

ARTIFICIAL INTELLIGENCE APPROACH TO MOMENTUM RISK-TAKING

IVAN CHEREDNIK, UNC CHAPEL HILL [†]

ABSTRACT. We propose a mathematical model of momentum risk-taking, which is essentially real-time risk management focused on short-term volatility of stock markets. Its implementation, our fully automated momentum equity trading system presented systematically, proved to be successful in extensive historical and real-time experiments. Momentum risk-taking is one of the key components of general decision-making, a challenge for artificial intelligence and machine learning with deep roots in cognitive science; its variants beyond stock markets are discussed. We begin with a new algebraic-type theory of news impact on share-prices, which describes well their power growth, periodicity, and the market phenomena like price targets and profit-taking. This theory generally requires Bessel and hypergeometric functions. Its discretization results in some tables of bids, which are basically expected returns for main investment horizons, the key in our trading system. The ML procedures we use are similar to those in neural networking. A preimage of our approach is the new contract card game provided at the end, a combination of bridge and poker. Relations to random processes and the fractional Brownian motion are outlined.

Key words: *news impact, decision-making, risk management, stock market, short-term volatility, momentum trading, fractional Brownian motion, artificial intelligence, machine learning, neural networks, cognitive theory, behavioral finance, card games, Bessel functions, hypergeometric functions*

1. INTRODUCTION

1.1. Objectives and tools. We propose a new theory of momentum risk-taking, which is basically real-time risk management, one of the key components of general decision-making. We focus on momentum risk-taking, *MRT*, when our decisions must be fast and mostly short-term. This is a development of "thinking fast" from [Ka]. Stock markets are the key to us; a new approach to short-term volatility and high frequency trading is the main theoretical result of this paper. Its implementation is a momentum trading system, which was extensively tested in stock markets, including real-time trading. The discussion of its performance is an important part of the paper. Stock markets provide a unique opportunity to test our theory, but the core mechanisms of *MRT* seem quite universal, well beyond investing. We will argue that *MRT* is a major purpose of any intelligence (not only with humans). Our results indicate that modeling such mechanisms is within the reach of artificial intelligence systems; they can be natural "ends" and also indispensable research "means", as we try to demonstrate.

We propose a new continuous mathematical model of news impact on share prices, and then describe its "stratified discretization", necessary to deal with discontinuous functions. The news impact of a single event is basically t^r in terms of time t with fractional powers (exponents) r multiplied by proper functions in the form $\cos(A \log(t) + Bt)$. The $\log(t)$ -periodicity here resembles that of Elliot waves. The t -periodicity is related to profit taking, which we associate with the asymptotic periodicity of Bessel functions. Mathematical understanding profit-taking is of obvious importance in the theory of market volatility; see e.g. [ACH, EN, FL, FPSS] concerning the latter. Hypergeometric functions serve the case of two events, which is connected with certain types of hedging. Generally basic (difference) hypergeometric functions appear here, but we stick to continuous models in this part of the paper.

As any theory, our one must be checked experimentally. Stock charts are the main examples for us; stock markets are quite a test for any risk-management theories. An obvious problem is that such charts are discontinuous, so the differential equations must be replaced by difference ones. Novel approaches to the discretization appeared necessary; cf. [ChS]. We restrict ourselves with relatively short time periods after the event; high volatility right after the news is mostly avoided. Then the core of our approach is the usage of tables of bids, which is based on ranked collections of sample time-forecasts for different time-horizons.

Given a chart, these tables provide a short-term prediction of its evolution, which involves the prior behavior in some "non-linear" way; cf. [Gu]. Forecasting here is not on the basis of derivatives of charts or their difference counterparts, though they are of course employed. The

usage of "global factors" and prior experience is the key for us, which is no different from the way our brain works.

Our tables are actually similar to bidding tables in contract card games, though the role of time, the non-linearity of our tables, and some other features have no counterparts with cards. In the realm of stock markets, the tables determine optimal horizons, expected durations of the investments, and also provides the corresponding short-term forecasts for the share-prices. We think that our brain "employs" similar auction-type procedures when risk-taking, so such *bidding tables* are universal well beyond playing cards and trading stocks.

A usual approach to understanding the ways our brain works is via carefully designed experiments, which are mostly focused on very specific, basic, simplified and sometimes artificial tasks. However, the simpler the challenges the more special and primitive tools our brain invokes. So laboratory experiments can generally clarify only very basic features; they are games in a sense. With any game, our brain readily switches to the corresponding optimal thinking mode, at least upon some training; we are very good with this. So the experiments mostly measure our ways to play this particular game. The risks must be as real as possible to force our brain to use its full potential, which is hardly possible in experiments. Real behavior of people is difficult to recreate in artificially designed situations, even well crafted.

It seems that the most promising, if not the only, rigorous approach to understanding risk-taking and other processes of this kind is to do our best with creating artificial intelligence systems and then comparing their decisions in real situations with those of people. Of course the "super-aim" here is to reach some "superhuman" levels, but even any "simple" reproduction of our real behavior is a breakthrough.

The automated momentum trading system based on our approach can be seen as a step in this direction; it is discussed in the second part of this paper. Its preimage is a new contract card game presented at the end. By design, this system uses only share-prices; i.e. it operates only on the basis of the technical analysis. So it is inevitably "late" with any decisions vs. professional traders and investors, and is subject to the bid-ask spread and many other factors reducing profitability. In spite of such disadvantages, the system proved to be profitable, which is some justification of our approach. The success of any AI system can be of course only an *indirect* confirmation of its principles.

We discuss the main features of our trading system in the paper and provide some typical results of its performance. Designing historic experiments was a serious consideration, to prevent the usage of any kind of "future". At least, this is impossible with real-time trading, where the system was tested systematically (with about 1000 companies). The results we provide can supply those who will implement

our approach and the tables practically with some benchmarks. We think that the *pont-tables* from Section 4.3 can significantly help to understand and get used to the *2-bid tables* from Section 3.3.

Importantly, we can always "explain", interpret to be exact, the trades our system makes; our system is not a black box and can shed light on the risk-taking preferences of the traders. This provides some *quantitative* model of "thinking fast" from [Ka]. Traders must quickly react to many unknown factors, which creates some special *market intuition* of obvious interest to cognitive theory and behavioral finance.

1.2. Organization of the paper. In the current section, we describe our approach and discuss its general origins, including risk-management and cognitive theory. *Momentum risk-taking* is essentially short-term forecasting based on whatever information available (frequently incomplete). We demonstrate that it can be modeled mathematically. Due to our focus on professional trading, we can disregard the *expected utility hypothesis* originated by Daniel Bernoulli, the asymmetry between loss and gain from *prospective theory*, and similar. The market agents are assumed to act "rationally" on the basis of the current news impact, so the purpose of our AI system is to capture their preferences.

Section 2 is on our mathematical model of market news impact, based on systems of differential equations resulting in Bessel functions, hypergeometric functions, and their degenerations. These systems are closely connected with new tools in harmonic analysis and random processes. As a demonstration of the universality of our system, we show that it models well the tree growth in a *difference setting*.

The connection with *fractional Brownian motion* (*fBM*) is briefly discussed at the end of Section 2.4. Our *price-functions* are related to the standard deviations and *transition probability densities* of the corresponding processes, which provides a statistical framework for our approach. See [Che, GJR, GNR] and [Bo] concerning *fBM* in studying market volatility and *power-laws* for price functions.

Using a single *fBM* with small *Hurst exponent* as a model for a price function creates a theoretical problem with the existence of *arbitrage* (some kind of "free lunch") due to the negatively correlated increments. However, *mixed fBM* are arbitrage free, and anyway we are doing only relatively short time-intervals, where this concern is not quite relevant. The author thanks Patrick Cheridito for a discussion.

We mostly consider the impact of one-two events. Statistical ensembles of news are mathematically significantly more challenging. The corresponding stochastic processes are similar to those in [BC]. Also, our trading system provides some experimental support for our approach to modeling the impacts of *isolated* consecutive events. The "multi-dimensional" theory of ensembles of events seems difficult to check experimentally and use practically.

Section 3 contains a reasonably complete description of the algorithms of our *trading system*. The results of extensive experiments, including real-time trading serve two purposes. *First*, we provide evidence for power-laws for price functions with exponents depending on the investment horizons (say, can be 0.137 for day-trading). *Second*, we provide some performance *benchmarks* for those who will follow our approach in their own trading systems. Our system has many new features, including the simultaneous running its multiple variants (sometimes even with identical *opti-parameters* but with different entry points), simultaneous pro-trend and contra-trend trading, the usage of the results of optimization for creating *weights* of companies, and so on. Potential followers must know what to expect, theoretically and practically. We also explain how testing the system was performed.

We do not discuss much the *machine learning* procedures we employ, namely the optimization of parameters and creating the company weights. The discretization parameters, counterparts of *action potentials for neurons*, are the key for us, but there are also important *difference* counterparts of first and second derivatives of the charts we use for forecasting and trading. There is vast *ML* literature on entropy, information theory, Bayesian predictive method and generative adversarial networks, *GAN*. The latter approach is somewhat similar to our auction-type procedure, when different decision-making "bids" from different investment horizons contest with each other; cf. [DB, HS]. See also [SC] about some general perspectives of *deep learning*.

Since we deal with a limited number of *opti-parameters* (all of them have theoretical meaning), a relatively straightforward *gradient method* is mostly used for the optimization. It is rare when our AI system cannot find the parameters providing a *solid* jump in performance for almost any "education periods", though their uniqueness is of course not granted. This is for individual companies or portfolios. The weights of the companies we use are based on the prior optimization. We omit the discussion of the usage of correlations between equities in this paper, which is common in automated investing systems. The impact of our optimization-based weights can be significant, but using them generally restricts the trading volumes, which is a consideration for us.

Section 4 is exceptional. We motivate our *2-bids* by designing a contract card game, *pont*, combining the elements of *bridge* and *poker*. It adds poker-style uncertainty to the bridge-type auction. The contract is declared on the basis of 6 cards, but the hand can consist up to 9, which is determined by the declarer, the winner of the auction. Thus we add poker risk-taking to bridge-type bids, which is similar to *2-bids* in our trading system. It appeared that the players can easily get used to such "fractional bids"; the size of the hand is the denominator. It

is closely connected with our approach to discretization (the key in any neural networking); our *2-bids* are discrete, though the threshold is subject to optimization. The play (taking tricks) has nothing to do with stock markets: *pont* is just a game. However the play makes the bidding sufficiently non-trivial to consider *pont* as a model of real risk-taking; this is missing in poker, where there is no actual "play".

1.3. AI and risk-taking. The purpose of artificial intelligence (AI) systems is to perform tasks that require human cognition. Actually, the aim here is to *exceed* human decision-making abilities using computers and machine learning at full potential. Even if the quality of automated decisions is mediocre, the cost efficiency, speed and the broad range of applications can be "superhuman" and result in great societal and economic benefits. There is a lot of progress with *narrow AI*, focusing at special tasks. However we are decades away from *general purpose AI* according to the conclusion from "The National Artificial Intelligence Research and Development Strategic Plan (2019 update)" by the National Science & Technology Council (USA). Astonishing versatility and flexibility of human intelligence remains quite a challenge, and not only because our brain contains about 100 billion of neurons.

Decision-making is the key test for any AI systems. This is quite a complex process. *Risk management* is one of its important components, which is generally a system of protection measures aimed at reducing future risks. Here the focus is mostly on general adjustments, not on exact timing. There is a direct analogy with predicting earthquakes; even if potential places are known, we do not know when, especially in advance. See e.g. [FL] for various aspects of risk management, including high-frequency trading, and [EN] for mathematical aspects.

Momentum risk-taking can be then broadly defined as *real-time* risk management, prompt responses to events and developments, short-term forecasting. Here timing is the key, though a lot of prior knowledge and experience is needed; see e.g. [EN]. The events we are reacting to are mostly not really new; almost always they have occurred before. The problem is to address quickly their strength and other factors involved. Real-time monitoring the developments before and after our actions is an important part of risk-taking. The response can be required immediately, so it can be difficult to understand what really affected our decision. *Thinking fast, intuition, subconscious processes* are certainly involved; this can be not too transcendental, a special mode of our brain to quickly manage time-sensitive information.

If the subconscious processing the signals is essentially similar to the usual (rational) one, then risk-taking AI systems can be quite relevant. Moreover, if this is true, then using AI can help a lot to understand which kind of "thinking fast" and "intuition" is involved here; this alone is quite a motivation of the present paper and our project, without any

reference to stock markets. One of our main observations (based on machine modeling) is that *core risk-taking* is actually controlled by very few parameters. Moreover, these parameters seem to be of universal nature, though they are obviously adjusted to serve concrete situations.

Both findings can be seen in stock markets. As some confirmation of broad nature of risk-taking, the results based on the optimization of individual companies are *only modestly* better than the results based on the optimization performed for the groups, "portfolios", of companies. Generally, the greater variety of different risk-taking tasks you went through, games included, the greater your risk-taking skills. This sounds quite obvious, but is very difficult to implement in any automated systems; developing *general purpose* artificial intelligence systems is needed here, not just those focused on specific tasks.

1.4. Universality of MRT. Let us try to outline which *minimal tools* seem necessary for any risk-taking. This will be not a biological (neuroscientific) or philosophical discussion. We mostly rely on the fundamental mathematical nature of the corresponding differential equations. Our brain does many things; the *decision-making* is one of the key for our (any) intelligence. Many aspects of our intellectual activities has no or almost no clear connection with *risk-management*, however the origins of quite a few of them still have something to do with decision-making. Science is an obvious example. Even if some research directions are focused on highly abstract objects, the value and motivation of such research can be not just our curiosity or sense of fulfillment; almost any research is somehow related to decision-making, at least historically. Also, many aspects of our intellectual life that seem or are "artificial", say the games we design and play, serve a clear purpose of developing and training our decision-making abilities (social skills included), including preparing us for real risk-taking.

With this pragmatic understanding of intelligence, there must be no significant difference between humans, other creatures, and artificial systems. Here *long-term* risk-management is quite different. Unconditional instincts and reflexes are generally the key for such management in nature. Our ability to "rationally" plan long-term is of course a special and cultural phenomenon. This requires at least a highly sophisticated concept of time, among many other intellectual abilities unique for humans. Generally, anything about long-term forecasting and planning seems beyond what we can hope to model mathematically, especially for the processes with high uncertainty.

However, upon restricting ourselves with relatively short intervals and with *momentum risk-taking*, for short *MRT*, mathematical modeling seems much more doable. Almost any creatures have some basic concepts of time in this range, sometimes at the level of chemical and

physical processes. *Thinking* plays significantly greater role for short-term forecasting and performing the corresponding actions vs. instincts and reflexes; this is not only for humans. Though some special *MRT*-type intuition is of course heavily involved, humans included.

It is not impossible that the core mechanisms of *MRT* can be observed in the "neural architecture" of our brain. One of the main mechanisms is the well-studied *action potential*; its counterparts are the key for the discretization in this paper. The action-type procedures between different options are present too. We claim that there must be at least one more important component here. Mathematically, any decision making requires some *price-functions*. Such "functions" must be present somehow, but it can be difficult to understand how such functions can be practically formed and "stored" in our brain.

Recall that *MRT* is news-driven short-term forecasting and the corresponding risk-taking. Our brain does a lot of things. For instance, about 50 percent of the cortex is doing vision. Our model is naturally focused only on *newly emerged* events. After *news* is determined (which is quite a process), the brain must do its initial classification and invoke the corresponding *weight or rank* of this news within the current task, which is basically the expected significance. The weight is of course based on the prior experience, learning included; having it somehow is a must for any decision-making systems.

This is actually the key. We demonstrate that the differential (or difference) equations for the *news-function* alone is mathematically insufficient without adding the *price-function*. Only with these two functions and their interaction, the corresponding mathematical model becomes satisfactory. The *news-function* basically measures the resources (the number of neurons) currently involved in the analysis of a particular event. The *price-function* measures an expected importance of this particular event vs. other events and the corresponding *expected* brain resources needed for its analysis. The latter depends on the news-function: the greater the number of neurons currently involved in the analysis of the news, the greater its potential importance. The initial "price of news" will increase when the news generates the neural activities greater than it was expected. Vice-versa, when the current number of neurons involved approaches some expected levels (provided by the price-function), the news "fades". Its impact can still continue to grow, as well as the price-function, but the brain will then attempt to reduce the resources used for its analysis.

This sort of interaction is essentially the system of differential equation we suggest, which can be generally solved in terms of power-type functions and Bessel functions. Accordingly, the prediction is that the *price-function* must be somehow formed, constantly updated, and stored in the brain to be used again and again when the events of this

kind emerge. We claim that such 2-function "interaction", *the actually needed resources vs. those expected to be used*, is necessary for any kind of *MRT*. This is of course a mathematical prediction, but the simplicity and fundamental nature of the corresponding differential and difference equations is a strong argument in its favor. Actually, these equations are relatively new, though with strong connection with classical special functions. *Nonsymmetric* Bessel functions, Dunkl operators and other latest tools in harmonic analysis are involved here.

An example: driving. Brain activities while driving a car is a convenient example of "general" *MRT*. Permanent basic visual information is a must here, and even more such and similar information can be "requested" to provide for *MRT*. This is very resource consuming, much greater than *MRT* itself. Also, as with many tasks, driving can be combined with talking, listening radio, thinking about something etc.

The actual beginning of *MRT* is when our brain identifies *events*. They can be some turns or road curves, especially those requiring special attention, road signs, pedestrians, neighboring cars, navigation matters and so on; see e.g. [arXiv:1711.06976](#), [arXiv:1906.02939](#) on *self-driving cars*. Importantly, such *categories* of potential events are supposed to be analyzed constantly and simultaneously, even if the next *news* is or will be in a particular category. There is an almost exact analogy with trading stocks, especially when they are treated independently, the main regime for our trading system: *all* stocks considered for potential investing and investment horizons must be constantly monitored, regardless of the current or expected positions.

Only some *events* will reach in our brain the level of *signals*. The separation of the signals from *noise* is quite a problem, which requires a lot of prior experience. By *noise*, we mean "insignificant events", those that hardly require special consideration. After the signals are determined, our brain is supposed to estimate the resources needed for the analysis of the signal. This stage requires invoking from the memory the latest *price* of the event, which is essentially an estimate for the *expected* brain resources (neurons) needed for its analysis.

Then a systematic *analysis* begins, which can trigger the number of neurons significantly different from what was initially "allocated". This can be because of unexpected complexity of the event, due to changing its priority for driving and so on. The greater the neural activity, the greater the growths of the corresponding *price-function*. However, when the activity becomes beyond the projected *price-levels*, our brain will attempt to reduce the number of neurons involved.

The risk-taking is this *analysis* and the corresponding driving maneuvers (when needed). The rank (category) of the news and the intensity of its impact must be high enough for this "action", which is

similar to the usage of our *2-bids*. Our main assumption is that *short-term news impact grows polynomially with some fractional exponent*. This provides *predictions* for the intensity of the corresponding brain activities, which can be used to end or restrict our analysis when they drop below some *termination curves*. Similar to trading stocks, this can help to optimize the usage of the brain resources by switching to new events when the importance of the current ones begins to "fade".

1.5. Games as concepts. AI systems not always follow the ways of our brain, even if the problems are human-related. However *nature*, our brain included, is definitely the prime source of concepts for any AI. Just to give an example, the airplanes are very different from birds, but the *concept* of flying is from nature. This is no different for AI. *Narrow AI systems*, in specialized well-defined domains, can sometimes follow "non-human", ways. However general AI systems are expected to borrow a lot from human intelligence, though the final implementations can be quite different: "aircrafts vs. birds".

Importantly, many faces of decision-making are reflected in the *games* we play. Some include timing, some do not. For instance, solving puzzles and playing chess are not focused on timing, unless in tournaments. On the other hand, poker and contract card games are time sensitive. The interaction and risks in card games are as close as possible to real life, for models of course, which they are. Investing is obviously closer to playing poker than to playing chess or bridge. Poker's bidding is a great model of dealing with uncertainties, but the risks are too "mathematical" and the actual "play" is missing. Solid rules and protocols make stock market some kind of a game, but here the risks are more than real. From this perspective, it provides a highly developed and quite universal "model" of risk-taking, which is of obvious interest.

Psychologically, games reflect life in various ways, potentially preparing us for real challenges; we naturally discuss only "intellectual games". Some are designed to deal with real tasks; playing them can be more dangerous than life itself. Using game theory, especially mean field games, is quite common in financial mathematics; see e.g. [GLL]. From this perspective, one can look for the games reflecting our *concept* of momentum risk-taking. We found none and invented a new one, *pont*, which is essentially a version of bridge with poker-style bidding.

Stock markets by design mean that their "agents" look only to their own interests and to market prices [GLL], though investing is a complex and very much interactive process with solid grounds in our psychology. Nevertheless investing is a great confirmation of the universality of momentum risk-taking, *MRT*. It looks like there is some general purpose risk-taking *source code* in our brain in charge of *all* kinds of *momentum* risks, which constantly improves itself whatever the nature

of the risks and uncertainty. If this is true, then we can try to use AI to understand this code and to model it!

Philosophically, we test here Kant's antinomy 2 (*atomism*), by considering risk-taking as composite substance, and his antinomy 3 (*causal determinism*) concerning the variability of decision-making. We study stock markets as "an end in themselves", disregarding their economic and societal purpose for the sake of mathematical modeling.

1.6. Momentum investing.

Marshmallow test. A well-known test for children, "one marshmallow now or two in 15 minutes", is actually one of the origins of our modeling risk-taking in stock markets. The latest psychological experiments found limited support to the thesis that *delayed gratification* with children leads to better outcomes in their future [WDQ]. Waiting for 15 minutes here can be expected for those who have already learned that "patience is rewarded", but not for all and not always. Also, the 15 minute interval can be not that short for little ones. Their impatience can depend on the age, social and economic background; some can simply favor short-term approaches. If the interval increases (say, days), some uncertainty is added, or the reward is diminished, the "impatience" can be well justified; the problem is "how much?".

Similar to [Ka], we began with some analysis of psychological roots. A starting point of our research was a postulate that we have quite a rigid "table" of risk preferences in our brain. To give the simplest example, if the return was 1% today and you count on extra 1% tomorrow, then do not sell. However, if only a fraction is expected tomorrow and even this is not granted, then sell now and avoid extra risks.

This is very basic; and obviously the interval matters here. What justifies risks for a day-trader can be not acceptable to the traders with greater investment horizons. Of course, the better someone's trading experience the more realistic expectations, and many other factors are involved. However the mechanism in our brain that determines acceptable risks seems quite universal to us. To give a model example: 1.5 marshmallow tomorrow vs. 1 now "sounds reasonable". Indeed, the offer "2 tomorrow" is quite acceptable (for adults), but maybe just too good; however, receiving tomorrow only 1 makes no sense, since we can have it right now. So our brain possibly takes the average here, which makes 1.5 tomorrow a reasonable compensation for the delay.

The auction in *pont* does almost exactly this. For instance, the smallest bid during the auction is $3/6$ (3 from 6), which means that you are obliged to take 3 tricks with 6 card (your initial hand), or, upon the "increases", 4 from 7-8, or 5 from 9 (requesting up to 3 additional cards). So the *pont-bids are actually fractional*; the next bid is $4/7$,

where your contract (if you win the auction) must be 4/6, 4/7, 5/8 or 6/9. The number of cards in your hand and the number of taken tricks reflect respectively the duration of the investment and the return.

The play itself is of course *not* market-related; this is simply a way to validate your bid. In real investing, the "contract" means opening a position and the "play" is finding the moment of its termination. The resulting return is similar to the value of the contract. There are many successful ways to invest; picking one of them resembles very much bidding in card games, but real "timing" is not well reflected in card games. *Pont* somehow addresses this; it is a model of our approach to comparing returns for different durations of positions. Interesting mathematics is involved here, including Bessel and hypergeometric functions. This is not like "comparing apples and oranges", though our brain routinely compares everything with everything.

There are of course stock market features well beyond *pont*. For instance, the execution risks are connected with the investment risks [EF]. Also, opening short positions and terminations of long ones are based on the same *sell signals*, so they are related. Mathematically, *pont-bids* are linear (our tables are nonlinear), but it captures our method well.

Market implementation. The termination rules we use are based on *termination curves*. These curves are directly linked to forecasting share prices. The hierarchy of basic *pont-bids* discussed above is such a curve (with 4 points): 3 tricks from 6 cards, 4 tricks from 7 or 8 cards, and 5 from 9. As with cards, the discretization of stock market bids is necessary for our trading system to work. The separation of the signals from noise, which we do successfully, absolutely requires such a discretization. Stock market charts are discontinuous functions by their nature, especially short-term. Also, the discretization of bids is closely related to the discretization of time, which is inevitable for finding the optimal time range of investments (in hours, days, weeks).

We will argue below that the prediction and termination curves are of type $const \cdot t^r$, where t is time and r is some fraction (generally, below 1/2). This assumption matches well *momentum investing*, which can be defined as "investing on news". It works well for individual companies, portfolios of companies, market indexes, including SPY, the spider, and for commodities; it seems to us of quite general nature.

We note that the optimization becomes significantly more involved for our trading system when *strict hedging* was imposed, i.e. when for any open position, an equal amount is invested in the opposite direction in SPY or similar; see [BLSZ]. Theoretically, hypergeometric functions are needed here; using $\{t^r\}$ becomes too approximate. The system works, but the returns are less impressive. More generally, the correlations between companies are important; this is beyond the system we present, though we do the group optimization.

In our approach, we do not even try to evaluate the news itself. Its impact is measured through the response of the markets via stock prices and trading volumes. Thus, the parameters we find and use actually reflect *investor risk-taking preferences*, which can be expected sufficiently stable. The trading frequency is one of the main factors here; see for instance [AI, ChS, CS]. The risk preferences of day-traders are quite different from those of mutual funds. The challenge is that a stock can be involved in trading with different frequencies and horizons, which was addressed in our *bidding tables*. This is especially applicable to trading indices; see e.g. [FPSS, GTW]; all kinds of trading patterns can be present here, but our system mostly manages them well. See [Bo, DB] on using typical time scales.

The design of our trading systems included many special market twists. For instance, the counter-trend (contrarian) variants of our trading system frequently outperform pro-trend ones. We actually used both variants simultaneously, which is some kind of hedging. Counter-trend trading can be successful because of several reasons. Our system needs time to measure the impact of the news to be sure that this is not "noise"; large trade sizes are a consideration too (see [GRS]). Counter-trend trading is not unusual in stock markets [CK]. Let us mention here that the initial version of our trading system mostly relied on the intersections of termination curves with actual charts, changing the directions of positions correspondingly. It worked reasonably, but reacted slowly to fast market moves, which was improved via "start 2-bids", where we used the same curves to produce signals for opening new positions; this complimented well using the intersections.

To trade real-time, our system was designed completely automated, a must for any AI even if they are used interactively. See [CJP] concerning various aspects of automated high-frequency trading. We note that the trades of our system are fully *explainable*; it is not a "black box". Only such AI can be really *trustworthy*; see e.g. [HG].

Acknowledgements. I am very thankful to David Kazhdan, who greatly contributed to the success of this project at many levels. The trading system discussed in the paper was tested (improved many times) thanks to support and supervision by Alexander Sidorenko; I am very grateful to him. The author thanks Mikhail Khovanov for various suggestions and Jean-Pierre Fouque for his kind interest.

2. MODELING NEWS IMPACT

In this section, a simple mathematical model of short-term impact of news is suggested. News-driven fluctuations of share prices are the core examples. We come to certain linear differential equations, which can be generally solved in terms of hypergeometric functions. We focus on

elementary solutions only. They have market applications, which were extensively tested in various stock markets, including real-time experiments. There is another way to obtain essentially the same equations via random processes, but it will not be touched upon in this paper. See [EN]; e.g. compare their News Impact Curves with our ones.

2.1. Hierarchy of news. Let us briefly describe the types of company or industry news, which can be *primary* and *secondary*. The primary ones are basically *core* events and announcements. For instance, (a) new products or acquisitions, (b) significant changes of earning estimates by the company, (c) upgrades or downgrades by leading market analysts. Major sector, industry or economy news are of this kind too.

Almost any core news generates a flow of secondary news in the form of (highly correlated) reports, reviews, and commentaries. They mostly present the same core news, but sometimes can impact our behavior even greater than the original event. In our model, commentaries will be generally treated on equal grounds with the core announcements.

By *reports*, we mean analysts' reports on the core event including perspectives and predictions. Then *reviews* collect and present the main findings in reports, mostly aiming at professional investors. Finally, the news itself and the findings above reach all consumers via mass media mostly in the form of *commentaries*.

Importantly, consumers will be influenced by all primary and secondary news more or less regardless of the level, the "distance" from the actual event. The actual originality is not the point here. So the impact of the commentaries can be significant and quite comparable with the impact of the event itself.

2.1.1. The basic equation. We assume that *the impact of an event at the moment t is proportional to the t -derivative of the total number of pieces of news reflecting the event after it and before t* . The coefficient of proportionality $0 < c \leq 1$ will be called the *reduction coefficient*; it depends on time, but mostly it will be treated as a constant.

The value $c = 1$ can be reached right after the news, and then c tends to 0 with time, depending on the "investment horizon" (hours, days, months); cf. [DB]. Let us comment on this. Generally,

- (i) analytic reports and all secondary news tend to soften the expected implications of the core news,
- (ii) commentaries of all kinds disperse the original core news and diminish the expectations even further,
- (iii) the longer time passes after the core event and the core news, the smaller their impact becomes.

All three mathematically mean that the coefficient c approaches zero as $t \rightarrow \infty$. Indeed, putting news into perspective is the purpose of analysis and commentaries, but this almost always reduces the original

expectations. In the momentum investing, the impact of news fades faster for short-term investing vs. long-term. Approximately, if the trading positions are in days or weeks than $c \sim 1/2$ can be expected vs. $c = 1$ for months; it can be significantly smaller for high-frequency trading. Our tables provide some "natural" c -coefficients for different trading frequencies, investment *categories*.

From now on, *news will be represented by a positive or negative real number*, i.e. we assign a numerical value to it. Also, we assume that the time distribution of news is essentially uniform in the following sense.

Let $N(t)$ be the total sum of news values (positive or negative numbers) released from 0 to moment t . Then the number of pieces of news (their total value, to be exact) arriving from t to $t + \delta$ for some δ , i.e. $N(t + \delta) - N(t)$, equals approximately $c \cdot \delta \cdot N(t)/t$, which is δ times the reduced average of *all* previous news from 0 till t . The greater the intensity (time-density) of commentaries etc. triggered by an event, which is $N(t)/t$, the greater the number of *new* commentaries. We come to the following differential equation:

$$(2.1) \quad \frac{dN(t)}{dt} = \frac{c}{t} N(t).$$

It can be solved immediately if c is a constant: $N(t) = A t^c$ for a constant $A > 0$. When $c = 1$ the growth of $N(t)$ is linear, i.e. the event does not "fade" with time and continues to attract *constant* attention. We disregard that $N(t)$ can be bounded; adding the "saturation" will be addressed later. A physics-style argument in favor of this equation is its *self-similarity*: the solutions are multiplied by some constants when the time units change, and c does not depend on the choice of units.

Tree growth. Equations of this type can be expected to have many applications. Let us give one example. We will switch to a difference counterpart of (2.1), naturally adding minimal "maturity":

$$(2.2) \quad f_n - f_{n-1} = \frac{c}{n-2} f_{n-2} - \lambda f_{n-1} \quad \text{for } n > 2, \lambda \geq 0.$$

When $\lambda = 0$, this is a variant of the famous *Fibonacci recurrence* with the birth rate $\frac{c}{n-2}$, i.e. when it is inversely proportional to "time". The term $-\lambda f_{n-1}$ restricts here over-population by allowing "emigration".

Setting $\lambda = 0, c = 1$, the fundamental solutions are: $f_n^0 = n$, $f_n^1 = D_n/(n-1)!$, where D_n is the number of *n-derangements*, permutations of n elements without fixed elements. The second solution approaches n/e as $n \rightarrow \infty$, so both have linear growth at infinity. We argue that f_n in (2.2) basically describes the size of a tree at its n th year.

In contrast to the "Fibonacci rabbits", trees grow linearly at most. The corresponding $f_n - f_{n-1}$ is proportional to the corresponding f_{n-2} , where the coefficient of proportionality, "the birth rate", is roughly the surface area of the root system divided by the volume of the tree. I.e. it is approximately $r^2/r^3 = 1/r$, where the "radius" of the tree r can be assumed linearly depending on n . The radius is qualitatively about the same for the tree and its root system. It is proportional to the number of *tree rings*; we obtain $\frac{c}{n-2}$. This describes the "middle stage" of tree growth. In the beginning, the volume of the tree is rather r^2 than r^3 , so the tree can grow exponentially for a short period of time. Also, only the "active part" of its root system contributes to the growth, which eventually diminishes r^2 to r or so. Mathematically, this gives the term $\frac{c}{(n-2)^2}f_{n-2}$ in (2.2) and results in the saturation of the tree size at the late stage of its life cycle, which matches real tree growth.

This is somewhat parallel to the claim above that the *reduction coefficient* c for $N(t)$ tends to 0 when $t \rightarrow \infty$. We note here that the saturation here can be of course simply due to the upper bounds for $N(t)$ or f_n , i.e. not because of the "geometric" argument we suggested above (via the root area divided by the volume); see Section 2.3.

There are obvious differences between *news impact* and *tree growth*. For instance, adding $-\lambda f_{n-1}$ is secondary for trees (due to their aging or similar growth reductions), but this term is of fundamental importance for the news. It reflects "pricing news"; see Section 2.2. Surprisingly such different processes are quite similar mathematically, which clearly indicates that (2.1) and (2.2) are of universal nature.

Without going into detail, let us mention that solving (2.2) and similar difference Dunkl-type equations generally requires *basic* (difference) hypergeometric functions and their variants. This is actually a relatively recent direction; see e.g. [Ch1].

2.2. Adding price targets. So far we have not considered the following market-style response to news: when the news is already *priced in*, i.e. the current share-price already includes it, the effect of further (secondary) news goes down. Similarly, when the stock is considered underpriced, positive commentaries have greater impact. There is a specific market way to address this: *upgrades and downgrades*. They generally set new *share-price targets*. The main difference here from general news is the dependence on the current share-price. Generally, *upgrades*, are *all* market, company or equity news of any levels *addressing (depending on) the share-prices*.

Similar to $N(t)$, we represent *upgrades* by positive or negative numbers, using the notation $U(t)$ instead of $N(t)$. Thus $U(t)$, the sum of values of upgrades, depends on the share-price. The following normalization $u(t) = U(t)/U(0) - 1$ will be convenient below.

Let P_t be the share price and $p(t) = (P_t - P_0)/P_0$ be the rate of return from the price-level P_0 . The equation above must be corrected for $u(t)$, since $U(t)$ goes down if the share-price "sufficiently" went up after the event, i.e. the news is already *priced in*. Similarly, it goes up if the stock is considered undervalued. This correction can be assumed proportional to $p(t)/t$, the average rate of change of $p(t)$ from 0, which is more "balanced" vs. taking $dp(t)/dt$ here. Thus we arrive at the differential equation:

$$(2.3) \quad \frac{du(t)}{dt} = \frac{c}{t} u(t) - \frac{1}{\sigma t} p(t).$$

We note that the term $p(t)/t$ can be replaced by "more aggressive" $p(t)t^{\nu-1}$ for $0 < \nu \leq 1$; see system (2.20&2.21) below. For instance it means for $c = 0$: the longer $p(t)$ grows as $t^{\nu-1}$, the greater the number of downgrades. I.e. $p(t) \approx \text{Const } t^{1-\nu}$ is considered non-sustainable.

We will switch from now on from $N(t)$ to $u(t)$. Here σ is qualitatively proportional to the P/E or P/S . More generally, it reflects the expected growth of the company. Mathematically, σ is essentially as follows.

Let us assume that $p(t)$ is basically linear in terms of t and "shift" $t = 0$ to the moment when the company is rated "strong buy". For sufficiently large t , we can assume that $u(t) \sim U(t)/U(0)$ and ignore $u(t)/t$; so $u(t) \sim 1 - p(t)/\sigma$ and $p(t_{max}) = \sigma$ at $t = t_{max}$ such that $u(t)$, the current rating of the company, becomes 0. This moment of time, t_{max} , is when analysts change their stock ratings from "buy" to "neutral" on the basis of its price valuation. So σ is essentially the *relative price-target*, i.e. $\sigma \sim p(t_{max}) = (P_{targ} - P_0)/P_0$, where t_{max} is the moment of time when the news is fully priced in. We will make this analysis somewhat more rigorous in Section 2.3.

Now let us involve the differential equation for the share-price. Almost no company event or news influences the share-price directly; this depends on the way the market reads the news. The simplest news-driven equation for $p(t)$ is as follows:

$$(2.4) \quad \frac{dp(t)}{\sigma dt} = \frac{a}{t} u(t) + b \frac{du(t)}{dt}.$$

As with $N(t)$, here $u(t)/t$ is the *average upgrade* from the zero moment of time, which measures the *global* news impact from 0, essentially the commonly used consensus rating of the company shares. The term with $\frac{du(t)}{dt}$ is *local*: the response to the rate of change of $u(t)$ at t .

2.3. Logistic modification. Before further analysis, let us touch upon the modification of equation (2.3) under the assumption that the number of upgrades or downgrades is limited. Let $\tilde{U}(t)$ be the sum of ± 1 for upgrades and downgrades, an integer. The relation with $U(t)$ is basically as follows: $\tilde{U}(t) = [U(t)]$ for the integer part $[x]$ of real x .

Since $\tilde{U}(t)$ is bounded, let $u(t) = U(t)/U_{top} < 1$ for some bound U_{top} . Then (2.3) must be modified if we want to use it for sufficiently large t . Namely, we must multiply the right-hand side of (2.3) by $(1 - u(t))$, which reflects the "number of remaining commentators". One has:

$$(2.5) \quad du(t)/dt = (1 - u(t))\left(\frac{c}{t}u(t) - \frac{1}{\sigma t}p(t)\right).$$

In the absence of the price-term, it is a well-known *logistic equation*, with the following modification: the interaction coefficient is proportional here to $1/t$. When $p(t) \equiv 0$, it can be readily integrated.

Equation (2.4) remains unchanged:

$$(2.6) \quad \frac{dp(t)}{\sigma dt} = \frac{a}{t}u(t) + b \frac{du(t)}{dt}.$$

System (2.5)&(2.6) has no elementary solutions for $a \neq 0$. Let us solve it when $a = 0$, for *b-investing* in the terminology below. One has:

$$(2.7) \quad u(t) = (\beta + Bt^{r-\beta})/(r + Bt^{r-\beta}), \quad r = c - b,$$

$$(2.8) \quad p(t) = \sigma(bu(t) + \beta), \quad 0 \leq \beta < r, \quad B \geq 0.$$

If $B > 0$, then $u(0) = \beta/r$, $p(0) = \sigma c\beta/r$, $u(\infty) = 1$, $p(\infty) = \sigma(b + \beta)$.

Let us assume that $u(0) = 0$, i.e. the rating of the company is "neutral" at $t = 0$. Then $\beta = 0$, $p(0) = 0$ and $p(\infty) = (P_{targ} - P_0)/P_0 = \sigma b$. So σ is $(P_{targ} - P_0)/(bP_0)$ for the price-target P_{targ} , which matches the interpretation of σ from Section 2.2 for $b \sim 1$.

When $a \neq 0$, the system can be solved *numerically*, but it is not clear whether the corresponding solutions are more relevant than those obtained from the original system (2.3)&(2.4). This is especially true if we do not focus on large t , and the simpler the better! Also, the stochastic and discontinuous nature of price fluctuations restricts using differential equations here. Furthermore, a, b, c, σ can depend on time and do depend on the basic time-intervals, which is another reason to stick to the simplest assumptions.

Thus, we will continue with system (2.3)&(2.4). Furthermore, to address the discontinuous and discrete nature of share-prices, we will later switch from this system to "tables" of its "basic solutions". The main conclusion we will need from the analysis performed above is that

$(P_t - P_{t_0})/P_{t_0}$ after the news at t_0 can be assumed $\text{Const } (t - t_0)^r$ for some r for short, but not too short, time intervals $[t_0, t]$.

2.4. Investing regimes. Let us solve system (2.3)& (2.4). Recall that it describes fluctuations of share-prices under *news-driven investing*. Both a, b there are non-negative. The term $b du/dt$ in (2.4) or (2.6) is typical for "local" *pure momentum investing*, when only the *latest* upgrades are taken into account. The term $a u(t)/t$ reflects a more "global", balanced and less "aggressive" approach, when the average of *all* news values after the event is considered.

We call the case $b = 0$ *pure a-investing*, and the case $a = 0$ *pure b-investing*. If both terms are non-zero, it is naturally *mixed investing*. The greater $t - t_0$ after the major event at t_0 , the greater chances that *a-investing* dominates.

Equations (2.3) and (2.4) can be readily integrated. Substituting $u(t) = t^r$, the roots of the characteristic equation are:

$$(2.9) \quad r_{1,2} = d \pm \sqrt{D}, \quad d = (c - b)/2, \quad D = d^2 - a.$$

Accordingly, unless $D = 0$, the formula for $p(t)$ is as follows:

$$(2.10) \quad p(t) = C_1 t^{r_1} + C_2 t^{r_2} \quad \text{if } D > 0 \quad \text{for some constants } C_1, C_2,$$

$$(2.11) \quad p(t) = t^d (C_1 \sin(\sqrt{-D} \log(t)) + C_2 \cos(\sqrt{-D} \log(t))) \quad \text{if } D < 0$$

We will consider only $d > 0$. For negative d , $p(t)$ approaches zero for large t and therefore this is focused on "the final stage" of the impact of an event; our model and trading system are designed to serve mainly the beginning of this period. We also assume that c is a constant and that $0 \leq c \leq 1$, so $d \leq 1/2$. In fact, c slowly goes to zero as t increases and the impact of the event gradually diminishes, but we will not do large t . Similarly, c may be greater than 1 right after the major event, but this stage is disregarded too; this is addressed in our trading systems by proper "discretization".

Let us briefly discuss the oscillatory regime in (2.11). It can happen only for *a-investing* or for the mixed one. According to (2.11), the *quasi-period* in terms of $\log(t)$ is $2\pi/\sqrt{-D}$. So the durations of the oscillations form a geometric sequence. The magnitude will grow in time as a power function of degree $0 \leq d \leq 1/2$. If $b = c$, then $d = 0$ and the function $p(t)$ is bounded.

If the news is important for the share-price, a can be significantly larger than d^2 . Then $\sqrt{-D} \sim \sqrt{a}$, and the *quasi-period* for the *logarithmic time* $\log(t)$ is about $2\pi/\sqrt{a}$, which clarifies the role of a .

Let $d = 1/2$ for pure *a-investing* (when $b = 0$). This gives $c = 1$, i.e. the initial news-function $N(t)$ grows linearly. Then the p -function

behaves as a sum of random independent jumps of the share-price by σ or $-\sigma$ for proper σ , "heads or tails", distributed uniformly. So our equations have some statistical meaning; cf. [Gu].

For the pure b -investing with $b > 0$: $p(t) = C_1 t^{c-b} + C_2$ and its leading term is $C_1 t^{c-b}$, since $a = 0$ and $c > b$. By the way, $p(0)$ may be non-zero here; for instance, we can set $p(t) = (P_t - P_{t_0})/P_{t_0}$ for any point t_0 in equation (2.4).

Now let us assume that $c > 2b$, and let $\hat{b} = 0, \hat{a} = b(c-b)$. Then the corresponding \hat{D} is $(c/2 - b)^2$, $\hat{r}_{1,2} = c/2 \pm (c/2 - b) = \{c-b, b\}$, and $\hat{p}(t) = \hat{C}_1 t^{c-b} + \hat{C}_2 t^b$. Since $c-b > b$, the leading term here coincides with that from the previous formula. We conclude that for $c > 2b$, pure b -investing gives essentially the same as pure a -investing for proper a . This happens for sufficiently large t : then b eventually tends to zero.

The difference between these two regimes becomes significant only when $b < c < 2b$, i.e. during the middle stage of the "impact period". Indeed, the exponent r_1 cannot be made smaller than $c/2$ for a -investing. As to b -investing, $r_1 = c-b < b$ approaches zero when the news "fades" and the contribution of du/dt to p can be disregarded.

Discussion. The leading exponent r in t^r , which is r_1 in (2.10) and d in (2.11), satisfies $d \leq r \leq 2d$ for $d = (c-b)/2$. Here $r \sim 2d$ occurs when b -investing dominates. The lower bound $r \sim d$ can be reached only when a -investing is strongly present. If $b = 0$, then $r = c/2$ for sufficiently large a . Recall that the news-reduction coefficient c is generally from 0 to 1; it is close to 1 when the initial news-functions $N(t)$ grows linearly. Practically, the values $r < 0.5$ indicate short-term positions. If $c = 1$, then $r \sim 1$ only if $a \sim 0 \sim b$. Each type of investing has its own natural time-intervals, *prime time-units*, and its own typical average durations of positions. The time-unit can be from hours (or smaller) to months, it was mostly $2h$ in our trading system. Let us refer to [Bo] on power-laws for price functions, though are approach is different (we study short-term news impacts).

The C -constants above are essentially proportional to the value of the news and are related to the company *momentum volatility*, which depends on the investment horizons (reflected in the tables below). See e.g. [EN, ABL, FPSS]. The dependence of the volatility on the horizon is reflected in our tables below; it is connected with the exponent r . The t -periodicity due to *profit-taking* is an important factor here. Then the *stochastic volatility* can be generally modeled via *Bessel processes*, similarly to the usage of *fBM* discussed a bit below.

Connection to statistical framework. The leading term t^r of our $p(t)$ is the square root of the *variance* $\text{Var}(B^H)$ of the *fractional Brownian*

motion $B_H(t)$ (*fBM* for short) for the *Hurst exponent* $H = r$, where r is as above. It also appears in the self-similarity property of *fBM*: $B_r(ts) \sim t^r B_H(s)$. One can try to introduce generalized *fBM* for the *full* solutions from (2.11) or even for those from Section 2.6 below in terms of Bessel functions. A more systematic way to link our ODE to SDE is via the Kolmogorov-type equations for the *transition probability density*; see e.g. equation (1.7) from [Kat] for Bessel processes.

We refer to [Che, GJR, GNR] for the basic properties of $B_H(t)$ and their applications in financial mathematics; *fBM* is an important tool for modeling *volatility* of stock markets. A *qualitative* reason for the connection with our approach is that the expected (percent) growth of the share-price is essentially proportional to the standard deviation of the corresponding stochastic process. Another (essentially equivalent) connection goes via expected values of *options*. We will not discuss the passage to SDE any further in this paper; at least, it explains that r is closely correlated with the market volatility.

2.5. Two events, comments. The impact of two events at $-\tau < 0$ and 0 on the share-price $p(t)$ can be naturally described by the system

$$(2.12) \quad \frac{du(t)}{dt} = \frac{c_0}{t}u(t) + \frac{c_\tau}{t+\tau}u(t) - \frac{1}{\sigma(t+\tau)}p(t),$$

$$(2.13) \quad \frac{dp(t)}{\sigma dt} = \frac{a}{t}u(t) + b\frac{du(t)}{dt} \quad \text{for } c \stackrel{\text{def}}{=} c_0 + c_\tau.$$

When $c_\tau = 0$, it describes the case when there is no news at $-\tau$, but this moment is taken as the *support* for the price-target; generally, price-targets do depend on historical levels. Let $b = 0$ here and below. We obtain: $t(t+\tau)d^2p/dt^2 + ((1-c)t + (1-c_0)\tau)dp/dt + ap(t) = 0$, which can be integrated in terms of hypergeometric functions. Namely, $p(t) = F(\alpha, \beta; \gamma, -t/\tau)$ is a solution for $\gamma = 1 - c_0$, $\alpha + \beta = -c$, $\alpha, \beta = -c/2 \pm \sqrt{c^2/4 - a}$; see e.g. [AS], Ch.15, or use Mathematica function `Hypergeometric2F1`[α, β, γ, x]. One can also take here $p_1(t) = t^{-\beta}F(\beta, -\alpha - c_\tau, 1 + \beta - \alpha, -\tau/t)$ and $p_2(t)$ upon $\alpha \leftrightarrow \beta$ in $p_1(t)$. When $\tau/t \sim 0$, such $p_{1,2}$ with proper coefficients of proportionality approach $t^{r_{1,2}}$ as $t \gg 0$ for $r_{1,2}$ from (2.9) under $b = 0$.

Using deviations. *Hedging* vs. SPY or some index is an example; see e.g. [BLSZ, BSV]. The assumption is that after the companies within the index reacted to some *index news* at the moment $-\tau$, a specific company's news arrives at 0. So if a position in a stock is *hedged* by investing an equal amount in the corresponding index in the opposite direction, the return will be $p(t) - p_{ind}(t)$, where $p(t)$ is governed by (2.12&2.13) and p_{ind} , the index' rate of return, is in the form of (2.10) or

(2.11) for proper parameters. Practically, our trading system automatically determines r_{ind}, C_{ind}, r, C such that $p(t) - p_{ind}(t) \simeq C t^r - C_{ind} t^{r_{ind}}$. However, more refined $p(t)$, solutions of (2.12&2.13) instead of $C t^r$, are significant here, especially for (relatively) small t .

We mention that it makes perfect sense to switch here to the corresponding *difference* equations. See e.g. [Ch2], Section 1, concerning the one-dimensional *global hypergeometric function*.

Practical matters. Such adjustments are quite natural, but it appeared that the elementary solutions of system (2.10)&(2.11) already describe well the real market processes when we focus on the impact of a *single* event and when the time interval is not too large. The following key features of these solutions can be observed in stock markets:

- (i) t^r -dependence of the envelope of the price-function for $0 < r \leq 1$,
- (ii) quasi-periodic oscillations of the price-function in terms of $\log(t)$.

Here t is the time from the event. In our trading system, (i) is the key; the periodic oscillations are addressed using different tools, not really connected with solving differential equations.

Quasi-periodic oscillations (our second observation) are more difficult to observe and measure. Mathematically, such oscillations are typical for *a*-investing and do not appear for pure *b*-investing. They are "around" the mean values, and generally require involved statistical analysis; cf. [FPSS]. They can be mostly seen only for relatively big t , so they can be "overwritten" by other general market and company news and trends. As to (i), the market evidence is solid.

From the perspective of *a*-investing, the term $p(t)/t$ is some kind of *profit-taking*, though we will argue below that taking $p(t)$ instead of $p(t)/t$ is more relevant for "pure" profit-taking. Practically, the events or commentaries are sometimes used simply as triggers when profit-taking. Under *a*-investing, such "overreacting" mathematically means that the coefficient a becomes relatively large; see (2.11).

Generally, our model "predicts" that in the absence of other major news, the intervals between consecutive rounds of *a*-type profit-taking tend to grow approximately as a geometric sequence, i.e. we arrive at some kind of Elliot waves (associated with Fibonacci numbers). Strictly speaking, the profit-taking is the effect of second order, i.e. for the share-price minus its expected average. Mathematically, the average satisfies (2.11) in our model. The oscillations of this difference are actually t -periodic, not just $\log t$ -periodic as for *a*-investing, which will be addressed below using Bessel functions.

It is important that *long-term returns* of different companies become comparable in spite of very different trading patterns and volatility. I.e. they become closer to each other almost regardless of their short-term

behavior. There are of course winners and losers, but the long-term rate of change is sufficiently uniform even for quite different types of companies. Mathematically, it means that the smaller r , the bigger the constants C in (2.10,2.11). We will reflect this in our g -functions (3.1-3.4) and tables, making "basic returns" comparable after 3-4 months. This can be important for extending our system to trading *options*.

To finish this discussion, let us emphasize that the analysis above is by no means restricted to stock markets. Market instruments and tools have various counterparts beyond trading equities. For instance, short-trading, profit-taking, hedging, doing derivatives are quite common in some forms, though reach the most sophisticated levels in stock markets. The discontinuous nature of market data is not unusual too; it will be addressed "practically" in Section 3.

2.6. Profit-taking etc. The model above addresses well *quasi-periods* under a -investing (or mixed investing). The periodicity with respect to $\log(t)$ is some kind of profit-taking, but the actual one is significantly more momentum: *sell when $p(t)$ reaches some level*. This is a major reason for short-term "periodic" volatility, which is an important feature of stock markets; see also [ACH]. Its role is crucial not only for short-term trading; see [FPSS]. Figures 3,8 there are the key for them and for us. The short-term volatility is "around" the mean value $\bar{p}(t) = p_{avrg}(t)$. By the way, the periodicity of the volatility provides an explanation of the profitability of counter-trend (contrarian) strategies.

For "pure" profit-taking, $u(t)$ must be understood as some market "consensus" on keeping a stock at its current price. So the "upgrade function" must react here to $p(t)$, not to $p(t)/t$ as above. This is relative to \bar{p} , an effect of "second order", so we will need to switch to $\tilde{p}(t) = (p(t) - \bar{p}(t))/\bar{p}(t)$ and the corresponding $\tilde{u}(t)$.

The most natural assumption is the proportionality of $d\tilde{p}(t)/dt$ to $\tilde{u}(t)$. Adding the term $a\tilde{u}(t)/t$ to (2.15) is possible too (see (2.21)), but the key change is the replacement of $p(t)/t$ there by $p(t)$. One has:

$$(2.14) \quad \frac{d\tilde{u}(t)}{dt} = \frac{c}{t}\tilde{u}(t) - \frac{1}{\sigma}\tilde{p}(t),$$

$$(2.15) \quad \frac{d\tilde{p}(t)}{\sigma dt} = e\tilde{u}(t).$$

This is almost exactly (3.14) from [ChM]. Generally, the *spinor Dunkl eigenvalue problem* is the differential equation for $\bar{v} = \{v_0(t), v_1(t)\}$:

$$(2.16) \quad \frac{d\bar{v}(t)}{dt} \stackrel{\text{def}}{=} \left\{ \frac{d}{dt}v_1, \frac{d}{dt}v_0 \right\} = \left\{ \frac{c}{t}v_1, 0 \right\} - \{ \lambda v_0, \lambda' v_1 \},$$

See [ChM], Sections 2,3, e.g. Lemma 3.4 there, and (2.28,2.29) below.

This is a spinor variant of the equation $\frac{dv(t)}{dt} = \frac{c}{2t}(v(-t) - v) - \lambda v$, where we switch to $v_0 = \frac{v(t)+v(-t)}{2}$, $v_1 = \frac{v(t)-v(-t)}{2}$, considering them as independent functions. I.e. we switch from v to a *super-function* \bar{v} , where λ is extended to a pair $\{\lambda, \lambda'\}$ acting on \bar{v} "diagonally".

To solve equations (2.14)&(2.15), we obtain:

$$(2.17) \quad t^2 \frac{d^2 \tilde{p}}{dt^2} - ct \frac{d\tilde{p}}{dt} + et^2 p = 0 = t^2 \frac{d^2 \tilde{u}}{dt^2} - ct \frac{d\tilde{u}}{dt} + et^2 u + cu,$$

$$(2.18) \quad \tilde{p} = A_1 \tilde{p}_1 + A_2 \tilde{p}_2, \quad \tilde{p}_{1,2}(t) = t^{|\alpha|} J_{\alpha_{1,2}}(\sqrt{et}) \quad \text{for } \alpha_{1,2} = \pm \frac{1+c}{2}.$$

Here the parameters a, c are assumed generic, $A_{1,2}$ are undermined constants, and we use the *Bessel functions* of the first kind:

$$J_\alpha(x) = \sum_{m=0}^{\infty} \frac{(-1)^m (x/2)^{2m+\alpha}}{m! \Gamma(m+\alpha+1)}.$$

See [Wa] (Ch.3, S 3.1). We will also need the asymptotic formula from S 7.21 there:

$$J_\alpha(x) \sim \sqrt{\frac{2}{\pi x}} \cos\left(x - \frac{\pi\alpha}{2} - \frac{\pi}{4}\right) \quad \text{for } x \gg \alpha^2 - 1/4.$$

The latter gives that $\tilde{p}_{1,2}(t)$ are approximately $\tilde{C} t^{c/2} \cos(\sqrt{et} - \phi_{1,2})$ for some constants $\tilde{C}, \phi_{1,2}$. Interestingly, the phases $\phi_{1,2} = \pm \frac{1+c}{2}\pi + \frac{\pi}{4}$ are uniquely determined by c . We conclude that for sufficiently big t , the function $p(t)$ under the profit-taking as above is basically:

$$(2.19) \quad \tilde{p}(t) \approx t^{c/2} (A \cos(\sqrt{et} + \pi c/4) + B \sin(\sqrt{et} - \pi c/4)),$$

for some constants A, B ; the t -period is $\frac{2\pi}{\sqrt{e}}$.

Let us now replace \tilde{p}/σ by $\hat{p} t^{\nu-1}/\sigma$ for $0 < \nu \leq 1$ and $d\tilde{u}/dt - e\tilde{u}(t)$ by $d\hat{u}/dt - e\hat{u}(t)/t$ in (2.14&2.15). The system becomes:

$$(2.20) \quad \frac{d\hat{u}(t)}{dt} = \frac{c}{t} \hat{u}(t) - \frac{t^\nu}{\sigma t} \hat{p}(t),$$

$$(2.21) \quad \frac{d\hat{p}(t)}{\sigma dt} = \frac{e}{t} \hat{u}(t).$$

It can be solved in terms of Bessel function too. The corresponding fundamental solutions are $\hat{p}_{1,2}(t) = t^{c/2} J_{\pm c/\nu}(\frac{2\sqrt{e}}{\nu} t^{\nu/2})$. One has:

$$\hat{p}_{1,2}(t) \approx \hat{C} t^{\frac{c}{2}-\frac{\nu}{4}} \cos(2\sqrt{et}^{\nu/2}/\nu - \psi_{1,2}) \quad \text{as } t \gg 0.$$

I.e. $\widehat{p}(t)$ it is slower than $\widetilde{p}(t)$ from (2.19) and the periodicity is for $t^{\nu/2}$ in this case; it even tends to 0 as $t \rightarrow \infty$ for $c < \nu/2$.

Finally, combining (2.19) with $p_{avg} = \bar{p}$ taken from (2.11), $p(t)$ can be assumed a linear combination of $t^r \cos(\rho \log(t) + \zeta) (1 - \epsilon \cos(\varrho t + \xi))$ for proper parameters $r, \rho, \varrho, \zeta, \xi, \epsilon$. This holds asymptotically, but seems basically sufficient for practical modeling momentum trading. We note here a connection with [Che], where the sum of Brownian motion, BM , with fBM was considered; see also the end of Section 2.4.

The t -periodicity of profit-taking is directly related to short-term volatility in stock markets. This is generally a stochastic phenomenon [EN, FL, FPSS]. However, as we see, the volatility due to profit-taking has solid "algebraic origins". Namely, relatively simple algebraic-type formulas *with few parameters*, which reflect investors' trading preferences, can *look* quite chaotic. This was actually the key for us: *there are very many traders, but possibly only very few trading patterns*.

Let us provide a numerical example of such "algebraic volatility". Using the g -functions from (3.1,3.2) with $1 \leq t \leq 150h$ (1 month), let :

$$(2.22) \quad p(t) = 0.4(1 - \sin(t)/3) \cos(2\pi \log(t))g(t, 1) \\ + 0.5(1 - \sin(t/5)/3) \sin(2\pi \log(t))g(t+12, 3).$$

In spite of relatively simple formula, the *fake chart* in Figure 1 exhibits a lot of volatility, which is mathematically hardly surprising for such trigonometric expressions. Before managing real charts, the system was "trained" to trade profitably such *fake* ones. It is momentum; catching the periods and quasi-periods was not an objective. We do not have sufficient "stability theory" for the periods. However the exponents r can be reasonably found by the system (automatically) for fake and real charts. In (2.22), $r = 0.137, 0.418$ for $g(1), g(3)$.

FIGURE 1. Model chart: "algebraic volatility"

2.7. Toward Macdonald processes. A natural passage from our differential equations to random processes is via considering *ensembles* of news-functions: $\{u^{(1)}, u^{(2)}, \dots, u^{(n-1)}, u^{(n)}\}$, at the moments $t_1 > t_2 > \dots > t_{n-1} > t_n$. Let us assume that they are governed by the same reduction coefficient c . Then a counterpart of (2.1) is the following system:

$$(2.23) \quad \partial u^{(i)} / \partial t_j = c \frac{u^{(i)} - u^{(j)}}{t_j - t_i} \quad \text{for } i \neq j,$$

$$(2.24) \quad \partial u^{(i)} / \partial t_i = c \sum_{j \neq i} \frac{u^{(i)} - u^{(j)}}{t_i - t_j},$$

which is a special variant of *rational* Knizhnik-Zamolodchikov equation of type A in the standard n -dimensional representation of the symmetric group \mathbf{S}_n . See e.g. [Ch1], Section 1.1. This means that news at t_i is positively influenced by that at j if $u^{(j)} > u^{(i)}$ or by that at $j > i$ if $u^{(j)} < u^{(i)}$; the impact is negative otherwise. Qualitatively, a stronger news *before* t_i increases the impact of $u^{(i)}$ and diminishes its impact if it arrives *after* t_i (and vice versa). Quantitatively, we divide here by $(t_i - t_j)$. Note that $u^{(1)} + \dots + u^{(n)}$ does not depend on t_j , so this is a process of "news-redistribution". In the case of $n = 2$, we obtain:

$$\begin{aligned} \partial u^{(1)} / \partial t_1 &= c \frac{u^{(1)} - u^{(2)}}{t_1 - t_2}, & \partial u^{(1)} / \partial t_2 &= c \frac{u^{(1)} - u^{(2)}}{t_2 - t_1}, \\ \partial u^{(2)} / \partial t_2 &= c \frac{u^{(2)} - u^{(1)}}{t_2 - t_1}, & \partial u^{(2)} / \partial t_1 &= c \frac{u^{(2)} - u^{(1)}}{t_1 - t_2}. \end{aligned}$$

Spinor Dunkl problem. This consideration is a special case of the following more general approach. Let \mathbf{S}_n be the symmetric group, s_{ij} the transpositions. To link our systems to the *Macdonald processes* from [BC] (in the nonsymmetric setting), we consider an *ensemble* of scalar "news-functions" $\{u^{(w)}, w \in \mathbf{S}_n\}$ depending on $\{t_i, 1 \leq i \leq n\}$ from the sector $t_1 > t_2 > \dots > t_{n-1} > t_n$. We set $w(f) \stackrel{\text{def}}{=} f(t_{w(1)}, \dots, t_{w(n)})$ for $w = (w(1), \dots, w(n))$. A counterpart of (2.1) is the following system:

$$(2.25) \quad \partial u^{(w)} / \partial t_i = c \sum_{j \neq i} \frac{u^{(w)} - u^{(ws_{ij})}}{t_i - t_j} + \lambda_{w(i)} u^{(w)} \quad \text{for } 1 \leq i \leq n.$$

It is equivariant under the action $u^{(w)} \mapsto u^{(vw)}$, $\lambda_i \mapsto \lambda_{v(i)}$ of $v \in \mathbf{S}_n$ (without touching $\{t_i\}$). This is the *spinor Dunkl eigenvalue problem* of type A in the terminology of [Ch2]. It can be integrated in terms of

multi-dimensional Bessel functions; the theory of the latter is relatively new even in (classical) symmetric setting [Op]. The original *Dunkl eigenvalue problem* is a system of differential-difference equation for a single $u = u^{(id)}$ above defined for *all* sufficiently general $\{t_i\} \in \mathbb{R}^n$, not only in the *sector* above, where we plug in: $u^{(w)} = w(u)$. This one is equivariant with respect to the action of $v \in \mathbf{S}_n$ on $\{t_i\}$ and $\{\lambda_i\}$ and u by permutations.

The λ -parameters are adjusted to the original *non-spinor* Dunkl eigenvalue problem. One can consider more general linear combinations in (2.25) (in the spinor case). Note that the price functions are not involved here; the usage of λ serves as some substitute.

Let us consider the case of $n = 2$, setting $u^{(0)} = u^{(id)}, u^{(1)} = u^{(s_{12})}$:

$$(2.26) \quad \frac{\partial u^{(0)}}{\partial t_1} = c \frac{u^{(0)} - u^{(1)}}{t_1 - t_2} + \lambda_1 u^{(0)}, \quad \frac{\partial u^{(0)}}{\partial t_2} = c \frac{u^{(0)} - u^{(1)}}{t_2 - t_1} + \lambda_2 u^{(0)},$$

$$(2.27) \quad \frac{\partial u^{(1)}}{\partial t_1} = c \frac{u^{(1)} - u^{(0)}}{t_1 - t_2} + \lambda_2 u^{(1)}, \quad \frac{\partial u^{(1)}}{\partial t_2} = c \frac{u^{(1)} - u^{(0)}}{t_2 - t_1} + \lambda_1 u^{(1)}.$$

Switching to $\tilde{u}^{(i)} = \exp(-(\lambda_2 + \lambda_1)(t_1 + t_2)/2)u^{(i)}$, $\lambda = (\lambda_1 - \lambda_2)/2$, and $x_{1,2} = t_1 \pm t_2$, $t_{1,2} = (x_1 \pm x_2)/2$, we obtain that $\partial \tilde{u}^{(i)}/\partial x_1 = 0$. Setting $y = x_2$, $f^{0,1} = \tilde{u}^{(0)} + \tilde{u}^{(1)}$, $f^1 = \tilde{u}^{(0)} - \tilde{u}^{(1)}$, we arrive at:

$$(2.28) \quad \frac{\partial \tilde{u}^{(0)}}{\partial y} = c \frac{\tilde{u}^{(0)} - \tilde{u}^{(1)}}{y} + \lambda \tilde{u}^{(0)}, \quad \frac{\partial \tilde{u}^{(1)}}{\partial y} = c \frac{\tilde{u}^{(1)} - \tilde{u}^{(0)}}{y} - \lambda \tilde{u}^{(1)},$$

$$(2.29) \quad \frac{\partial f^0}{\partial y} = \lambda f^1, \quad \frac{\partial f^1}{\partial y} = 2c \frac{f^1}{y} + \lambda f^0, \quad \frac{\partial^2 f^0}{\partial y^2} = \frac{2c}{y} \frac{\partial f^0}{\partial y} + \lambda^2 f^0.$$

The last equation can be integrated in terms of Bessel functions; cf. (3.14) from [ChM], equation (2.17) above, and also [Ch1], Section 2.4. However in contrast to the solution from (2.18), the function f^0 will not oscillate due to the positivity of λ^2 ; we assume that $\lambda \in \mathbb{R}$.

Similar to (2.18), adding the profit-taking term results in $\lambda^2 \mapsto \lambda^2 - a$ for some constant $a > \lambda^2$. This will provide the desired oscillations; we omit details and generalizations.

3. MARKET IMPLEMENTATION

3.1. Major challenges. *The first major challenge* with the mathematical analysis of stock charts and other market information is that the corresponding functions are of discontinuous nature. Automated high-frequency trading adds a lot of volatility too [CJP]. This makes the separation of the signals from noise and trading involved.

The second challenge is that even if the news and has clear meaning, the corresponding trading decisions can depend on many factors. For instance, it can be simply too late to invest in this particular news. Executing large orders can be with significant losses right after the news, and so on. By the way, the *counter-trend* (contrarian) variants of our trading system, i.e. those selling when the share-price goes up and so on, can outperform the *pro-trend* variants.

The third challenge is picking right moments for closing positions. We use the *termination curves* discussed below and the "signals" opposite to the direction (long or short) of the position taken, determined automatically. Obviously, the *bid-ask spread* reduces the profitability; see [KS]. This is one of the reasons why we optimize *returns per positions*; the positions generally last from 5 to 10 days.

The fourth challenge is that a *significant* variety of (profitable) strategies is needed to address market volatility. In our system, using counter-trend and pro-trend variants simultaneously, employing different *opti-parameters*, and varying the moments when the system receives quotes provide reasonable stability. The number of different profitable variants of the system is practically unlimited: 12 "production lines" were used in real-time experiments.

The fifth challenge is using weights, which for us are mainly those based on the results of the prior optimization. We obviously rely mostly on the equities the most suitable for our system, i.e. those performed the best during the optimization process. However, the *opti-parameters* and weights based on the past performance can fail in future.

The sixth is simply due to the novelty of our approach. The usage of our *2-bid tables* for creating momentum trading systems, trading options and *technical analysis* of stocks requires experience. The pontables from Section 4.3 can help to get used to our *2-bids*. Also, we provide various performance results of our own system, which can be used as "benchmarks" for those who follow our approach.

3.2. Forecasting. The work of our system is based on the *forecasting curves*, automatically produced time-predictions for share-prices. The *termination curves* are their shifts up or down with some coefficients of proportionality providing some room before their intersection with the actual share-price graphs. These intersections trigger the terminations of the taken positions (if any). This is similar to trading US-style options, when the termination curves are horizontal lines shifted up or down for calls or puts. The curves we use are essentially $b(\text{time})^r$ for "bids" b and exponents r , assigned to the 7 "categories" discussed below (main 4 and their 3 consecutive averages).

The bids are discrete and must be large enough (at least 1) to form an *admissible 2-bid*, which is a pair $\{b = \text{bid}, c = \text{category}\}$. The 2-bids are ranked *lexicographically*, first with respect to b (the bigger the

better) and then, if the bids coincide, with respect to c : the smaller c and its prime time-interval the better. The "winner" is the top bid. *Bids below the threshold in their categories are ignored as noise.* The thresholds for prime-intervals are 1, 2, 3.5, 7 for $c = 1, 3, 5, 7$ times some common rescaling coefficient β ; see the tables below.

The basic functions we use are as follows:

$$(3.1) \quad g(t, 1) = 0.5 \cdot \text{Floor}[1548 (0.26t + 0.74)^x - 1548]/100 + 1, \quad x = 0.137,$$

in the case of the *super* category ($c = 1$),

$$(3.2) \quad g(t, 3) = 2 \cdot \text{Floor}[10 (2(t/d) - 1)^x]/10 \quad \text{for } x = 0.418,$$

in the case of the *ultra* category ($c = 3$),

$$(3.3) \quad g(t, 5) = 0.1 \cdot \text{Floor}[22.875 (2.024 \frac{t}{5d} - 1.024)^x + 12.125], \quad x = 0.5678,$$

in the case of the *extra* category ($c = 5$),

$$(3.4) \quad g(t, 7) = 3.5 \cdot (\text{Floor}[10.25 (t/(22d))]/10 + 1), \text{ i.e. here } x = 1,$$

which serves the *regular* category ($c = 7$),

where t is measured in hours; $1h$ is the prime time-interval in the super case, $d = 6.5h$, the duration of one Wall Street business day, is that in the ultra-category. Accordingly, the prime time-intervals are 1 week = $5d$ in the extra category and 1 basic month = $22d$ in the regular category. Here $x \approx 0.137 + \log(u)/6$ for $u = \{1, 1d, 2.5d, 22d\}$, where $2.5d$ (instead of $5d$ for $c = 5$) is due to some practical reasons. Qualitatively, x is supposed to depend linearly on the logarithm of the corresponding prime time-interval, but this can vary.

Here $\text{Floor}[z]$ means the maximal integer no greater than z . For $0 < t < t^\bullet$, where $t^\bullet = 1, 1d, 5d, 22d$ correspondingly (t_i^\bullet will be used here for $i = 1, 3, 5, 7$), we extend the functions above by a uniform linear formula: $g(t^\bullet)(2t + t^\bullet)/(3t^\bullet)$. Also, we define g -functions for even categories $c = 2i$, where $2i = 2, 4, 6$, as the averages of the neighboring g , i.e. $g(t, 2i) = (g(t, 2i - 1) + g(t, 2i + 1))/2$; the prime time-intervals are $t_{2i}^\bullet = 2t_{2i-1}^\bullet$ (not the corresponding averages).

Finally, the basic functions will be $bg(t, c)$, where b is the bid (an integer), c the category. The trading system automatically determines the bids *backward* as price-changes in percent divided by the corresponding g . This is performed at every moment when the system obtains quotes in all 7 categories, and with some *depth*, the number m of steps back. I.e. it constantly calculates for the *rescaling coefficient* β :

$$(3.5) \quad b_i(m) = \text{Floor}\left[100\beta \frac{|p_t - p_{t-mt_i^\bullet}|}{g(mt_i^\bullet, i)p_{t-mt_i^\bullet}}\right], \quad 1 \leq i \leq 7, \quad \beta \geq 1,$$

for the corresponding t_i^\bullet and a sequence $m = 1, 2, 3, \dots$ (mostly, 1 month back); here p_t is the share-price at t , $|\cdot|$ the absolute value.

Then the highest 2-bid $b_{i_o}(m_o)$ among all i and m becomes the *top 2-bid*; if two 2-bids coincide, the smaller m_o the better. The corresponding $b_{i_o}g(t - t_o)$ for $t_o = t - m_o t_{i_o}^\bullet$, shifted and with some proportionality coefficient, becomes the *termination curve*, which can be changed if a higher *top 2-bid* arrives. To improve the performance, the top 2-bids are renewed only when $\pm p(t)$ *decelerates* with some threshold (subject to optimization); \pm for long/short or \mp for the "counter-trend". Also, the system constantly produces *top start 2-bids*, changed when $\pm p(t)$ *accelerates* (with their threshold). They are used for opening positions, forecasting and terminations of the trades in the opposite mode.

Finally, the *trading signals* are the increases of the *top 2-bids* or *top start 2-bids* and the intersections with the termination curves.

Consecutive increases of top bids for the same equity in the same direction are used to open multiple positions: of level 1 on the first bid, of level 2 for the first increase and so on. The trades based on level 2,3 bids mostly outperform those of level 1. However omitting level 1 bids significantly reduces the total amount that can be invested; in professional trading, the greater the better.

3.3. Tables of two-bids. Recall that there are four categories *super (1)*, *ultra (3)*, *extra (5)*, and *regular (7)*, and also intermediate even categories. They are governed by different bid-tables, where *2-bids* are pairs (b, c) . Usually b are integers from 1 to 5. Practically, 2-3 categories are mostly used for individual companies, though the system becomes less stable with 2 categories. This can be greater than 3 when trading indices, but 3 seems reasonably optimal. The average durations of positions are mostly in the range from 3-15 days for us, so the regular category rarely occurs in our simulations and real-time runs.

The termination can be *only* due to the signals, unless for clear "hangs", which requires a special consideration; see e.g. [BDM]. The signals here are intersections with termination curves or *start bids* in the opposite direction. So the average durations can be adjusted only by choosing proper combinations of categories and initial parameters; all parameters are subject to machine optimization. The system finds many "profitable" and stable combinations of parameters, which can be used to obtain desired durations of positions and for other adjustments. New positions are mostly open due to the new *start bids*.

Using different initial values of parameters, pro-trend and counter-trend (contrarian) modes, weights and so on results in many different variants. Also, much depends on the moment the system enters the market, obtain quotes and the prior history. *The system was proved to be able to produce a lot of profitable trading lines*, which resembles

very much human decision-making. Even with playing simple games, there are almost always various ways to win; so one can choose.

Super table ($c = 1$):

$b \setminus h$	1 h	2 h	1 d	5 d	1 m	3 m
1	1	1.5	3	6.5	11	15
2	2	3	6	13	22	30
3	3	4.5	9	19.5	33	45
4	4	6	12	26	44	60
5	5	7.5	15	32.5	55	75
6	6	9	18	39	66	90.

Here and below $1d$ equals 6.5 hours, $1m$ means 22·6.5h, $3m = 65 \cdot 6.5h$ (working days only). The (expected) return at t for a bid b and category i is simply $bg(t, i)$, assuming that the initial moment is $t = 0$.

Ultra category ($c = 3$):

$b \setminus d$	1 d	2 d	5 d	15 d	45 d	6 m
1	2	3	5	8	13	20
2	4	6	10	16	26	40
3	6	9	15	24	39	60
4	8	12	20	32	52	80
5	10	15	25	40	65	100
6	12	18	30	48	78	120.

Here, additionally, $6m$ means 6 months, which is 126d, 2 months are (approximately) 45d; d always means 6.5h. Only working days are counted.

Extra category ($c = 5$):

$b \setminus w$	1 w	2 w	1 m	3 m	9 m
1	3.5	5.5	8.5	15.5	28
2	7	11	17	31	56
3	10.5	16.5	25.5	46.5	84
4	14	22	34	62	112
5	17.5	27.5	42.5	77.5	140,

where, as above, 1 week = 5 days, 1 months = 22 days, 3 months = 65 days, 9 months = 191 day, 12 months = 252 days (to be used next).

Regular category ($c = 7$):

$b \setminus m$	1 m	2 m	4 m	12 m
1	7	10.5	17.5	44.5
2	14	21	35	89

3		21	31.5	52.5	133.5
4		28	42	70	178.

Comparing the categories. Let us compare the minimal admissible bids (basic returns) in the different categories for the 13 basic durations, mostly taken from the tables above. Those from the tables above are in bold; the others are calculated using the corresponding g -functions:

cat	1h	2h	1d	2d	1w	2w	3w	1m	2m	3m	4m	6m	9m
7	—	—	—	—	—	—	—	7	10.5	14	17.5	23.8	34.3
5	—	—	—	—	3.5	5.5	6.9	8.5	12.7	15.5	18.0	22.2	28
3	—	—	2	3	5	6.8	8	9.6	13	15.2	17.0	20	23.8
1	1	1.5	3	4.3	6.5	8.5	9.7	11	13.6	15	16.1	17.8	19.7

Recall that we set as above:

$$(3.6) \quad \begin{aligned} 1d &= 6.5h, \quad 1w = 5d, \quad 1m = 22d, \quad 2m = 45d, \\ 3m &= 65d, \quad 4m = 86d, \quad 6m = 126d, \quad 9m = 191d. \end{aligned}$$

Also, recall that 2-bids are ranked naturally: first b , the bigger the better, then c (when b coincide) with the priority to smaller c , the shorter the durations of positions the better.

Note that for $b = 1$, which is the smallest bid, the returns after 3 or 4 months are approximately comparable for all 4 categories. This is by design. Also, the expected return at $2t_i^\bullet$ is 1.5 greater than that at t_i^\bullet , which is the prime time-interval for the corresponding category ($i = 1, 3, 5, 7$), with a minor deviation for $i = 5$ (the extra category). Also, the curves we use for prediction (and termination) heavily depend on the category, but they produce reasonably comparable returns after 3-4 months; we aim at using and trading options here.

Any bid is automatically considered in all "higher" categories. For instance, the smallest possible bid, which is the return of 1% next hour, in super category, is "equivalent to" 3% next day, so it "beats" the smallest ultra-bit, which is 2% a day. Then it is supposed to generate 6.5% next week (vs. minimal 3.5% in the extra category), and 11% next month (vs. 7% in the regular category). To make this table working, 2 times every bid in the same column from the comparison table (with the same durations) is supposed to be greater than any bid there, which holds. This matches well bidding in contract card games: the greatest bid wins regardless of the suit.

The functions we used above are designed to provide such natural logical inter-relations when comparing bids from different categories. Also, an integrality of some (not all) bids is a consideration. This can help to use these tables manually without computers, though the mathematical discretization is the main point here.

To avoid any misunderstanding, the bids above begin with 1 (1% per hour in the super category) mostly for the sake of readability. The trading system divide these tables (all of them) by the *common* rescaling coefficient β . For instance, the division of all bids by 2 makes sense: 0.5% per hour is more realistic than 1%. Such rescaling significantly increases the number of "admissible 2-bids", which is generally needed for the trading system to be stable and react promptly to the changes of share-prices. This coefficient β is subject to machine optimization, as well as all other parameters.

Finally, let us provide the table where we compare in the same way the minimal bids in all 7 categories:

cat	1h	2h	3h	1d	2d	4d	1w	2w	1m	2m	3m	4m
1	1.	1.49	2.27	3.	4.31	5.92	6.49	8.44	10.99	13.57	15.01	16.16
2	—	1.28	1.87	2.5	3.65	5.16	5.74	7.62	10.29	13.28	15.1	16.57
3	—	—	—	2.	3.	4.4	5.	6.8	9.6	13.	15.2	17.
4	—	—	—	—	2.54	3.71	4.25	6.15	9.05	12.85	15.35	17.5
5	—	—	—	—	—	—	3.5	5.5	8.5	12.7	15.5	18.
6	—	—	—	—	—	—	—	4.97	7.75	11.6	14.75	17.75
7	—	—	—	—	—	—	—	—	7.	10.5	14.	17.5.

3.4. Basic system operations.

SIGNALS. Producing *buy signals* and *sell signals* is the main purpose of our (any) trading system. When trading, our system generally processes the quotes for the periods about one month backward, employing the parameters obtained during the prior optimization and the weights based on the optimization too.

There can be multiple signals in the same direction, the first, the second and so on. The consecutive number of a signal is called the *level of the signal*. Using such levels is a special feature of our system. Generally the signals of levels 2-3 are better "protected" than those of level 1, the first signals in a certain direction; only the signals of level 1,2,3,4 were used in real-time runs.

Statistically, the number of signals of level 1, $NL1$, matches that for 2+3+4: $NL1 \sim NL2 + NL3 + NL4$. Then $NL2 \sim NL3 + NL4$, and so on. The combination of signals of level 2 and 3 gave better performance than the usage of all (statistically, about 20% better than that for level 1), but the signals of level 1 are also of good quality.

The signals are mostly treated as *orders*. For instance, one sells short on a *sell signal* and then buys to cover upon the first *buy signal*. This is the other way around for the counter-trend trading. The signals can be due to sufficiently big bids or intersections with termination curves. The positions can be opened on the first, second signal or the signals of higher *levels*. The positions of all levels are terminated altogether after the *first* signal comes in the opposite direction.

Practically, up to 4 simultaneous positions can be open with an equity if the signals of all 4 levels were present. All of them will be closed at once upon the *first* signal in the opposite direction. We suggested some ways to split the termination of big positions into several steps, say, involving “neighboring lines”, however this was not tested. Executing large orders is a well-known market concern [MCL, GRS, CJP].

Using *levels* resembles using *leverage*, but the system does it in its own ways. Also, we note that the signals are produced independently for different equities, although the system can work in more sophisticated regimes, including different variants of hedging.

RETURNS. The *return per one position* is the main quantity the system optimizes. Here the ask-bid spreads, the slippage with execution of the orders, and the broker commission must be subtracted from the *returns*, practically, about 0.15-0.25% per one position for “professional trading”. *We always calculate pure returns, without taking the spread and similar losses into consideration.* The returns we provide below are mostly pure returns *per position*, but we always calculate the usual (pure) returns during the periods under consideration too.

Pure returns like 0.4% per position are, generally, sufficient for the profitability; the system can do better than this in spite of relying on quotes only, as the source of market information, various delays and charges. The actual durations of the positions the system created were mostly in the range of 5-10 days.

OPTIMIZATION. The optimization procedures can be for trading *Longs Only*, *Shorts Only*, or (mostly) for trading both, *L & S*.

The optimization (“education”) periods are of obvious importance. Our system does not have any prior information about the market and equities beyond the information that it can extract from the data provided during the optimization periods. They can be historical or based on prior trades by the system. Generally, the optimization periods have to be 1 year or longer. Ideally, they must be *diverse*, i.e., must contain sufficiently long periods when the stock goes up and when it goes down. The more “difficult” the optimization period, the better and more stable the out-of-sample returns.

These factors are of importance for choosing the optimization periods, and creating real “trading lines”. However after this, the real-time adjustment of parameters becomes entirely automated. Mostly, the “real-time optimization” is for 6-months periods backward.

Generally, the durations from 1 to 2 years of the optimization periods are statistically reasonably to react properly to different types of volatility and various market trends. However 6 month periods and a simplified optimization are good enough to keep “lines” running, until they are redesigned on the basis of more systematic optimization.

DURATIONS. The end-user can request the *desired average durations* of positions. For our system, the range from 5 to 10 days was considered reasonable. However, if the categories, trading modes and the companies to trade are prescribed, it is for the system to determine the most optimal "lengths" of positions. The positions are opened and closed entirely on the basis of the *signals*, so the *desired duration* is not imposed in any form during trading and tests. Generally, if the actual duration (*length*) of positions during the control (out-of-sample) period appears sufficiently close to the *desired duration*, then this is just a confirmation that the optimization was relevant. Stable *rhythm* is an important indicator of stability of the system.

3.5. Testing the system. Multiple experiments were conducted using the historical and real-time data. Special attention was paid to trading liquid companies and SPY, the trust that owns stocks in the same proportion as that represented by the SP500 stock index.

CONTROL PERIODS. The most systematic historical testing was for the period 2006/01/01-2007/04/13. More exactly, five 4 month's *control periods* (out-of-sample!) were taken:

Period 1: 2006/01/01-2006/04/30, Period 2: 2006/04/01-2006/07/30, Period 3: 2006/07/01-2006/10/30, Period 4: 2006/10/01-2007/01/30, Period 5: 2007/01/01-2007/04/13. The last period was a little shorter.

The historical testing consisted of

- (i) optimization during the 12 month's *optimization period* taken backward from the beginning of the *control period*,
- (ii) "trading from scratch" during the next 4 month's *control period* with closing all positions at the end of the period.

Note that the control periods overlap (1 month), to simulate continuous trading, without closing all open positions at the ends of periods; this is how the system really works. The optimization periods and the *corresponding* control periods do not overlap of course. The system was used in the *pro-trend* variant in this test.

We evaluate the **AVERAGE 4 MONTH RETURN** for five 4 month's *control periods* by the formula:

$$\text{AVRG RETURN} = 88 * \left(\sum_{i=1}^5 \text{RET}_i * \text{NUM}_i \right) / \left(\sum_{i=1}^5 \text{LNGTH}_i * \text{NUM}_i \right),$$

where 88 is the average number of business days during 4 months, and RET_i , NUM_i , LNGTH_i are the corresponding RET , NUM , LNGTH , the average return per position, the number of positions and the average length (duration in business days) of one position during the corresponding 4 month's period.

TRADING SPY (LONG ONLY). Let us provide the results of control "trading" SPY, without short positions and in the pro-trend regime. Generally, trading SPY is quite a challenge; see e.g. [FPSS] concerning some aspects of its fluctuations. Mathematically, long and short trading, are on equal grounds; addressing possible negative developments is part of any risk-managements, which is quite universal.

The results for the signals of 4 levels are presented separately. By `num`, `ret`, `length` we denote the number of (long only) positions, the returns per position, and their durations for each level. The number in (\cdot) is the corresponding *standard deviation*. The averages for all 5 periods, `RETURN`, `LNGTH`, and `AVR CHANGE` are provided. We mention that `RETURN` becomes 15.3% in the (well-tested) variant with `LNGTH`=5.53d, instead of 3.0d, which can be more suitable for end-users; the duration can be made even longer, but this can reduce profitability.

TRADING SPY (LONG ONLY)

AVERAGE POSITION LNGTH: 3.0 d;

AVERAGE 4 MONTH RETURN: 14.9%;

AVR SPY 4 MONTH CHANGE: 4.80%.

PERIOD: 20060101-20060430, SPY CHANGE=4.6%

num=2	ret=1.28(0.22)	length=2.0d	lev=4

PERIOD: 20061001-20070130, SPY CHANGE=8.5%

NUM=12	RET=0.59(0.35)	LNGTH=2.2d	ALL
num=8	ret=0.46(0.33)	length=2.4d	lev=1

num=3	ret=0.89(0.12)	lngth=2.3d	lev=2
num=1	ret=0.8(0.09)	lngth=0.8d	lev=3
PERIOD: 20070101-20070413, SPY CHANGE=2.0%			
NUM=17	RET=0.1(1.47)	LNGTH=2.4d	ALL
num=8	ret=0.08(1.58)	lngth=2.4d	lev=1
num=5	ret=0.22(1.7)	lngth=2.2d	lev=2
num=3	ret=0.31(0.52)	lngth=2.2d	lev=3
num=1	ret=-0.94(0.02)	lngth=3.1d	lev=4.

Short trading with a market that essentially goes up is quite a challenge for any trading system. Short trading here provides some "insurance" for the periods when SPY goes down. Some losses can be acceptable when it goes up, but the system actually remains profitable. Let us demonstrate this for the same periods and data. As we wrote, the bid-ask spread is not counted, not too high for liquid assets.

TRADING SPY (SHRT ONLY)

num=735      ret=0.69     lngth=5.1     lev=4

```

num=416	ret=0.76	lngth=5.3	lev=5
num=237	ret=0.6	lngth=5.6	lev=6
num=131	ret=0.55	lngth=5.7	lev=7
num=76	ret=0.57	lngth=5.5	lev=8
num=54	ret=0.99	lngth=4.9	lev=9
num=27	ret=0.52	lngth=5.	lev=10.

A simplified optimization was performed here, with only 2 *fixed* categories ($c = 2, 4$) and reduced number of iterations. For this period, 24 stocks (from 165) performed negatively, including INTC, DELL, EBAY. Trading such "heavy-weighters" generally requires full optimization and at least 3 categories. However here we made the optimization fully uniform for all companies and fast, aiming at thousands of companies. The optimization for INTC or similar, if this is the objective, must be done more thoroughly. The following 24 companies had negative returns:

ADBE	num=	90	ret=-0.29%	lngth=3.9
AMGN	num=	49	ret=-0.48%	lngth=9.1
APA	num=	66	ret=-0.25%	lngth=5.6
BJS	num=	68	ret=-0.88%	lngth=6.9
CHK	num=	58	ret=-0.7%	lngth=8.1
CHS	num=	74	ret=-0.4%	lngth=6.1
COF	num=	49	ret=-0.05%	lngth=6.4
COP	num=	45	ret=-0.51%	lngth=9.2
DELL	num=	88	ret=-0.32%	lngth=4.8
EBAY	num=	101	ret=-0.51%	lngth=4.3
EOG	num=	82	ret=-0.64%	lngth=5.4
HD	num=	47	ret=-0.05%	lngth=8.5
INTC	num=	89	ret=-0.53%	lngth=7.1
JNJ	num=	26	ret=-0.94%	lngth=11.6
MMM	num=	50	ret=-0.53%	lngth=7.2
MOT	num=	67	ret=-0.86%	lngth=5.3
NBR	num=	80	ret=-0.99%	lngth=5.3

SNDK	num=	90	ret=-0.73%	lngth=2.8
SUN	num=	79	ret=-1.04%	lngth=3.8
SYMC	num=	83	ret=-0.69%	lngth=4.2
TEVA	num=	80	ret=-0.15%	lngth=4.2
TWX	num=	46	ret=-0.27%	lngth=10.4
XLNX	num=	82	ret=-0.16%	lngth=5.5.

Here and above only signals of levels no greater than 4 were used for trading. We invested symbolic \$100 in every position, so multiple signals in one direction increased this amount up to \$400, which resembles trading on margin. The first signal in the opposite direction (for this stock) results in the termination of all positions. This regime can significantly improve profitability. Higher levels are more frequent for actively traded companies, so this is some kind of leverage.

We do not use weights here. Let us just mention that investing only in 100 companies from 165 above with the best optimization results constantly improves the performance of the systems; which is a variant of using weights. However, some companies with solid optimization returns, i.e. suitable for our system, performed just so-so during the control periods. This is the nature of stock markets, discussed well in the literature; see e.g. [YZ].

Let us now provide some auto-generated results of *real-time* trading simulation with 170 companies, similar to those listed above, under *long & short* with 4 levels (L1,L2,L3,L4), and for 3 "production lines" (A,B,C). The lines were with different "opti-parameters" and/or different entry points; "B" was counter-trend. The first half, "no weights", describes the uniform trading of all companies, the second half is for the 100 companies with the best returns during the optimization:

TRADING FROM 2007, 2, 20 TO 2007, 6, 4; ALL, NO WEIGHTS:

RET AVR A:	RETL1=0.68	RETL2=0.76	RETL3=0.89	RETL4=1.04
RET AVR B:	RETL1=0.67	RETL2=0.7	RETL3=0.86	RETL4=0.84
RET AVR C:	RETL1=0.61	RETL2=0.7	RETL3=0.75	RETL4=0.75

TRADING FROM 2007, 2, 20 TO 2007, 6, 4; FOR 100 FROM 170:

RET AVR A:	RETL1=0.57	RETL2=0.79	RETL3=1.16	RETL4=1.4
RET AVR B:	RETL1=0.96	RETL2=1.04	RETL3=1.23	RETL4=1.23
RET AVR C:	RETL1=1.08	RETL2=1.11	RETL3=1.19	RETL4=1.17.

The returns here are per position; the average position lasted about 5 days; SPY increased 5.5% during 2007/02/20-2007/06/04. Actually about 1000 companies were traded for this period combined in groups based on trading volumes, with about 170 in each. Every company was traded in 12 different "lines", so the total was 72 lines. The average return was about 0.7% per position; the average position was about 5 days. The results above are for 3 lines only.

The optimization procedure is based on the gradient method and is actually not far from the methods used in *networks*; see [BBO, HG]. It was almost always with solid returns for any equities and "learning

3.6. Some charts. To clarify the logic of the decision-making inside the system we will provide the performance graphs describing in detail pro-trend, long&short "trading" SPY and XAU (Gold & Silver) using the historical stock quotes *once a day*. All signals, trades, positions and returns can be seen under sufficiently high magnification. These charts are upon the optimization, so we provide them mostly to clarify the "logic" of the system. Generally, using day-quotes only is a serious demerit; the system works reasonably, but the performance is worse than trading SPY above with 3 quotes a day.

We use green, grey and cyan correspondingly for the price-change, the returns based on level 1 signals, and those based on level 2 signals. Correspondingly, buy-sell signals are marked by blue-red rectangles-ovals; large ones mark trades for level 1 signals. See Figures 2.3.

FIGURE 2. SPY, Long-Short, Daily Historical Quotes

FIGURE 3. XAU, Long-Short, Daily Historical Quotes

Trading indices and commodities generally requires special approaches; see e.g. [FPSS, GTW]. Our system manages them reasonably,

but it appeared necessary to increase the number of used categories to 4, especially for SPY, versus our usual 2-3 for individual companies. This is natural, since indices and some commodities are subject to many kinds of investing and hedging. This generally creates a lot of "noise" and makes it difficult to catch timely their "response to news". Their charts, especially short-term, are of very stochastic nature. Nevertheless our (automated) discretization procedures and other parts of our algorithms proved to be efficient.

The moments of buy signals (all of them, of all levels) are marked by blue rectangles; the large ones correspond to level 1 signals. Accordingly, the sell signals are marked by red ovals; large for level 1. The blue and red vertical lines connect the level 1 execution points in the middle of the *grey* graph with those of the green equity chart. *The returns graphs are changed only upon the terminations.* The cyan graph is for the trades based on level 2 signals; here vertical lines are not used. The returns are in percent from the beginning of the graph.

To help the readers, we provide a fragment of the XAU Figure 3. For example, here the first level 1 trade, marked by a large red oval (the first such), lasted till the first large blue rectangle and was executed at a loss: a vertical drop of the grey strip after the termination; XAU went up significantly and "unexpectedly" here. However the next trade, which was short on the sell signal of level 2, shown by the next (small) red oval, appeared successful: a small increase of the cyan strip.

These two charts are upon the optimization, so they only evaluate the quality of the optimization, i.e. what our automated optimization procedure produced for this period. Only control periods (out-of-sample!) can be used to estimate real profitability. However these charts clarify the "logic" of the system. By the way, its unstable performance in the beginning can be expected; the system needs sufficient "history".

By *simple returns* here, we mean the total returns of SPY and XAU during the considered period (green curves). Only signals of levels 1,2 were used for "trading" (grey and cyan).

USING WEIGHTS. Let us provide the performance results for the following 2 periods: 3/21/2001/3/21 (9:30) - 6/14/2001/6/14 (13:30), 2000/10/24 (9:30) - 2001/6/10 (13:30), with correspondingly 60 and 113 days. The graphs below are in terms of "trading points", when the system "visits the market" (receives quotes), here 3 times a day. So the number of points is approximately 180 and 339 for these control periods. We focus on using *weights* based on the prior optimization returns. Namely, the better optimization returns, the greater amounts to invest in this stock. Picking the companies with optimization returns greater than some limit is a variant of using such weights. The 75

companies were traded, long & short, pro-trend (i.e. essentially under mean reversion trading); they were mainly taken from the list of the most liquid ones. Sharpe Ratio (SR) is Mean Standard Deviation.

By "straight", we mean that symbolic \$100 were invested per any position (long or short) for the companies with the optimization (prior!) returns $> 0\%$ and $> 20\%$. The latter bound was adjusted to reduce the number of traded companies approximately by 50%. Generally, using the weights (or using " $> 20\%$ ") improves the performance, but not always significantly vs. " $> 0\%$ ", depending on the market types. "Red" is used for simple (actual) portfolio returns (based on the changes of share-prices), "blue" for the returns the system achieves.

FIGURE 4. 75 Companies, L&S, 3 Quotes a day

4. PONT, A CARD MODEL

4.1. General design. This game is a combination of *bridge* and *Russian preference* with poker-style auction. The name "bridge" was derived from earlier "biritch", so we make it further from the origin (and shorter). It utilizes a standard deck of 52 cards or a smaller one of 36 cards. The auction is quite different from that of bridge and involves more risks. See here and below [Pa]. The bidding does not use the denomination of suits. The player who starts the auction has no advantage. The cards may be updated while bidding, which resembles

draw poker. The winner of the auction, the declarer, determines the final number of cards per hand as part of the declaration of the contract: the trump and the minimal number of tricks to be taken.

Following suit and the use of trump cards is similar to bridge-type games. The scoring is simpler than that of bridge. The declarer's award is based on the value of the contract depending upon whether or not it was made. The game can be for 2, 3, 4 players, 2 partnerships, or for 1 versus computer. There is also a poker-like version. All variants are almost equally dynamic and playable.

Stock market connections. The game, especially the auction, can be considered as a simple model of playing the market, especially under momentum "investing on news". The bids then are some counterparts of the forecasts of share-prices. The play checks the quality of the bid, but this is not related to real trading, where this quality is the return upon the termination of the position taken.

The number of cards per hand and the number of taken tricks reflect respectively the duration of the investment and the return. The downplay and *misère* resemble a bit selling short, but this is superficial. This is a game: just a model.

The suits are substitutes for the time-horizons of investments or the companies considered for investing. They are on equal grounds in *pont* in contrast to other bridge-type games. Given a suit, the better cards the more reasons to make it a trump. In our trading system, the category of the top bid determines the time-horizon of the investment, though the categories are ranked in contrast to suits in *pont*.

The players compete to become *the declarer*, which is somewhat similar to winning the "right" to invest. The upgrades and increases are designed to reflect real-time actions. The bids are actually *2-bids*, which adds some "timing"; they depend on the size of hands (from 6 to 9), which has no counterparts in other bridge-type games.

The *play* itself has little to do with real playing the stock markets. For instance, the use of trump cards and positions of players around the table have no market analogues. The role of such special elements of card games is diminished in *pont*. However they are inevitable; the game must be not too primitive. Also, more playable games have stronger roots in our psychology. Making *pont* playable was a challenge since it uses unusual *fractional bids*, related to our approach to risk-taking. This was a test of the principles of our trading system. we think that playing *pont* can help to get used to our *2-bids* and in real playing the stock markets, possibly better than playing poker or bridge.

4.2. Description. The game uses a standard card deck of 52 cards for 4 players or a smaller, four-suit deck of 36 cards (from the ace down to the 6), when there are two or three players. In the case of 4 players, they may divide themselves into two partnerships; here the whole deck is used too. The dealers are changed clockwise after each game. The cards are dealt singly in the clockwise order and face down, giving each player six cards. After the players pick up their hands, the dealer starts the auction by making the bid or passing.

Auction. A *bid* is a fraction N/D with the denominator D is from 6 to 8 and the numerator N is no larger than D . Generally speaking, the bid is the expected number of tricks to be taken (N) divided by the final number of cards per hand (D). The latter may be from 6 to 9. The fraction must be no smaller than $3/6$ for 3 or 4 individual players, and no smaller than $4/6$ for 2 players or partnerships. The fractions $4/8$, $7/7$, $8/8$ are excluded. The bids $3/6$, $4/7$, and $5/8$ are not allowed for 2 players, but are accepted for 3 or 4 players.

The auction proceeds clockwise with each player either making a bid that is not lower than the previous ones of other players; for instance, $4/6$, $5/7$, $6/8$, $5/6$, $6/7$, $7/8$, $6/6$ may be claimed after $4/6$. Otherwise say "pass". Bidding is forbidden after the first bid was made if a player has already passed. Passing is allowed after bidding only if there are other players who did not pass; also, the last remained (survived) player may not pass. The round of bidding continues until the *last bid*, when a player (who then becomes the *closer*) repeats his/her previous bid for the first time, or simply says "close". If the others (two opponents for the team variant) passed after this, the closer becomes the *declarer*. Otherwise there is no declarer.

More rounds are necessary if all players passed or at least two of them claim the same bid. To start the next round, the dealer *upgrades* the cards, giving out a card per hand face down. Then each player picks up the card and after this removes one card from the hand by laying it face down. I.e. the hands must be 6 again. Then the closer (or the dealer if all passed) claims first, repeating or enlarging his/her last bid, and the auction continues following the same rules until the first repetition. Those who passed during the previous rounds do not bid, unless all passed. The cards may be upgraded only twice.

Taking no tricks. If all passed after the last (the second) upgrade, the dealer leads to start the *downplay* notrump, where the players are trying to win the smallest number of tricks. Also, the closer starts the downplay if two or more players (or both teams, if applicable) do not pass after the second upgrade, which is the last, but claim *coinciding* bids, i.e. neither of them is the winner.

At the end of the game, the numbers of taken tricks will be diminished by the minimum number, which is to make it zero at least for one player, and subtracted from the corresponding scores. In the case of 2 players, this diminished number must be divided by two before subtracting; e.g. the player who took 4 tricks will lose 1 point, which is 4 minus 2, the number of tricks of the opponent, divided by 2.

A player may claim *misère*, which means that no tricks will be taken. This may be done only before the first upgrade, and bitten by 6/7 or higher for 2 players (teams), by 5/6 or higher for 3 or 4 players. *Misère* is played notrump. The declarer makes the opening lead by placing the card on the table face up. If there are 3 or 4 individual players all cards are placed face up on the table after this. It is the same for partnerships, but the partner does not participate laying his/her cards face down. The *misère* contract is defeated if either of the opponents finds the way where the declarer takes at least one trick.

The play. After the auction, the declarer may *increase*, asking the dealer to deal out 1 card per player face down. The procedure can be repeated several times, but the maximal number of cards per hand must be no greater than 9. The declarer picks up the cards every time. The others will do this only after the declaration of the contract. Then the declarer declares the *contract*, choosing the trump suit or notrump, which is allowed, and stating the minimal number of tricks to be taken (including the partner's tricks for the partnerships). The denominator "D" equals the number of cards per hand after the last increase.

The number of tricks to win cannot be smaller than the final number of cards per player (after the last increase) times the fraction from the last declarer's bid. The bid "*misère*" can be changed by the declarer by the contracts 6/7, 7/8, 8/9, 6/6, 7/7, 8/8, 9/9. It is the same for 2,3,4 players, and the partnerships. Also, the last bid 6/8 can be changed by *misère* if there were no upgrades and increases. The partner's hand is discarded *face down* when playing *misère* in the team variant.

The declarer starts the *play* trying to take enough tricks to fulfill the contract or take no tricks for *misère*. For partnerships, anytime during the play the declarer may ask the partner to place all his cards face up on the table and then he/she starts playing both of the partnership hands (unless in *misère*). All players have to follow suit if they can. Otherwise they must trump. Only the declarer may lead a trump. Other players may do this only if they have no other suits left. The play lasts until the declarer (together with the partner if applicable) takes the necessary number of tricks or the contract is defeated.

Score system. At the end of the play, the declarer's *score* goes up by the *value* of the contract, the number of tricks from the contract minus 3 for 2 players (or partnerships) and minus 2 for 3-4 individual

players, if the contract was made. Otherwise this value is subtracted from the score. If the last bid *before the first upgrading* was more or equal than $5/6$, then this value goes up by one, called *premium* (when adding or subtracting). The same *premium* is added to *misère*, treated as $5/6$ when calculating the score (3 points for 2 players/teams and 4 points for 3,4 individual players). A fulfilled contract of fraction $= N/D = 1$, gives 1 *bonus point* for 2 players (partnerships) and 2 bonus points for 3-4 individual players. For 3 or 4 individual players, successful contracts $5/6, 6/7, 7/8, 8/9, 9/10$, and *misère* add 1 bonus point to the declarer's score. In contrast to the premium, the bonus is not subtracted from the score if the contract fails.

There is another, somewhat more involved, variant of the *pont score system* with more "punishment" for defeated contracts. The play goes till the end. If the number of taken tricks is less than it was declared than the score of the declarer is diminished by the value of the contract multiplied by the number of missed tricks. Say, if the declare took the necessary tricks but one, the score becomes smaller by the value of the contract. This score system is for experienced players.

Finally, the *rewards* will be proportional to the scores of the players diminished by their arithmetic mean, that is the total of all scores divided by the number of players. The partners may redistribute the total partnership reward (the sum of their rewards). The standard recommended way is as follows. If both rewards are positive or negative then it is the same as for individuals. If the first reward is positive, the second is negative, and the total is negative, then the first partner doesn't pay. If the total is positive here, then the second partner receives nothing (and pays nothing).

Bidding table. The following table is the list of bids in the increasing order and the corresponding minimum contracts for different numbers of cards per hand. The stars (adding 1 point each to the score) show the premium **p** for declaring during the *first* round of the auction and the bonus **b** for making the contract.

3-4 individual players			contracts	2 players(partnerships)			
<i>names</i>	b	p	bids:	tricks / cards	:bids	p b	<i>names</i>
<i>1</i>			3/6:	3/6, 4/7, 4/8, 5/9	: —		—
<i>1+1</i>			4/7:	4/6, 4/7, 5/8, 6/9	: —		—
<i>1+2</i>			5/8:	4/6, 5/7, 5/8, 6/9	: —		—
<i>2</i>			4/6:	4/6, 5/7, 6/8, 6/9	:4/6		<i>1</i>
<i>2+1</i>			5/7:	5/6, 5/7, 6/8, 7/9	:5/7		<i>1+1</i>
<i>2+2</i>			6/8:	5/6, 6/7, 6/8, 7/9	:6/8		<i>1+2</i>
<i>m</i>	*	*	m/6:	..., 6/7, 7/8, 8/9	:5/6	*	<i>2</i>
<i>3</i>	*	*	5/6:	..., 6/7, 7/8, 8/9	:m/6	*	<i>m</i>

$3+1$	$*$	$*$	6/7:	6/6, 6/7, 7/8, 8/9	:6/7	$*$	$2+1$
$3+2$	$*$	$*$	7/8:	6/6, 7/7, 7/8, 8/9	:7/8	$*$	$2+2$
4	$**$	$*$	6/6:	6/6, 7/7, 8/8, 9/9	:6/6	$*$	$*$
							3.

Here *misère* ($m = \mathbf{m}/6$) has the same list of admissible contracts as **5/6** but is ranked higher for 2 players (partnerships) and lower for 3 or 4 individuals. Recall that the *misère* contract may be played after the last bid **6/8** or smaller; **m/6** is omitted in the column of contracts.

The names of the bids are convenient when bidding. The name gives the number of additional card (after +) and the value of the (lowest) contract coinciding with the bid, calculated without the premium and bonus. For instance, the value of $2+2 = \mathbf{6/8}$ for 3,4 players equals $2+2=4$. For 2 players, the contract $1+2 = \mathbf{6/8}$ gives 3 points.

4.3. Variants.

Basic-Pont (BP). The simplest version of the game is the *basic pont*, which is played without *misère*, and "premium". The table is also simplified by dropping the bids of denominator 8 (the $+2$ -bids):

3-4 individuals			contracts		2 players(teams)		
names	b	bids:	tricks / cards	:bids	b	names	
1		3/6:	3/6, 4/7, 4/8, 5/9	: —		—	
1+1		4/7:	4/6, 4/7, 5/8, 6/9	: —		—	
2		4/6:	4/6, 5/7, 6/8, 6/9	:4/6		1	
2+1		5/7:	5/6, 5/7, 6/8, 7/9	:5/7		1+1	
3	$*$	5/6:	5/6, 6/7, 7/8, 8/9	:5/6		2	
3+1	$*$	6/7:	6/6, 6/7, 7/8, 8/9	:6/7		2+1	
4	$**$	6/6:	6/6, 7/7, 8/8, 9/9	:6/6	$*$	3.	

Poker-Pont (PP). Another variant is *poker pont* for 2, 3, 4 individual players. It follows the table of the *basic pont*, without bonuses.

bids:	contracts	5/7:	5/6, 5/7, 6/8, 7/9
3/6:	3/6, 4/7, 4/8, 5/9	5/6:	5/6, 6/7, 7/8, 8/9
4/7:	4/6, 4/7, 5/8, 6/9	6/7:	6/6, 6/7, 7/8, 8/9
4/6:	4/6, 5/7, 6/8, 6/9	6/6:	6/6, 7/7, 8/8, 9/9.

PP-betting. As in poker, each player puts up *ante* (one chip or more) to form a *pool*, which consists of the *pot* and the sectors, one for a player. A player always puts chips in the corresponding sector. The dealer starts *betting*, adding chips to the pool or putting nothing, *passing*. The player on the dealer's left may pass, *call* by putting the same, or *raise* by adding extra chips of his/her own. Other players continue clockwise until all have finally called any raises. A player may raise

after passing if the latter was before the first raise. Passing is allowed after raising or calling if there are other players who did not pass.

The first player who calls without adding is the *closer*. If all other players passed, the closer is the *declarer*. If there is no declarer, the dealer upgrades cards and the closer starts another round of betting by raising or doing nothing. Those who passed before if at least one player raised may not bid. There are *optional upgrades* in *poker pont*; they may be omitted. Then the card will be dealt to the next player. A player who upgrades puts a chip to his/her sector (per each new card). The number of upgrades is no more than 3 (for 4 rounds of betting). If still all pass after the last upgrade then the *ante* goes to the pot, the dealer is changed clockwise, and a new game starts.

PP-play. If there are two or more players who put the same number of chips (regardless of the extra chips for upgrades which may be different), then the closer begins one round of bidding among those players only. It is as in the *basic pont*; the declarer is a player claiming the highest bid. If still there is no declarer, there will be no more upgrades. Then the dealer moves all chips but *ante* from the sectors to the pot, and the next dealer starts a new game.

The declarer may increase several times (no more than 3), adding a chip per increase to the pool. After the declaration of the contract all opponents pick the cards and *respond* or pass clockwise starting with the first on the declarer's left. One must add one chip per each increase (totally, the current number of cards per hand minus 6) to the pool to respond and become an *active opponent*. Other opponents are *passive*. However all participate in the play, which follows the standard rules.

The declarer leads and wins the pool (including the pot) when making the contract. If the latter is defeated then all the opponents, active and passive, take chips back from their sectors and the active opponents divide the declarer's chips and the pot among themselves proportionally to the number of taken tricks. The fractions are ignored and the remaining chips (if any) go to the pot. If there are no active opponents, the declarer takes his/her chips back even in the case of the failure (but not the pot). The contract has to be the minimal possible for the current number of cards per hand. Namely, 3/6, 4/7 for 3-4 players, 4/6, 5/7 for 2 players, and 6/8, 6/9 for either. It may not be lower than the last bid if there has been a round of bidding to determine the declarer.

4.4. Comments.

Additional rules. Extra penalties can be added for breaking the rules. The opponents may decide to diminish the declarer's or partnership's score by the value of the contract if the declarer (partnership) made a mistake against the rules when playing. *Vise versa*, in the case of opponent's mistake, the declarer has the right to consider the contract

to be fulfilled and the other player(s) may decide to subtract its value (or its doubled value) from the score of the opponent whose fault is it. In the *poker pont*, the contract is considered to be defeated in the case of a declarer's mistake. If it is an opponent's mistake, the chips from the pool are distributed as if the contract were defeated, and the opponent who made a mistake gives this very number of chips to the declarer. These are basics, to be developed by players.

The following regulation could improve the coordination of the opponents (for 3 or 4 individual players) and may be added to the rules. The opponents has to play the lowest card higher than the card of the declarer& partner to win the trick if they can. However the card must be the lowest possible to leave the trick to an opponent whose card already beats the cards of the declarer&partner. As to the partnerships, a general regulation is to at least repeat the bid of your partner if you have 2 sure tricks or more, i.e. could win two tricks for any trump. For instance, it may be either "A A", or "A K" in the same suit, or "A" in one suit and "K Q" in another. When you pass, but the opponents don't, it can stimulate your partner to pass or claim *misère*. To avoid this, it makes sense to bid if you can count on 3 (or more) tricks upon declaring your trump, especially if you have honors and the hand seems good for the increases. Just to give an example of such *coordination*.

A computer version. The computer realization of the variant for two players is based on the following principles. The computer is programmed to selects the best one considering several random choices of the hand of the player (taking into account all information about the cards of the player appearing during the play). It does the same when bidding and declaring, but diminishes the most likely bid and contract by one level. The simplest *one-way version* is when the computer never bids (and has no score), and the player either determines the contract (without upgrades) and then plays following the standard rules or passes subtracting 2 points from his/her score. It follows *basic pont*. However the bidding scale and the admissible contracts starts from 4/7 considered as $0+1$ and giving 1 point. More generally, $0+k$, which means $(3+k)/(6+k)$, is counted as k points for $k=1, \dots, 6$.

The computer basic strategy is to win the trick leaded by the player with the smallest possible card and to play the lowest card otherwise. If it has no proper suit and no trump left, the card can be the lowest (from the shortest suit, if there are several cards of the same rank). However the suits where the player has no cards according to the information during the process of play are considered the best. When the computer leads, then the suit where the player has no cards is the first choice too. If the highest card (one of them if there are several of the same rank) has the *adjacent* one in the same suit (say, the pairs "A K" or "K Q")

are adjacent), or the next card in the suit is lower by 4 or more (say, "A 10"), then this is the second choice for leading. Otherwise the suit must be the longest and the card the highest among the longest suits. However the longest suit where the two highest cards are adjacent is considered first. If still there are several choices the computer decides randomly. These are of course very basic considerations; the actual computer program can be significantly more developed.

4.5. Concluding remarks. Let us stress that our trading system is not a *black box*; the logic of its decisions concerning trading stocks (any instruments) can be fully reconstructed and understood; cf. [HG]. We found not many situations where its decisions could be questioned on the basis of the usual *technical analysis*, though the system uses the stock-charts and its own prior decisions in novel ways. *Pont* clarifies some principles of our approach and test them "psychologically". We also hope that playing *pont* can help to get used to our *2-bids*.

The bidding table of *pont* and the one used for system's 2-bids (b, c) are similar, and this is not just an analogy! The auction and bidding seem fundamental for any intelligence. This can be within some expert system, inside our brain or AI. Poker and contract card games serve well the humankind as a risk-taking playground: they obviously capture something important about human cognition. See [Pa].

Obviously, using computers makes bidding formal and not "immediately understandable". The automated optimization and *deep learning* are even more difficult to interpret, even if every optimization step can be seen in detail, as in our programs. Generally, machine learning is fully "trustworthy", only if the results can be clearly interpreted "humanly". In our trading system, the optimization is mostly of this kind due to a small number of parameters our system deals with. The main are the categories, the modes (long/short, pro/counter), key thresholds, and some derived parameters like the average duration of positions; all are meaningful to investors. Our usage of power functions in the tables of 2-bids has solid grounds too, as we tried to demonstrate.

The discretization, which is necessary to separate noise from signals, is not really "intuitive", but the "action potentials" are always necessary and any usage of computers requires discretization. In our trading system we made the discretization as "human" as possible. The author of the paper is a specialist in discrete theories (mostly "integrable"), but the market reality resulted in non-standard auction-style *stratified discretization*. It is new, though using the data stratification and sample curves is common in *neural networking*. It is likely that our approach reflects the risk-taking processes in our brain; its successful market implementation can be regarded as some confirmation.

The importance of finding optimal relation between the decisions and sampling frequencies is well recognized. Let us quote [Si]:

Though available data are sampled at discrete intervals of time - daily, weekly, and so on - it need not be the case that economic agents make their decisions at the same sampling frequency. Yet it is not uncommon for the available data, including their sampling frequency, to dictate a modeler's assumption about the decision interval of the economic agents in the model. Almost exclusively, two cases are considered: discrete-time models typically match the sampling and decision intervals - monthly sampled data mean monthly decision intervals, and so on - whereas continuous-time models assume that agents make decisions continuously in time and then implications are derived for discretely sampled data. There is often no sound economic justification for either the coincidence of timing in discrete-time models, or the convenience of continuous decision making in continuous-time models.

This is actually the key problem we address in our trading system and this paper: how to coordinate different "decision intervals" and what is optimal decision-making based on a simultaneous analysis of several "frequencies". This is a must for AI systems focused on trading and of obvious importance well beyond stock markets.

Timing the market is and always was a great challenge, but now we have a new chapter: a systematic AI-based *research* and optimization of the process of investing. The usage of AI is a must here because the only reliable way to test performance of any trading system is (a) when it is fully(!) automated (machine learning included), (b) when someone else (not the creator) runs it, (c) the design and analysis of the experiments is as rigorous as possible, and (d) all findings are confirmed by real-time trading, which obviously requires full automatization.

We provide a sufficiently complete description of the basic principles of our trading system and the ways it was tested. Not all aspects of our approach were addressed here. The system consists of a lot of programs; many are used for technical processing data, including but not limited to managing historic and real-time quotes, practical matters like splits-dividends, and so on. Quite a few serve the optimization, historical and real-time. The real-time optimization uses the system own history of trades, upgrading the parameters is "while trading" (normally during weekends). Historic simulations require a lot of special software too. This is on top of *actual trading programs* and those monitoring the performance. The coordination of such a ramified combination of service, optimization and action programs is quite a test for any system; this is no different from the ways our brain works.

Beyond stock markets. The stock markets can be considered as a great model for many aspects of decision-making. In our approach, the impact of "events" is measured *indirectly*, via the responses of the "agents", which is quite standard in sociology and statistical physics. Many of our findings seem of universal nature. For instance, our

equations connecting *price-functions* with the *news-functions* can be equally used to model the relation between the *expected* resources for a task and those actually used, presumably including our brain.

"Investing" has its special features. Under *momentum risk-taking*, the agents seek to optimize their actions: (a) entering the "game" quickly when a clear signal is detected, and (b) exiting when some price-function reaches expected levels. Practically, we use here *tables of 2-bids* and *forecasting-termination curves*. Theoretically, power functions and their generalizations, Bessel and hypergeometric functions, are of significance here, as it was demonstrated in Section 2.

Importantly, we focus on the time-intervals when the *news impact* remains growing. The main reason is obvious: an objective of any trading is to capture local maxima of price-functions. Also, it is quite likely that *other* events and profit-taking will occur before the "natural decay" of the news impact. This is common in mathematical finance and physics to analyze the asymptotic behavior of correlation functions, which generally vanish at infinity; we model only short-term impacts.

Our brain can be considered as a kind of social system, though with huge number of neurons and very complex interactions. Assuming this, "events" reveal themselves via some waves of "mass behavior". Accordingly, such waves are likely to be the main information available to individual neurons and the key source of their "decisions", governed by *action potentials* and similar mechanisms. Eventually our brain creates some "images" of the underlying events. We are even able to form this way *abstract concepts*, such as *space-time*. Philosophically, let us at least mention here Kant; see e.g. [Ja].

Our analysis of stock markets, especially the simplicity of the basic differential equations we propose, can be an indication that the *power-laws* for the impacts of "events", auction-type procedures, and certain *price-functions* are present in the biology of the brain at the neural level. This is related to *neural networking*. The *price-function* generally measures the current *importance* of the event and the corresponding *expected* resources needed for its analysis. Our brain will try to diminish the neural activity when some "price-levels" are reached, though *the price* (the importance) varies depending on the intensity of the triggered brain activity. This can even result in *periodic* "waves of interest" in an event: an auto-mechanism for its abiding analysis, which we mathematically associate with Bessel functions. There is of course some "macro-management" too, say timely corrections of the failed decisions. The mechanisms of such conscious or unconscious "re-visiting" the analysis of past events are obviously complicated.

4.6. MRT: main findings.

(1) Cognitive science. The origin of our approach in cognitive science is the concept of *momentum risk-taking*, *MRT*, which can be defined

as short-term decision-making and forecasting based on the real-time monitoring the actions of other agents. Poker and our *pont* are good examples of games with similar data, but stock markets are of course the main source of this concept. In contrast to *thinking-fast* and *thinking-slow* from [Ka], when the "agents" can generally choose between two modes of thinking (unless in specially crafted experiments), there is no such choice here and high uncertainty is generally involved. Investors are assumed to decide "optimally" on the basis of the current news impact. Our restriction to short-term decisions and forecasts makes it possible to propose a mathematical, *quantitative* model of *MRT*, in contrast to *thinking-fast*, which is generally *qualitative*.

(2) **Toward general-purpose AI.** The restriction to *MRT* seems a realistic approach to *general purpose* AI systems. *MRT* is obviously one of the key parts of any intelligence, not only with humans. There is an astonishing universality of momentum risk-taking; those who master it in one field, can generally use their expertise in other fields upon proper (sometimes little) training. We think that almost the same *risk-taking curves* (we call them *forecasting or termination curves*) govern quite a spectrum of short-term risk-management tasks and that the corresponding "learning" is quite uniform almost regardless of the concrete tasks. The neural *action potentials* provide some discretization and timing, but there must be other mechanisms in the biology of the brain serving *MRT*. Some are beyond the immediate purpose of *MRT*, for instance the analysis of prior decisions. Expecting errors and correcting them is what intelligence is about.

(3) **Modeling MRT.** Importantly, *MRT* can be modeled mathematically, which we perform thanks to our focus on *short-term* management. The power growth of our forecasting curves holds only for relatively short periods "after the event". The corresponding differential equations modeling news impact seem sufficiently reliable to us. The trading system described in Section 3 is an experimental confirmation: it is based on the "power-law" for price-functions with exponents depending on the corresponding *investment horizons*. Mathematically, an argument in favor of our approach is a model of *profit-taking* in terms of Bessel functions. This relates the periodicity of profit-taking to the asymptotic periodicity of Bessel functions: a new approach to the *market volatility*, one of the key subjects in quantitative finance.

(4) **Market volatility.** The closest approach to our one we found in the vast literature on volatility in stock markets is based on the *fractional Brownian motion*, *fBM* with *Hurst exponents* reflecting the investment horizons. For instance, the usage of *fBM* explains theoretically why the volatility is extreme for day-trading (with low Hurst exponents). Some statistical variant of our approach is a consideration of a linear combination of 2-3 *fBM* corresponding to "heterogeneous time

scales”. Let us refer here at least to [Che, DB]; see Section 2 above. The approach via *fBM* does not separate the *profit-taking* from the “stochastic” volatility of stock markets, which is of key importance for practical trading (and our system). Our theoretical analysis indicates that *Bessel processes*, generalizing *fBM*, are likely to emerge here.

(5) **Some perspectives.** As it was quoted in the Introduction, we are decades away from *general purpose* AI (USA National Science & Technology Council). However, one can hope that some “prototypes”, can be designed faster than this. Even limited “deep learning” we (mostly) use in our experiments described in Section 3, provided efficient “human-like” behavior of our trading system. It was entirely focused on investing, but designing this kind of *MRT* for various tasks (with uniform and sufficiently fast machine learning) seems quite doable. It will require (i) further developing the mathematical model of *MRT* we suggested, (ii) finding its roots in the biology of the brain and psychology, (iii) improving the learning and risk-taking algorithms and making them really universal, (iv) experiments, and more experiments.
