Study of Non-Uniform Channel Polarization and Design of Polar Codes with Arbitrary Rates

Robert M. Oliveira and Rodrigo C. de Lamare

Abstract—In this paper, we present the concept of non-uniform channel polarization and a scheme for rate-compatible polar code construction for any codeword length using additive white Gaussian noise (AWGN) channels and the successive cancellation (SC) decoder. A Non-Uniform Polarization technique based on the Gaussian Approximation (NUPGA) is developed and an efficient rate-compatible design technique is devised and the partial order for designing universal polar codes, which performs as well as GA but with much lower complexity.

In [7] and [8] we have a comparative study of the performance of polar codes constructed by various construction techniques using the AWGN channel and the successive cancellation (SC) decoder. Construction of polar codes based on AWGN channel and GA have been reported in [9] and [10]. In Fig. 1, we observe that its performance is comparable to that of the GA and MC methods. For $n \leq 8$ and $R = 1/2$ the GA and MC construction methods have the same result. Because of its low complexity, the GA method is widely adopted as a cost-effective design alternative for the construction of polar codes and is therefore used in this work.

I. INTRODUCTION

Polar codes, introduced by Arikan [1], were proved to achieve the symmetric capacity of binary input symmetric discrete memoryless channels (B-DMCs) under a Successive Cancellation (SC) decoder as the codeword length goes to infinity. Polar codes are based on the phenomenon of channel polarization. The channel polarization theorem states that, as the codeword length $N$ goes to infinity, a polarized bit-channel becomes either a noiseless channel or a pure noise channel. The information bits are transmitted over the noiseless bit-channels and the pure noise bit-channels are set to zero (frozen bits). The construction of a polar code involves the identification of channel reliabilities values associated to each bit to be encoded. This identification can be effectively performed for a code length and a specific signal-to-noise ratio.

Among the most well-known code construction techniques are the Bhattacharyya-based approach of Arikan [1], the Density Evolution (DE) schemes of Mori [2], [3] and Tal [4], the Gaussian Approximation (GA) technique of [5] and the Polarization Weigh (PW) algorithm [6]. The Bhattacharyya parameter-based approach that was proposed by Arikan along with Monte-Carlo (MC) simulations to estimate bit channel reliabilities [1]. The DE method proposed in [2] and [3] can provide theoretical guarantees on the estimation accuracy at a high computational cost. Extending the ideas of [2],[3], Tal [4] devised two approximation methods by which one can get upper and lower bounds on the error probability of each bit-channel efficiently. Since DE includes function convolutions, its precision is limited by the complexity. A bit-channel reliability estimation method for additive white Gaussian noise (AWGN) channels based on GA of DE has been proposed in [5], giving accurate results with limited complexity. The PW algorithm [6] is a recent attempt to study the construction of polar codes and is therefore used in this work.

For a generalization of the construction of polar codes, we recall that the code length $N$ of standard polar codes is limited to powers of two, i.e., $N = 2^n$. To obtain any code length, puncturing, shortening or extension are typically performed. A review on puncturing and shortening techniques can be found in [11], which include designs based on the weights of the generator matrix [12] and a polarization-driven criterion [13]. In practice, the design of the code is made for $N = 2^n$ and rate-compatible code design techniques use a specified criterion for shortening, puncturing or extension to generate a codeword that is $2^{n-1} < N' < 2^n$. The noiseless channels of the resulting codeword are then chosen so that the original order of channel polarization is kept unchanged [13].

In this paper we present the concept of non-uniform polarization, which allows the construction of rate-compatible...
polar codes considering the polarization of channels with arbitrary distribution of the Bhattacharyya parameter. The original construction of Arikan \cite{Arikan2009} considers a unique Bhattacharyya parameter to all channels, which we call uniform polarization. We develop a Non-Uniform Polarization technique based on the Gaussian Approximation (NUPA) for designing rate-compatible polar codes of arbitrary length. In the proposed NUPA technique the shortened channels are polarized for a more efficient choice of noiseless channels. Simulations compare the proposed NUPA technique with existing approaches.

The rest of the paper is organized as follows. In Section II, we present a brief introduction to polar codes, outline our notation, and describe the encoding and SC decoding of polar codes. In Section III, we review the principles of polarization theory of polar codes. In Section IV, we discuss the non-uniform polarization of polar codes and show that the definitions in the previous section remain valid. In Section V, we give a detailed description of the proposed NUPA technique along with the pseudo-code for its implementation. We present our simulation results in Section VI and the conclusions in Section VII.

II. Polar Codes

In this section we present an introduction to polar codes. Using the notation proposed by Arikan \cite{Arikan2009}, we describe below the fundamental principles of the codes and decoders.

Given a B-DMC $W : \mathcal{X} \rightarrow \mathcal{Y}$, where $\mathcal{X} = \{0, 1\}$ and $\mathcal{Y}$ denotes the input and output alphabets, respectively, we define the channel transition probabilities as $W(y|x)$, $x \in \mathcal{X}$, $y \in \mathcal{Y}$. After channel combining and splitting operations on $N = 2^n$ independent uses of $W$, we get $N$ successive uses of synthesized binary input channels $W^{(i)}_N$ with $i = 1, 2, \ldots, N$. The $K$ more reliable sub-channels with indices in the information set $\mathcal{A}$ carry information bits and the remaining sub-channels included in the complementary set $\mathcal{A}^c$ can be set to fixed bit values, such as all zeros, for the symmetric channels.

A polar coding scheme is uniquely defined by three parameters: code-length $N = 2^n$, code-rate $R = K/N$ and an information set $\mathcal{A} \subset [N]$ with cardinality $K$. The polar encoding is performed on the constraint $x_i^N = u_i^N G_N$, where $G_N$ is the transform matrix of the parent code, $u_i^N \in \{0, 1\}^N$ is the source block and $x_i^N \in \{0, 1\}^N$ is the code block of the parent code. The source block $u_i^N$ is comprised of information bits $u_{A_i}$ and frozen bits $u_{A^c}$. The $N$-dimensional transform matrix can be recursively defined as $G_N = B_N F_2^\otimes n$, where $\otimes$ denotes the Kronecker product, $F_2 = \begin{bmatrix} 1 & 0 \\ 1 & 1 \end{bmatrix}$ and $B_N$ is the bit-reversal permutation matrix. Then, the codeword is transmitted to the receiver through $N$ independent channels.

Having known the past decoded bits $\hat{u}_i^N = (u_1, \ldots, u_N)$ and received sequence $y_i^N = (y_1, \ldots, y_N)$, the likelihood ratio (LR) message of $u_i$, $LR(u_i) = \frac{W_N^n(y_i^N, u_i^{N-1})}{W_N^n(y_i^N, \hat{u}_i^{N-1})}$, can be recursively calculated under the successive cancellation (SC) decoding algorithm \cite{Arikan2009}. Then, $\hat{u}_i$, an estimated value of $u_i$, can be computed by:

$$f(x) = \begin{cases} h_i(y_i^N, \hat{u}_i^{N-1}), & \text{if } i \in \mathcal{A}, \\ u_i, & \text{if } i \in \mathcal{A}^c. \end{cases}$$

where $h_i : \mathcal{Y} \times \mathcal{X} \rightarrow \mathcal{X}$ is decision function:

$$h_i(y_i^N, \hat{u}_i^{N-1}) = \begin{cases} 0, & \text{if } W_N^n(y_i^N, u_i^{N-1}, 0) \geq W_N^n(y_i^N, \hat{u}_i^{N-1}, 1) \\ 1, & \text{otherwise.} \end{cases}$$

for $y_i^N \in \mathcal{Y}^N$, $\hat{u}_i \in \mathcal{X}^{i-1}$.

Let $K$ denote the number of information bits. Let $N$ denote the code length of the basic polar codes, and let $M$ denote the code length of the shortened polar codes, where $K < M < N$. Let $P$ denote the shortening pattern, which is the index set of the shortened bits, and $|P| = N - M$ denote the number of shortened bits. The code rate $R$ of the shortened codes is $R = K/M$.

III. Uniform Polarization Channel: Arikan Construction

In this section we present the basic concepts of channel polarization when the identical channel is considered. Let $W : X \rightarrow Y$ denote a general symmetric binary input discrete memoryless channel (B-DMC), with input alphabet $X = \{0, 1\}$, output alphabet $Y$, and the channel transition probability $W(y|x)$, $x \in X$, $y \in Y$. We write $W_N$ to denote the channel corresponding to $N$ uses of $W$: thus $W_N : X \rightarrow Y$ with

$$W_N(y_i^N|x_i^N) = \prod_{i=1}^{N} W(y_i|x_i)$$

The channel mutual information with equiprobable inputs, or symmetric capacity, is defined by \cite{Arikan2009}

$$I(W) = \sum_{y \in \mathcal{Y}} \sum_{x \in \mathcal{X}} \frac{1}{2} W(y|x) \log \frac{W(y|x)}{\frac{1}{2} W(y|0) + \frac{1}{2} W(y|1)}$$

and the corresponding reliability metric, the Bhattacharyya parameter is described by \cite{Arikan2009}

$$Z(W) = Z_0 = \sum_{y \in \mathcal{Y}} \sqrt{W(y|0)W(y|1)}$$

For any B-DMC $W$, we have

$$\log \frac{2}{1 + Z(W)} \leq I(W) \leq \sqrt{1 + Z(W)^2}$$

Applying the channel polarization transform for $n$ independent uses of $W$, after channel combining and splitting operation we obtain the group of polarized channels $W_n^{(i)} : X \rightarrow X \times X^{i-1}$, $i = 1, 2, \ldots, n$, defined by the transition probabilities

$$W_n^{(i)}(y_i^{(1)}, u_1^{(i-1)}|u_i) = \sum_{u_{i+1}^{n-1}} \frac{1}{2^n-1} W_n(y_i^n|u_i^n)$$

where $N = 2^n$ is the code length.

Channel polarization is an operation by which one manufactures out of $N$ independent copies of a given B-DMC $W$.
and a second set of $N$ channels $W^{(i)}_N : 1 \leq i \leq N$ that show a polarization effect in the sense that, as $N$ becomes large, the symmetric capacity terms $I(W^{(i)}_N)$ tend towards 0 or 1 for all but a vanishing fraction of indices $i$.

Fig. 2. The Channel $W_2$

The recursion combines two independent copies of $W$ as shown in Figure 2 and obtains the channel $W_2 : X^2 \rightarrow Y^2$ with the transition probabilities

$$W_2(y_1, y_2|u_1, u_2) = W(y_1|u_1 \oplus u_2)W(y_2|u_2). \quad (8)$$

The construction tree used in channel polarization is shown in Fig. 3. Note that it considers a uniform value of the Bhattacharyya parameter that is represented in the tree by $W$.

Fig. 3. The tree process for the recursive channel construction.

For any B-DMC $W$, $N = 2^n$, $n \leq 0$, $1 \leq i \leq N$, the transformation $(W^{(i)}_N, W^{(i)}_N) \rightarrow (W^{(2i-1)}_2, W^{(2i)}_2)$ is rate-preserving and reliability-improving in the sense that

$$I(W^{(2i-1)}_2) + I(W^{(2i)}_2) = 2I(W^{(i)}_N) \quad (9)$$

Channel splitting moves the rate and reliability away from the center in the sense that

$$I(W^{(2i-1)}_2) \leq I(W^{(i)}_N) \leq I(W^{(2i)}_2) \quad (11)$$

$$Z(W^{(2i-1)}_2) \geq Z(W^{(i)}_N) \geq Z(W^{(2i)}_2) \quad (12)$$

The reliability terms further satisfy

$$Z(W^{(2i-1)}_2) \leq 2Z(W^{(i)}_N) - Z(W^{(i)}_N)^2 \quad (13)$$

$$Z(W^{(2i)}_2) = Z(W^{(i)}_N)^2 \quad (14)$$

The cumulative rate and reliability satisfy

$$\sum_{i=1}^{N} I(W^{(i)}_N) = NI(W) \quad (15)$$

$$\sum_{i=1}^{N} Z(W^{(i)}_N) \leq NZ(W) \quad (16)$$

IV. NON-UNIFORM CHANNEL POLARIZATION

In this section, we present the proposed non-uniform channel polarization construction through the use of non-identical channels, that is, with different Bhattacharyya parameters and generalize the equations of Section III.

If the channels are independent but not uniform, then $W^{(i)}_N: X(i) \rightarrow Y(i)$, as shown in Fig. 4, where we rewrite eq. (1) as

$$W^{(N')}_{N'}(y_1^{N'}|x_1^{N'}) = \prod_{i=1}^{N'} W^{(i)}(y_i|x_i) \quad (17)$$

Fig. 4. The non-uniform channel $W_{N'}$

We consider $N \rightarrow N'$ with the same cardinality and in such a way that their transition probabilities $W^{(i)}_N(y|x)$ and $W^{(j)}_N(y|x)$ may differ if $i \neq j$. A non-identical channel corresponds to a channel with different qualities. As in [1], given any B-DMC $W^{(i)}_N$ the same definitions of the symmetric capacity (2) and the Bhattacharyya parameter (3) are adopted as performance measures, and rewritten as

$$I(W^{(i)}_N) = \sum_{y \in Y} \sum_{x \in X} \frac{1}{2} |W^{(i)}_N(y|x)\log \frac{W^{(i)}_N(y|x)}{W^{(i)}_N(y|0) + \frac{1}{2}W^{(i)}_N(y|1)} \quad (18)$$

$$Z(W^{(i)}_N) = \sum_{y \in Y} \sqrt{W^{(i)}_N(y|0)W^{(i)}_N(y|1)} \quad (19)$$

We notice that the relation in (4) is equivalent and can be rewritten as

$$\log \frac{2}{1 + Z(W^{(i)}_N)} \leq I(W^{(i)}_N) \leq \sqrt{1 + Z(W^{(i)}_N)^2} \quad (20)$$

where (5) remains valid.

The proposed $W_2$ channel with the transition probabilities of (6) can be written as

$$W_2(y_1, y_2|u_1, u_2) = W^{(1)}_2(y_1|u_1 \oplus u_2)W^{(2)}_2(y_2|u_2) \quad (21)$$

and with the proposed transformation $(W^{(1)}_2, W^{(2)}_2) \rightarrow (W^{(1)}_2, W^{(2)}_2)$, we can rewrite (7) and (8) as

$$I(W^{(1)}_2) + I(W^{(2)}_2) = I(W^{(1)}_2) + I(W^{(2)}_2) \quad (22)$$

$$Z(W^{(1)}_2) + Z(W^{(2)}_2) \leq Z(W^{(1)}_2) + Z(W^{(2)}_2) \quad (23)$$

The rate in (9) and the reliability in (10) are described as

$$I(W^{(1)}_2) \leq I(W^{(1)}_2) \leq I(W^{(2)}_2) \quad (24)$$
We have modified (30) in order to make it applicable to arbitrary code lengths, with \( f = Z(W_{N_i}^{(2i-1)}) \) and \( g = Z(W_{N_i}^{(2i)}) \) according to Fig. 5:

\[
\begin{cases}
Z(W_{N_i}^{(2i-1)}) = \phi^{-1}(1 - (1 - \phi(Z(W_{n/2}^{(i)}))))^2 \\
Z(W_{N_i}^{(2i)}) = 2Z(W_{n/2}^{(i)})
\end{cases}
\]

The proposed NUPGA algorithm can be written as a generalization of the PCC-3 algorithm in [7], which employs the GA algorithm.

**Algorithm 1 Proposed NUPGA Algorithm**

1. **INPUT:** \( N, K, P \) and design-SNR \( EdB = (RE_b/N_0) \) in dB
2. **OUTPUT:** \( F \in \{0, 1, \ldots, N-1\} \) with \( |F| = N - K \)
3. \( S = 10^{EdB/10} \) and \( n = log_2 N \)
4. \( z \in R^N \), Initialize \( Z(W_{i}^{(1)})^N = 4S \)
5. Apply the shortening vector \( Z(W_{i}^{(1)})^N = [Z(W_{1}^{(1)})]^N \) and \( P \)
6. for \( i = 1 \) to \( n + 1 \) do
7. \( d = 2^{i-2} \)
8. for \( b = 1 \) do \( 2^{(i-1)} \) to \( N \) do
9. for \( k = 0 \) to \( d - 1 \) do
10. if \( Z(W_{k+b}^{(i-1)}) = 0 \) or \( Z(W_{k+b+d}^{(i-1)}) = 0 \) then
11. \( Z(W_{k+b}^{(i)}) = Z(W_{k+b}^{(i-1)}) \)
12. \( Z(W_{k+b+d}^{(i)}) = Z(W_{k+b+d}^{(i-1)}) \)
13. end if
14. \( Z(W_{k+b}^{(i)}) = \phi^{-1}(1 - (1 - \phi(Z(W_{k+b}^{(i-1)}))))(1 - \phi(Z(W_{k+b}^{(i-1)})))) \)
15. end for
16. end for
17. \( F = \) indices of smallest elements \( (z, N - K) \)
18. return \( F \)

As an example consider \( N = 4 \) and \( K = 2 \) and initially the scheme without shortening. Then we have that the non-shortening vector is \( P = \{1, 1, 1, 1\} \). The expected result for \( F = \{0, 1, 0, 1\} \). Now consider the shortening vector \( P = \{1, 1, 1, 0\} \). Then, the evolved bit channel capabilities are \( Z(W_{N_i}^{(i)}) = \{0.21, 1.64, 2.28, 0\} \) and the new information set \( F = \{0, 1, 1, 0\} \).

**VI. Simulation Results**

In this section, we evaluate the performance of the proposed NUPGA algorithm described in Section IV and compare it with the shortened polar code technique of [12], which is one of the most effective shortening techniques. We assess the Bit Error Rate (BER) and Frame Error Rate (FER) performances of the polar codes using BPSK for data transmission over an AWGN channel. We consider different shortened codewords, rates and variations of the SC decoder and the SC list (SCL) decoder. In Fig. 6 we show the performance under SC decoder as described in [11], whereas Fig. 7 show the performance under SC [13] with list size \( L = 16 \) and Fig. 8 shows the performance under Cyclic Redundancy Check (CRC) Aided list decoding (CA-SLC) [14] with list size \( L = 16 \) and CRC24.
In the first example, depicted in Fig. 6, we show the performance of the original Arikan’s polar codes with length $N = 512$, and their rate-compatible versions with $N' = 320$ and $K = 160$ using the approach of Wang [12] and the proposed NUPGA technique. In Fig. 7 we show the performance of a codeword of length $N' = 400$, $K = 200$ for the rate-compatible designs and CA-SCL with $L = 16$. In Fig. 8 we show the performance of a codeword of length $N' = 400$, $K = 50$, CA-SCL with $L = 16$ and CRC with $L = 24$. We can observe performance gain in all simulations, and the gain is higher in the low rate case, shown in Fig. 8.

![Fig. 6. Performance of polar codes with $N = 512$ and rate-compatible codewords with $N' = 320$ and $K = 160$.](image)

![Fig. 7. Performance of polar codes with $N = 400$, $K = 200$ and CA-SCL with $L = 16$.](image)

In future works, we will consider comparisons with various LDPC design [15], [16], [17], [18], [19] and decoding strategies [20], [21] and will examine the integration of the proposed NUPGA algorithm with multiple-antenna systems [22], [23], [24] for both transmit [25], [26], [27], [28] and receive processing [29], [30], [31], [32], [33], [34], [35], [36], [37], [38], [39].

![Fig. 8. Performance of polar codes with $N = 400$, $K = 50$ using CA-SCL with $L = 16$ and CRC = 24.](image)

**VII. Conclusions**

In this paper, we have proposed a rate-compatible scheme for constructing polar codes for any size using a non-uniform channel polarization technique. We have then developed the NUPGA code design algorithm based on the non-uniform channel polarization and the GA technique. The standard construction based on the polarization keyword with $N = 2^n$ is limited to the integer values $n$. With the proposed NUPGA algorithm we can design polar codes for any code length. Simulations illustrate the excellent performance of NUPGA for short codes.
