\beta^s < \beta$) as can be seen in figure 10. As shown in table II, β^s decreases from $x_1 \rightarrow x_4$. Consequently, the tilting shock wave results in a negative pressure gradient by reducing M_1^s and β^s from $x_1 \rightarrow x_4$. Additionally, a small decrease in upstream pressure p_1 and an increase in α supports the formation of the pressure gradient by simply decreasing β and therefore β^s (figure 10). Hence, these results suggest that the tilting motion of the reflected shock and the alteration of the flow angle upstream of this shock are the primary mechanisms responsible for the reduction of M_1^s and β^s , and thereby for the formation of the pressure gradient downstream of the reflected shock.

At later times, the vortex ring propagates further downstream (see figures 14 and 15). Thus the disparity in the angle dictated by the first triple point and that required by the VRES increases. Hence, a kink forms gradually within the shock wave (figures 14 and 15), separating the reflected shock and the VRES. A dotted line in figures 14 and 15, originating from K separates two regions A and B, downstream of the reflected shock and the VRES respectively. The TOS model is applied to three points for each region (figure 14 and 15). The corresponding results are presented in table III and IV. We first evaluate the results for region A, before proceeding further with region B. The comparison of the CFD pressure distribution at $\tau = 3.88$ to $\tau = 6.30$, shown in figures 13 - 15, exhibits an increase of the gradient in $-\nabla p$ region with time. In conformity with the CFD pressure distribution, the TOS results predict an increase of the pressure gradient with time downstream of the reflected shock; the pressure gradient $p_2(x_1)/p_2(x_4)$ increases by approximately 8 % between $\tau = 3.88$ and $\tau = 4.60$, and by 86% from $\tau = 4.60$ to $\tau = 5.81$ (tables II to IV). A comparison of the shock velocity S indicates that the tilting motion of the reflected shock becomes significantly stronger as $S(x_4)/S(x_1)$ increases with time. The quantity $S(x_4)/S(x_1)$ increases by approximately 26 % from $\tau = 3.88$ to $\tau = 4.60$ and 1800% from $\tau = 4.60$ to $\tau = 5.09$ (tables II to IV). For the reasons indicated above, the strong tilting results in a stronger compression, as $\Pi_{\tau=5.09} > \Pi_{\tau=4.60} > \Pi_{\tau=3.88}$, where $\Pi = \frac{p_2}{p_1}(x_1)/\frac{p_2}{p_1}(x_4)$. Hence, the gradient of the $-\nabla p$ region increases with time. The tilting of the shock is not the only mechanism by which the $-\nabla p$ changes as a function of time: there is also a small increase in the pressure gradient upstream of the reflected shock $p_1(x_1)/p_1(x_4)$ of 11, 17 and 30% from $x_1 \rightarrow x_4$ between $\tau = 4.60$ and $\tau = 5.09$. Similarly, there is an increase in the flow angle α of 5.5° , 8.3° and 16.6° , respectively. Nevertheless, the contribution of these mechanisms is relatively small compared to the gradients induced by the motion of the shock; the tilting of the reflected shock is the main reason for a pronounced pressure gradient downstream of the reflected shock wave.

As seen by the TOS model and the numerical simulations both the size and strength of the $-\nabla p$ region grow with time. The flow evolution from $\tau = 4.60$ to $\tau = 5.09$ (figure 14) shows that the reflected shock (T₁-K) elongates with time. Consequently, the $-\nabla p$ region covers a wider area downstream of the reflected shock, as shown in figure 14(b). However, the $-\nabla p$ region occurs only downstream of the reflected shock, from T₁ to K, and ends at the A-B-interface. These observations based on the CFD results agree again with the results from the TOS analysis, shown in table III; the $-\nabla p$ region elongates from x_1 to x_4 (figure 14(b)), as the pressure p_2 decreases from $x_1 \rightarrow x_4$, but there is a positive pressure gradient from A to B at their interface, as $p_2(x_5) > p_2(x_4)$ shown in table III. This positive pressure gradient is the origin of a new shock wave, the shocklet, as will be discussed in the following.

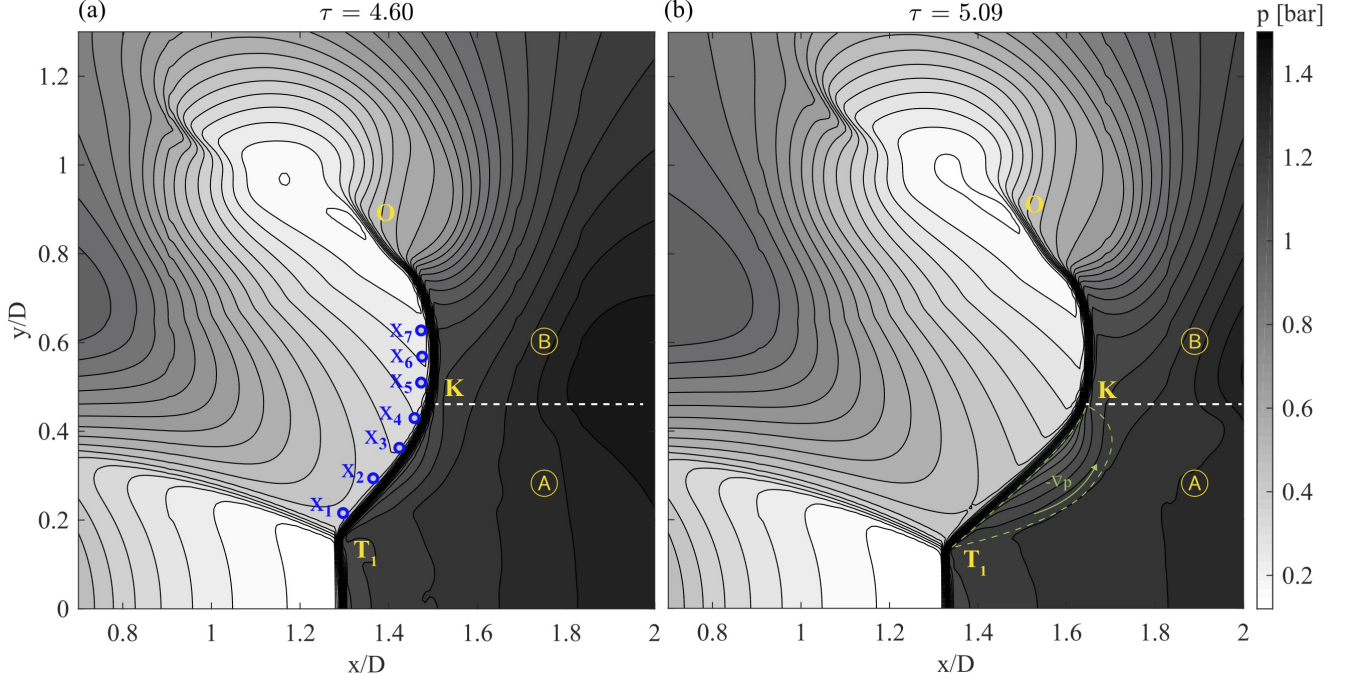

FIG. 14: (a) pressure distribution at $\tau = 4.60$ as derived from the numerical simulations at constant inflow conditions with $Ms = 1.71$. T_1 and O represents the first triple point and the tail of the VRES. The TOS model is applied for x_1 to x_7 . The result of the TOS analysis is given in table III. (b) pressure distribution at $\tau = 5.09$.

TABLE IV: TOS results for $\tau = 5.81$, shown in figure 15(a).

Evolution of the pressure distribution downstream of the VRES

The formation of a positive pressure gradient from A to B can be further examined by considering the TOS results for the region B given in table III. As shown in figure 14 and also indicated by the shock velocity S for x_5 to x_7 in table III, the VRES tilts barely, but translates predominantly in the axial direction. This is also the case for the approaching flow in region B, indicated by small α for x_5 to x_7 in table III. The combination of the vertical shock, moving in the axial direction and small α results in significantly large shock angles β , leading to high-pressure ratios $\frac{p_2}{p_1}$ in region B (x_5 to x_7 in table III). Hence, the pressure in region B is higher than A in the vicinity of their interfaces; there is a positive pressure gradient from A to B.

Figure 15(a) shows the flow evolution at a later stage in time for $\tau = 5.81$ and $\tau = 6.30$. The corresponding TOS results for x_1 to x_7 at $\tau = 5.81$ are given in table IV. The evolution of the $-\nabla p$ region can be evaluated for an extended period of time based on the pressure distribution $\tau = 4.60$ to $\tau = 6.30$ shown in figures 14 and 15. It is evident that the $-\nabla p$ region enlarges further and its pressure gradient increases with time. Similar to the $-\nabla p$, also the pressure gradient in region B becomes more distinctive with time. The TOS results confirm again the CFD results, showing an increase in pressure

gradient with time in both regions A and B, as $[p_2(x_1)/p_2(x_4)]_{\tau=5.81} > [p_2(x_1)/p_2(x_4)]_{\tau=4.60} > [p_2(x_1)/p_2(x_4)]_{\tau=3.88}$ and $[p_2(x_5)/p_2(x_7)]_{\tau=5.81} > [p_2(x_5)/p_2(x_7)]_{\tau=4.60}$. Both, the CFD and the TOS results show the pressure gradients in both regions A and B increase with time. The pressure gradient downstream of the reflected shock in region A, from T₁ to K, is negative. In contrast, there is a positive pressure gradient in region B, from O to K, as marked in figure 15(b). Hence, the increase in the pressure gradient in A and B results in higher pressure ratio along the A-B-interface. Based on the TOS results, shown in (table III and IV), the pressure ratio $p_2(x_5)/p_2(x_4)$ increases from $\tau = 4.60$ to $\tau = 5.81$ by 102 %. The result of this evolution can be observed in figure 15(b). The negative pressure gradient from T to K and the positive pressure gradient from O to K lead to an increase of the pressure within a very small region, between the $-\nabla p$ and $+\nabla p$ regions (figure 15(b)). As both pressure gradients intensify with time, an abrupt pressure change occurs at the intersection of these regions. Consequently, the abrupt pressure rise leads to the formation of a new shock wave.

Now, the formation of the second triple point and the shocklet can be summarized. The abrupt pressure rise, which necessitates the formation of the shocklet, is induced by the evolution of the pressure distribution downstream of the reflected shock. The pressure downstream of the reflected shock is highly affected by the displacement of this shock wave over time. This is due to two main facts; firstly, the flow velocity upstream of the reflected shock is higher than the propagation velocity of the shock wave. Consequently, the flow downstream of the shock wave is driven by the prior motion of this shock wave. Secondly, the displacement of the reflected shock is non-uniform along the shock wave with the reflected shock tilting toward the jet center line, driven by the convection of the vortex ring. As the vortex ring moves further away from the first triple point, the angle dictated by the first triple point and the one required from the part of the shock wave, which is embedded in the vortex ring (VRES), differ. Hence, a kink appears within the shock wave, which separates the reflected shock from the VRES. Due to the rotational motion of the reflected shock, a negative pressure gradient arises in the radial direction, from the jet core to the jet boundary. This pressure gradient increases with time, as the reflected shock extends and rotates further. Hence, the pressure becomes relatively low downstream of the reflected shock. Its minimum value occurs right below the kink. In contrast, the pressure downstream of the VRES is relatively high. This is mainly due to the nearly axial displacement of the shock wave, leading into large shock angles along the wave. Consequently, the pressure above the kink becomes much higher than below the kink, resulting in an abrupt pressure rise. As the abrupt pressure rise leads into the formation of a new shock wave (shocklet), the kink becomes a triple point. Finally, the shocklet, the reflected shock and the VRES forms the second triple point configuration of the transient supersonic starting jet.

IV. CONCLUSION

The dynamic evolution of a starting transient supersonic flow has been studied by utilizing numerical simulations and high-resolution high-speed schlieren measurements. It has been shown that for a sufficiently strong leading shock, the interaction of the secondary shock system with the VRES will result in the formation a second triple point. Experimental evidence is provided for the presence of a second triple shock configuration along with a shocklet between the reflected shock and the slipstream, which results in the formation of further KH vortices.

A simple model was developed based on 1D shock relations, in an attempt to determine the source of pressure distributions in the flow which could give rise to the shocklet. A comparison of the output of this model to the results of the numerical simulations suggested that the shocklet forms due to a different mechanism than the classical Mach reflection responsible for the first triple point.

The formation of the second triple point is initiated by the transient motion of the reflected shock, which is induced by the convection of the vortex ring. As the vortex ring overtakes the Mach disk, the part of the reflected shock next to the core begins to tilt, while the outer part of the shock propagates almost uniformly further downstream. Consequently, a kink appears in the reflected shock, separating the reflected shock from the vortex ring embedded shock. Downstream of the reflected shock a negative pressure gradient in radial direction occurs, which is caused by the rotational motion of the reflected shock wave. This pressure gradient region grows in size and strength, as the reflected shock elongates and rotates further. Hence, the pressure just below the kink decreases with time. In contrast, the pressure downstream of the vortex ring embedded shock, particularly in the vicinity of the kink, is relatively high. Therefore, an abrupt pressure rise along the kink takes place. The kink becomes a triple point, while the abrupt pressure rise results in the formation of a new shock wave.

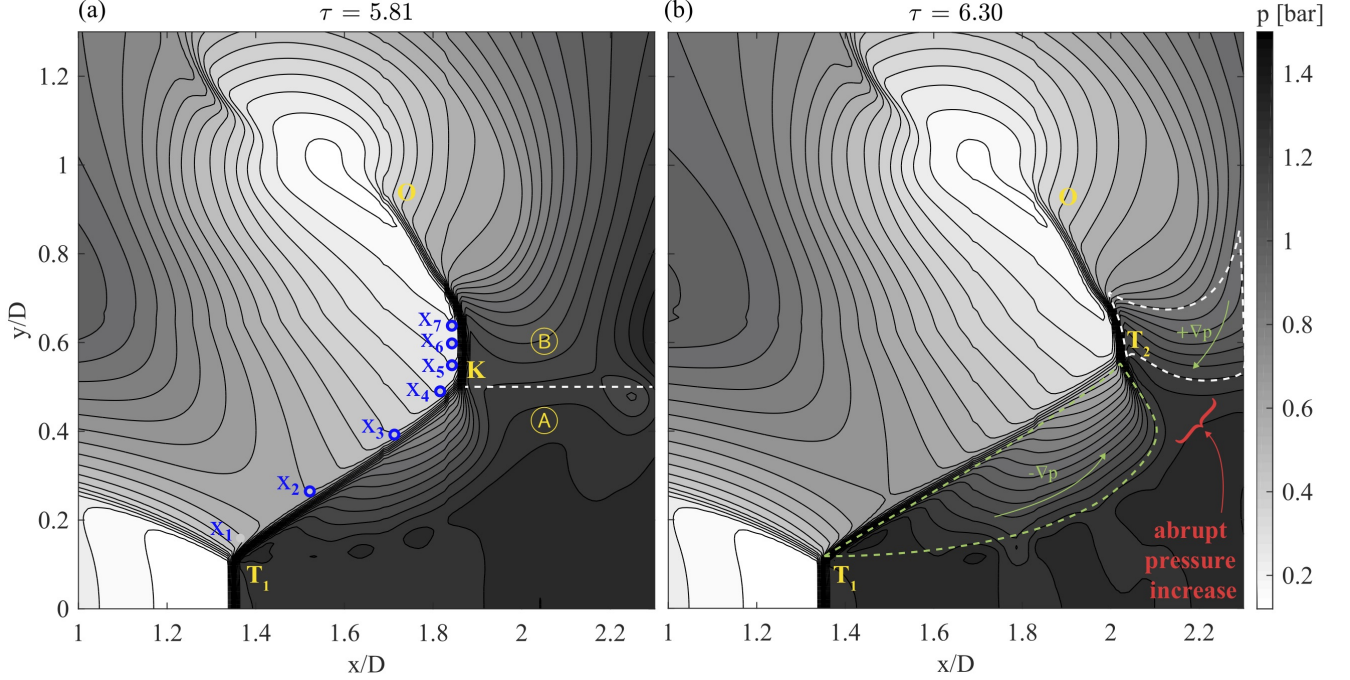

FIG. 15: (a) pressure distribution at $\tau = 5.81$ as derived from the numerical simulations at constant inflow conditions with $Ms = 1.71$. T_1 and O represents the first triple point and the tail of the VRES. The TOS model is applied for x_1 to x_7 . The result of the TOS analysis is given in table IV. (b) pressure distribution at $\tau = 6.30$.
