(Dated: August 24, 2020)

We considered the problem how to handle the exploding number of possibilities to be sorted into irreducible classes by using a clustering tool when its input capacity cannot accommodate the total number of the possibility. Concrete situations are explained taking examples of atomic substitutions in the supercell modeling of alloys. The number of the possibility sometimes amounts to \( \sim \) trillion being too large to be accommodate. It is hence not practically feasible to identify how many irreducible classes exist by straightforward manner even though there are several tools available to perform the clustering. We have developed a stochastic framework to avoid the shortage of capacity, providing a method to estimate the total number of irreducible classes (the order of the classes) as a statistical estimate. A prominent conclusion derived here is that the statistical variation of the number of classes at each sampling trial is working as a promising measure to estimate the order.

I. INTRODUCTION

It is an omnipresent task to classify a large number of data into some groups by individual attributes. Beyond the handling based on clear classification rules, the clustering driven by unsupervised learning techniques has well been developed [1–4]. An innately concomitant situation along the purpose of the clustering is the large amount of data to be classified. The larger it gets, the more accurate in general the statistical quality of the estimations becomes, showing the superiority of data science. However, the size of data can often be too large to be accommodated into a single clustering process. Let us set up the problem as follows: Suppose we have a clustering tool that can process up to \( l \) samples. The tool classifies \( l \) reducible samples (as input) into \( M(l) \) irreducible groups (as output) based on some attributes. Let the maximum possible number of the samples be \( L \geq l_{\text{max}} \), \( G = M(L) \) is the total number of the irreducible attributes that we want to know. However, we cannot identify \( G \) when \( l_{\text{max}} \ll L \) because of the limitation of the input capacity.

To illustrate the problem more concretely, let us consider a magnetic alloy, \( \text{Nd}_{1-x} \text{Ce}_x \text{La}_2 \text{Fe}_{14} \text{B} \), which is composed based on \( \text{Nd}_3 \text{Fe}_{14} \text{B} \) by substituting a part of Nd-sites with Ce or La. Supercell methods in \textit{ab initio} calculations are used to describe such atomic substitutions modelled as a periodic array of a cell structure. [5] The size of the cell (specified by how many Nd to be accommodated) is chosen so that the given concentration \((x, y)\) is captured by the ratio of the number of atoms. [5] To describe \( \text{Nd}_{0.9} \text{Ce}_{0.225} \text{La}_{0.075} \text{Fe}_{14} \text{B} \), 40 Nd-sites are substituted by nine Ce and three La. The number of possible atomic configurations in this case would amount to \( 40!/ (28!9!3!) = 1,229,107,765,600 = L \) (total reducible samples to be classified). These ‘raw’ configurations can further be classified into subgroups of \( G \) configurations based on the theoretical framework to identify equivalent structures under the symmetric operations. [6] The number of the subgroup, \( G \), gets reduced by several orders, typically \( G \sim 100 \) even for \( L \sim \) trillion. Once we identify \( G \), we can construct concrete \( G \) representative configurations as irreducible structures by a recursive way. Several packages in Materials Science provide such a tool to perform the classifications [7, 8] but their input capacity, \( l_{\text{max}} \), cannot handle such a large number of \( L \sim \) trillion.

The present study has worked on the problem to identify \( G \) even for \( l_{\text{max}} \ll L \). A stochastic method is proposed to identify \( G = M(L) \) utilizing a tool giving \( M(l) \) \((l \ll L)\) with \( l_{\text{max}} \ll L \). The method repeats the numbers of the sampling to calculate \( M(l) \), getting the statistics, \( M(l) \), by which it estimates \( G \). The estimation can be achieved in far fewer trials than \( L/l \), as shown in this study. For the above example of the classification of crystal structures, we note that there is more powerful, deterministic framework (Polya’s theorem), though the present method can handle it as well. However, the method described in this paper can handle a broader category of the problem. The method only relies on a tool to provide \( M(l) \), which can be a machine-learning tool to perform a clustering, where the classification rule is not necessary to be based on any clear principles like solid state physics, group theory etc. as in the example. When combined with existing clustering tools, the method can expand the scope of the tools beyond the limitation of input capacities (depending on the memory capacity in the computations).

If \( l_{\text{max}} \) can get around several times of \( G \), we will see the convergence of \( M(l) \rightarrow G \) to identify the number of irreducible groups \( G \), as shown in Fig. [1]. This strategy still re-
quires costs because, in general, it is laborious to identify whether a monotonic behavior has reached at the convergence, still requiring enough number of $l$. The method explained here gives a powerful breakthrough, providing another way to identify $G$ as a position of the peak of a measure. We derived that $V[M(l)]$ (the variance of $M(l)$) with respect to the random choice of $l$ members of reducible samples takes a maximum when $l \sim G$.

![Figure 1](image1.png)

**FIG. 1.** Estimation of the number of irreducible classifications ($M$) for given $l$ reducible samples. As $l$ increases to some extent, the estimated $M(l)$ gets converged into the true number $M(L)$ ($L$ is the maximum possible size of reducible samples). The plot is taken from the case of Nd$_{0.7}$Ce$_{0.25}$La$_{0.05}$Fe$_{14}$B.

**II. OUTLINE OF THE RESULTS**

To formulate the variance of $M(l)$, we shall introduce a probability for a set of $l$ samples to be sorted into $M$ irreducible classes, denoted as $P(l, M; G)$. The expectation value, $\bar{M}$, and its variance $V[M(l)]$ are then given as

$$\bar{M}(l) = \sum_{M=1}^{G} M \cdot P(l, M; G),$$

$$V[M(l)] = \sum_{M=1}^{G} (M - \bar{M}(l))^2 \cdot P(l, M; G).$$

For $l = 1$, the sample surely corresponds to an irreducible class, namely $\bar{M}(0) = 1$ regardless of the choice of the sample; hence $V[M(1)] = 0$. In another limit with larger $l$, we know the convergence $\bar{M}(L \to L) = G$, and hence $V[M(L \to L)] \to 0$. As such, we expect $V[M(l)]$ to have a maximum peak as a function of $l$ in the range of $1 < l < L$. We can actually derive that the $V[M(l)]$ has a peak at around $l \sim G$, shown as follows.

![Figure 2](image2.png)

**FIG. 2.** Plots of $l_0$ at which the variance $V[M(l)]$ has a peak. The results are obtained by numerical simulations with several different sizes $G$. For each $G$, we generated ten different cases of the multiplicities for each irreducible structure randomly. Then we naively picked up a sampling with $l$ to identify $M(l)$, and then evaluate the variance for each $l$ to get its behavior with a peak at $l = l_0$. The plot is observed to be scaling with $l_0(G) = G$ broken black line), leading to a conclusion that we can estimate $G$ from the position of the peak of $V[M(l)]$.

With the most simplified assumption that the size of each irreducible class (i.e., the number of elements inside each class) is identical, we can derive an asymptotic behavior,$$
P(l, G, M) \sim \left(1 - C \exp \left[\frac{G - M + 1}{G} (l - M)\right]\right) \times \exp \left[-\frac{G - M}{G} (l - M)\right],$$

$$C = \left(1 - \frac{G^{C_M} \cdot M!}{G^l}\right),$$

as given in the appendix, [VI A], [VI B] and shown in Fig. 5. By substituting this into Eq.(2), we can show that the variance $V[M(l)]$ has a peak around $l \sim (G + 1)$ (VI C). Even without such an assumption used in the analytical treatments, numerical verifications have shown that the conclusion is kept unchanged, as shown in Fig. 5. We can get a rough understanding that the $V[M(l)]$ has a peak at around $l \sim G$ from a schematic picture as shown in Fig. 3. For tiny sizes of samplings, $l \sim 1, 2, \ldots$, we expect $M(l) = l$ with little duplications, specifying the raising up of the behavior at smaller $l$. The convergence, $M(l) \to G$, at larger $l$, then leads to the schematic behavior, as shown in Fig. 3. By vertical red arrows on the dependence $M(l)$, we schematically show the widths of variances around it. Since the maximum possible value for $M(l)$ is $G$, the tail of the variance cannot go beyond $M(l) = G$, and then the widest possible
FIG. 3. A schematic picture to show the variance of $M(l)$ would take a maximum at $l \sim G$. At fewer (larger) $l$, $M(l)$ is expected to behave like $M(l) = l \ (M(l) = G)$. Exact solution (red line) and approximated solution (blue line) of $M(l)$. These are derived from equation (6) and (3), respectively. Vertical red arrows schematically show the widths of variances around it. Since the maximum possible value for $M(l)$ is $G$, the tail of the variance cannot go beyond $M(l) = G$, and then the most widest possible tail would occur at the intersection $P$ in the figure, identified as $l = G$.

III. DISCUSSIONS

Though that’s still within the extent of a heuristic finding, we note that $10 \times V[M(l_0)]$ provides a quite reliable estimate for $G$ ($l_0$ denotes the peak position of $V[M(l_0)]$). As shown in Fig. 4, the estimate seems rather firm than another estimator, $l_0 \sim G$ in Fig. 2.

IV. CONCLUSION

We have formulated a stochastic framework to handle the vast number of samples ($L \sim \text{trillion}$) to be classified by any clustering tool to find out the total number of irreducible classes $G$. It is sometimes the situation we considered that $L$ is too large to be accommodated into the capacity of the input size of the tool because of the limitation of the memory- or file-size. Among $L$, the framework randomly picks up a set of samples with the size $l (\ll L)$ being affordable by the capacity, to be sorted by a clustering tool into $M$ classes. By repeating the sampling with varying the size $l$, we get the statistics $\{M(l)\}$. We have derived that the variance of $M(l)$ takes maximum at $l \sim G$. Though there is no rigid mathematical verifications, we heuristically found that $G$ is estimated as the quantity around ten times of $l_0$.

V. ACKNOWLEDGMENTS

The computations in this work have been performed using the facilities of Research Center for Advanced Computing Infrastructure at JAIST. VI. APPENDIX

A. Derivation of the probability

We denote the probability to get \( M \) irreducible classes after a clustering tool processes over \( l \) reducible samples as \( P(l, M; G) \), where \( l \) samples are randomly taken from a population having total \( G \) irreducible classes. The situation is equivalently described like 'distributing color envelops into \( l \) pigeonholes with one each, where an envelop has \( G \)-color variation, but only \( M \) (\(< G\)) colors are found over the pigeonholes’. Though the multiplicity for each color (i.e., the number of envelops with each color) is generally different each other, we put an assumption that the multiplicity is the same for each color. We can then evaluate \( P(l, M; G) \) in more simplified manner analytically, though we shall examine later whether the final conclusion is not so affected by the assumption. Letting the number of cases be \( a(l, M; G) \), the probability is written as

\[
P(l, M; G) = a(l, M; G)/ \sum_{i=1}^{G} a(l, i; G). \tag{4}
\]

It can be denoted that

\[
a(l, M; G) = G C_M \times F,
\]

where \( F \sim M^l \) (the most rude estimation). The rude estimation still includes the cases where the total colors over the pigeonholes gets less than \( M - 1 \). We have to exclude the cases as,

\[
F = M^l - \text{[total (M - 1) colors]} - \text{[total (M - 2) colors]} - \cdots - \text{[total one color]},
\]

so that the total number should be just \( M \). Noticing that [total \((M - k)\) colors] under the factor \( C_M \) just corresponds to \( a(l, M - k; M) \) [i.e., even providing \( M \) choices, \( l \) pigeonholes only amount to \((M - k)\) colors in total], we get

\[
F = M^l - \sum_{i=1}^{M-1} a(l, i; M),
\]

leading a recurrence,

\[
a(l, M; G) = G C_M \cdot \left[ M^l - \sum_{i=1}^{M-1} a(l, i; M) \right]. \tag{5}
\]

We shall analyze the recurrence further by the asymptotic evaluations as below. To check the asymptotic evaluations, we can come back to the recurrence relation above, generating a series \( a(l, M; G) \) by increasing \( M = 1, 2, \cdots \) in a straightforward manner.

The denominator of Eq. (4) is evaluated as,

\[
\sum_{i=1}^{G} a(l, i; G) = G^l,
\]
since each term under the summation corresponds to the case with 'just equals to $i$ colors', counting of which over $i = 1 \sim M$ amounts to the total cases of assigning $G$ colors into $l$ pigeonholes allowing any duplications ($= G^l$). $P(l, M; G)$ is therefore evaluated as

$$P(l, M; G) = gC_M \cdot \left[ M! - \sum_{i=1}^{M-1} a(l, i; M) \right] \over G^l, \quad (6)$$

under the assumption.

B. Asymptotic evaluations

We decompose the probability $P(l, M; G)$ ('just $M$ colors') into

$$P(l, M; G) = A(l, M; G) \cdot D(l, M; G), \quad (7)$$

where $A(l, M; G)$ is the probability to get 'more than $M$ colors ($\geq M$)', while $D(l, M; G)$ denotes the rate to get $M$ over the possible range of ($M \sim G$) for $A$. $D(l, M; G)$ is easily described as

$$D(l, M; G) = {a(l, M; G) \over \sum_{i=M}^G a(l, i; G)}. \quad (8)$$

Considering the complementary of $A(l, M; G) (\geq M)$, the $Q = (1 - A)$ corresponds to the case with [$\leq (M - 1)$]. If we define

$$Q(l, M; G) = \sum_{i=1}^M a(l, i; G) \over G^l, \quad (9)$$

the complementary relation is expressed as

$$A(l, M; G) = 1 - Q(l, M - 1; G), \quad (10)$$

where we intentionally shift the definition of $M$ for $Q$ so that the upper limit of the summation in Eq. (9) to be $M$.

Considering $Q(l + 1, M; G)$ based on Eq. (9), we get,

$$\sum_{i=1}^M a(l + 1, i; G) \over G^{l+1} = \left[ G \sum_{i=1}^M a(l, i; G) - (G - M) a(l, M; G) \right] \over G^{l+1}. \quad (11)$$

which is understood as follows: Imagine that the already existing $l$-pigeonholes include total $M$ colors, being corresponding to the first summation appearing in the nominator in the right-hand side. Multiplying $G$ to the summation means the counting all the possibilities for $(l+1)$-pigeonhole to have any color. That includes the cases with total $(M + 1)$ colors, those should be excluded since we are considering the cases with 'total $M$ colors' because of the argument of $M$ in $Q(l + 1, M; G)$. The part to be excluded is the product of $a(l, M; G)$ (the already existing pigeonholes have $M$ colors) times $(G - M) [l + 1$ pigeonhole gets a new color which is not found in the already existing pigeonholes]. With these meanings, we get the nominator of Eq. (11).

From the first term in the nominator of Eq. (11), we make up $Q(l, M; G)$ to get,

$$Q(l + 1, G, M) = Q(l, M; G) - \left[ (G - M) \over G^l \right] a(l, M; G) \quad (12)$$
as a recursion of $Q(l, M; G)$. Assuming the form,

$$\left[ (G - M) \over G^l \right] a(l, M; G) = \alpha(l, M; G) \cdot Q(l, M; G), \quad (13)$$

and that $l$ to be treated as if it is continuous variable, then we get a differential equation,

$$\partial Q(l, M; G) \over \partial l = -\alpha(l, M; G) Q(l, M; G) \quad (14)$$

From Eq. (13), the integrant $\alpha$ is asymptotically evaluated as,

$$\alpha(l, M; G) = \left[ (G - M) \over G^l \right] a(l, M; G) \sim \left[ (G - M) \over G \right] \sum_{i=1}^M a(l, i; G),$$

since the summation in the denominator is almost dominated by its leading term $a(l, M; G) \sim M^l$. This leads to an asymptotic form of $A(l, M; G)$ to be

$$A(l, M; G) = 1 - C \exp \left[ -\left( \left( G - (M - 1) \over G \right) \right) l \right]. \quad (15)$$

Similarly, we shall derive an asymptotic form of $D(l, M; G)$ via differential approximations, finally as given in Eq. (18) by considering $D(l + 1, M; G)$. We remind that the nominator and the denominator of Eq. (8) mean $\text{[Denominator; Number of cases with $(\geq M)$ colors] and $\text{[Nominator; Number of cases with $(= M)$ color]}$, respectively, where we are considering the total number of colors ($M$ or whatever) included over pigeonholes. Then we consider a newly added pigeonhole $(l + 1)$-th on the already existing ones $l$ pigeonholes. We have two possibilities for the new pigeonhole those, '(x) new one doesn’t gets a new color than those in the already existing pigeonholes' or '(y) new one gets a new color'. For the already existing pigeonholes, we sort the cases into three as 'a) the pigeonholes are getting $(1 - (M - 2))$ colors', 'b) getting $(M - 1)$ colors', and 'c) getting $M$ colors'. Since we are considering the cases with $(\geq M)$ only, the case (a) can be excluded from the present consideration [because it gives at most $(M - 1)$ color when $(a)^{(y)}$ occurs]. For (b) and (c), we finally get the conclusion that the contributions to $D(l + 1, M; G)$ are made as 'Denominator; [(c)+(b)+(y)]' and 'Nominator; [(b)^{(y)}+(c)^{(y)}](x)' as explained as follows. For the denominator $(\geq M)$, (c) contributes to it regardless of $(c)^{(x)} [= M]$ or $(c)^{(y)} [= (M + 1)]$. Its 'number of cases' is then

$$\text{Denominator[(c)] = } G \cdot \sum_{i=M}^G a(l, i; G),$$

where $G$ is the number of the color-choice for $(l + 1)$-th pigeonhole. For (b), only $(b)^{(y)}$ contributes with $M$ colors, as

$$\text{Denominator[(b)^{(y)}]} = [G - (M - 1)] \cdot a(l, M - 1; G).$$
where \([G - (M - 1)]\) is the possible choice for \((l + 1)\)-th one to have a new color not appearing in \(l\) pigeonholes. Total contributions for the denominator amount to

\[
\text{Denominator}[(c)+(b)^*(y)]
= G \sum_{i=M}^{G} a(l, i; G) + \{G - (M - 1)\} \cdot a(l, M - 1; G). \tag{16}
\]

Similar way of counting for the nominator (num. of colors = \(M\)) gives the result of contributions, 'Nominator[(b)^*(y)+(c)^*(x)]', where

\[
\text{Nominator}[(b)^*(y)+(c)^*(x)]
= \{G - (M - 1)\} \cdot a(l, M - 1; G) + M \cdot a(l, M; G). \tag{17}
\]

By technically separating the second term in the nominator as \(M = G - (G - M)\), we get

\[
a(l + 1, M; G) = \frac{Ga(l, M; G)}{G \sum_{i=M}^{G} a(l, i; G) + \{G - (M - 1)\} a(l, M - 1; G) + (G - M) a(l, M; G) + \{G - (M - 1)\} a(l, M - 1; G) + \sum_{i=M}^{G} a(l, i; G) + \{G - (M - 1)\} a(l, M - 1; G) + \frac{(G - M)}{G} a(l, M; G) + \frac{\{G - (M - 1)\} a(l, M - 1; G) + \sum_{i=M}^{G} a(l, i; G) + \{G - (M - 1)\} a(l, M - 1; G)}{G}}.
\]

Since \(a(l, M; G) \sim M\), we can neglect terms with \(a(l, M - 1; G)\) to get

\[
a(l + 1, M; G) = \frac{a(l, M; G)}{G \sum_{i=M}^{G} a(l, i; G) + \{G - (M - 1)\} a(l, M - 1; G) + \sum_{i=M}^{G} a(l, i; G) + \frac{(G - M)}{G} a(l, M; G) + \sum_{i=M}^{G} a(l, i; G) + \{G - (M - 1)\} a(l, M - 1; G) + \frac{(G - M)}{G} a(l, M; G) + \frac{\{G - (M - 1)\} a(l, M - 1; G) + \sum_{i=M}^{G} a(l, i; G) + \{G - (M - 1)\} a(l, M - 1; G)}{G}} ,
\]

leading to

\[
D(l + 1, M; G) = D(l, M; G) - \left(\frac{G - M}{G}\right) D(l, M; G).
\]

Regarding \(l\) being continuous, we get

\[
\frac{\partial D(l, M; G)}{\partial l} = -\left(\frac{G - M}{G}\right) D(l, M; G)
\]

\[
\therefore \ D(l, M; G) = \exp \left[-\left(\frac{G - M}{G}\right)(l - M)\right]. \tag{18}
\]

where the constant of integration is determined so that \(D(l, M = 1; G) = 1\) can be satisfied.

Substituting Eqs. \(15\) and \(18\) into Eq. \(7\), we get

\[
P(l, M; G) \sim \left\{1 - C \exp \left[-\left(\frac{G - (M - 1)}{G}\right)l\right]\right\}
\]

\[
\times \exp \left[-\left(\frac{G - M}{G}\right)(l - M)\right]
\]

as given in Eq. \(3\) in the main text. At \(l = M\), it reduces to

\[
P(l, M; G)_{l=M} = \frac{cC_M \cdot M!}{G^M} , \tag{19}
\]

where it corresponds to the counting of possible permutations of \(M\) chosen from \(G\) colors, leading

\[
C = \left(1 - \frac{cC_M \cdot M!}{G^M}\right). \tag{20}
\]

Since asymptotic evaluations have harmed the original normalization for \(P\), we again introduce a normalization factor,

\[
Z(l, G) = \sum_{M=1}^{G} P(l, M; G) , \tag{21}
\]

by using of which

\[
P'(l, M; G) = \frac{1}{Z(l, G)} \left\{1 - C \exp \left[-\left(\frac{G - M + 1}{G}\right)(l - M)\right]\right\}
\]

\[
\times \exp \left[-\left(\frac{G - M}{G}\right)(l - M)\right] , \tag{22}
\]

becomes the probability to be applied to Eq. \(2\) in the asymptotic region. As shown in Fig. 5 the asymptotic evaluation performs fairly well to reproduce the behaviors of original form. Comparisons between the asymptotic behavior (Approx.) and the original one of \(P(l, M; G)\) with \(G = 5\), as the functions of \(l\) with several different \(M\).
C. Identifying l = l₀ where the variance takes maximum

By using Eq.(22) to evaluate the variance, Eq.(2), we get

$$\frac{\partial}{\partial l} V[M(l)] = \frac{1}{Z^2} \left\{ \sum_{M=1}^{G} M^2 \left( \frac{\partial P}{\partial l} \right) - w \sum_{M=1}^{G} M^2 P \right\}$$

$$- 2 \bar{M} \left\{ \sum_{M=1}^{G} M \left( \frac{\partial P}{\partial l} \right) - w \sum_{M=1}^{G} MP \right\}$$

(23)

where we define

$$\bar{M} = \sum_{M=1}^{G} MP' = \frac{1}{Z} \sum_{M=1}^{G} MP$$

$$w = \sum_{M=1}^{G} \left( \frac{\partial P}{\partial l} \right)$$

and an approximation C \approx 1 is used. Since we can see as in the further appendix that P and its derivative under the summations in each term of Eq.(23) take steep peaks like \( \sim \exp(M - M₀)^2 \), we can evaluate them as

$$F_2 = \sum_{M=1}^{G} F(M) \cdot \frac{\partial P}{\partial l} \sim F(M₀^{(2)}) \cdot \frac{\partial P}{\partial l} = M₀^{(2)}$$

(24)

$$F_1 = \sum_{M=1}^{G} F(M) \cdot P(l, M; G) \sim F(M₀^{(1)}) \cdot P(l, M; G)$$

(25)

$$Z = \sum_{M=1}^{G} P(l, M; G) \sim P(l, M; G₀^{(0)})$$

(26)

For \( F_2 \), there are two peaks \( (M₀ = G \text{ and } l) \) as shown in Fig.3, leading

$$\sum_{M=1}^{G} F(M) \left( \frac{\partial P}{\partial l} \right) \sim F(G) \left( \frac{\partial P}{\partial l} \right)_{M=G} + F(l) \left( \frac{\partial P}{\partial l} \right)_{M=l}$$

(27)

By using an asymptotic evaluation of \( \partial P/\partial l \) given in Eq.(32), we get

$$\sum_{M=1}^{G} F(M) \left( \frac{\partial P}{\partial l} \right) = \frac{1}{G} \left[ F(G) + (G - l + 1) f(l) \right]$$

(28)

For \( F_1 \) and \( Z \), the derivations given in Fig.3 lead to

$$\sum_{M=1}^{G} F(M) P(L, M; G) \sim F(l - 1) \cdot P(L, M; G)_{M=(l-1)}$$

$$\sum_{M=1}^{G} P(L, M; G) \sim P(L, M; G)_{M=(l-1)}$$

(29)

By defining

$$P(l, M; G)_{M=(l-1)} \approx \left( 1 - e^{-\frac{l_{M-1}}{\bar{M}}} \right) e^{-\frac{(G-M_{M-1})}{\bar{M}}} =: g(l)$$

each term in Eq.(23) is evaluated as

$$Z \sim g(l), \quad \bar{M} \sim (l - 1), \quad w \sim \frac{G - l + 2}{G}$$

$$\sum_{M=1}^{G} MP \sim (l - 1) g(l), \quad \sum_{M=1}^{G} M^2 P \sim (l - 1)^2 g(l)$$

$$\sum_{M=1}^{G} M \left( \frac{\partial P}{\partial l} \right) \sim \frac{1}{G} \left[ G + (G - l + 1) l \right]$$

$$\sum_{M=1}^{G} M^2 \left( \frac{\partial P}{\partial l} \right) \sim \frac{1}{G} \left[ G^2 + (G - l + 1) l \right]$$

(30)

respectively. Substituting them into Eq.(23) leads to

$$\frac{\partial V}{\partial l} = \frac{1}{g(l)} \left[ \frac{G^2 + (G - l + 1) l^2}{G} - \frac{(G - l + 2)(l - 1)^2}{G} \right]$$

$$- 2 (l - 1) \left[ \frac{G + (G - l + 1) l}{G} - \frac{(G - l + 2)(l - 1)}{G} \right]$$

$$= \frac{1}{G g} \left[ l^2 - (3 + 2G) l + (2 + 3G + G^2) \right]$$

$$\propto \left[ l - (G + 1) \right] / \left[ l - (G + 2) \right]$$

to get a conclusion that the variance has the maximum at \( l = (G + 1) \) or \( (G + 2) \).

D. Peaks of P and its derivative

Taking the the derivative of Eq.(3), the approximation,

\( (G - M + 1) \sim (G - M) \), leads to

$$\frac{\partial}{\partial l} P(l, M; G)$$

$$\sim \frac{1}{G} e^{-\frac{G - M}{\bar{M}}} \left[ 2 (G - M + 1) e^{\frac{G - M}{\bar{M}}} - (G - M) \right]$$

(31)

The factor \( e^{\frac{G - M}{\bar{M}}} \sim e^{M^2} \) takes its maximum value \( (= 1) \) at the peak otherwise vanishes steeply. The value is realized when \( M = G \) or \( M = l \), accompanied by the value of the derivative,

$$\frac{\partial}{\partial l} P(l, M; G) \sim \frac{1}{G} [(G - M) + 1]$$

(32)

to be picked up from the summation as the product with the \( F(M) \) in Eq.(27).

With \( (G - M + 1) \sim (G - M) \) again applied to Eq.(3), it leads to

$$P(l, M; G) \sim \left( 1 - e^{-\frac{G - M_{M-1}}{\bar{M}}} \right) e^{-\frac{G - M_{M-1}}{\bar{M}}}$$

Taking \( \partial P/\partial M = 0 \) to get the condition for the peak, we obtain

\( (G - M) (l - M) = G \cdot \ln 2 \)

\( M^2 - (l + G) M + G (l - \ln 2) = 0 \)
To simplify the factorization, we take further approximations on the term $G(l - \ln 2)$ as $G \sim (G + 1)$ and $\ln 2 \sim 1$, getting

$$M^2 - (l + G)M + (G + 1)(l - 1) = 0,$$

which is easily factorized as

$$[M - (G + 1)][M - (l - 1)] = 0.$$

This provides a conclusion that the peak occurs at $M \approx (l - 1)$, leading to Eq. (29) [another root, $M = G + 1$, does not match with the setting of the problem, $M < G$].
