SUMMARY

A new approach is presented to compute the seismic normal modes of a fully heterogeneous, rotating planet. Special care is taken to separate out the essential spectrum in the presence of a fluid outer core. The relevant elastic-gravitational system of equations, including the Coriolis force, is subjected to a mixed finite-element method, while self-gravitation is accounted for with the fast multipole method (FMM). To solve the resulting quadratic eigenvalue problem (QEP), the approach utilizes extended Lanczos vectors forming a subspace computed from a non-rotating planet – with the shape of boundaries of a rotating planet and accounting for the centrifugal potential – to reduce the dimension of the original problem significantly. The subspace is guaranteed to be contained in the space of functions to which the seismic normal modes belong. The reduced system can further be solved with a standard eigensolver. The computational accuracy is illustrated using all the modes with relative small meshes and also tested against standard perturbation calculations relative to a standard Earth model. The algorithm and code are used to compute the point spectra of eigenfrequencies in several Mars models studying the effects of heterogeneity on a large range of scales.

1 INTRODUCTION

Planetary normal modes are instrumental for studying the dynamic response to sources including earthquakes along faults and meteorite impacts as well as tidal forces (Dahlen & Tromp, 1998; Lognonné, 2005). For a review of Earth's free oscillations, we refer to Woodhouse & Deuss (2007). The low-lying eigenfrequencies contain critical information about the planet's large-scale structure and provide constraints on heterogeneity in composition, temperature, and anisotropy. Rotation constrains the shapes and possible density distributions of planets. The effect of rotation on the seismic point spectrum is well understood and has been observed for decades (Park et al., 2005, Fig.1). The observation of spectral energy at low-frequency toroidal modes in vertical seismic recordings of the 1998 Balleny Islands earthquake (Zürn et al., 2000), is a manifestation of the three-dimensional heterogeneity of the mantle structures and rotation.
Early studies of normal modes of a rotating, elliptical Earth utilized Rayleigh’s principle to approximate the associated eigenfrequencies [Backus & Gilbert 1961; Benioff et al. 1961; Dahlen 1968]. Later, perturbation theory [Dahlen & Sailor 1979] was developed and utilized the eigenfunctions of a spherically symmetric Earth model to estimate first- and second-order splitting due to rotation and ellipticity (Dahlen & Tromp 1998, Section 14.2 and Appendix D.4). Spectral perturbation theory initially was based on self-coupling or group-coupling approaches, while later full-mode coupling schemes have been considered (Dahlen 1968, 1969; Woodhouse & Dahlen 1978; Woodhouse 1980; Park 1986; Park & Gilbert 1986; Park 1990; Romanowicz 1987; Lognonné & Romanowicz 1990; Hara et al. 1991; 1993; Um et al. 1991; Lognonné 1991; Deuss & Woodhouse 2001; 2004; Al-Attar et al. 2012; Yang & Tromp 2015; Akbarashrafi et al. 2017). The issue with these coupling approaches is that the basis used does not lie in the space of normal modes of a rotating planet which is important, in particular, in the presence of a fluid outer core.

In our previous work (Shi et al. 2019), we separated the essential spectrum and introduce the mixed finite-element method for fully heterogeneous non-rotating planets. In a separate paper (Shi et al. 2018), we introduced a highly parallel algorithm for solving the resulting generalized eigenvalue problem using a polynomial filtering Lanczos method (Li et al. 2016). Here, we extend our previous work and include rotation in the elastic-gravitational system through the Coriolis force as well as the centrifugal potential with the appropriate constraints on the shapes of the (fluid-solid) boundaries. We utilize extended Lanczos vectors computed in a non-rotating planet – with the shapes of boundaries of a rotating planet and accounting for the centrifugal potential – as a truncated basis to reduce one of the equivalent linear forms of the quadratic eigenvalue problem (QEP). The normal modes computed are guaranteed to lie in the appropriate space of functions. The reduced system can be solved with a standard eigensolver. The proposed method is accurate as we demonstrate in our computational experiments using a full mode expansion in relatively small models. We also test our computations against standard perturbation calculations relative to a standard Earth model.

We apply our algorithm and code to studying Mars models through point spectra of eigenfrequencies. This is motivated by the InSight (Interior exploration using Seismic Investigations, Geodesy and Heat Transport) (Baker et al. 2013; Lognonné et al. 2019) mission to Mars. It is expected that a set of eigenfrequencies is observable (Panning et al. 2017; Bissig et al. 2018). Here, we select one Mars model (Khan et al. 2016) from the set of blind tests (Clinton et al. 2017; van Driel et al. 2019) and combine it with the topography (Zuber et al. 1992; Smith et al. 1999) and a three-dimensional crust (Belleguic et al. 2005; Goossens et al. 2017) to create a realistic Mars model. We compute the low-lying eigenfrequencies and study the general effects of rotation and heterogeneity combined.

The outline of this paper is as follows. In Section 2, we revisit the form and physics of the elastic-gravitational system of a rotating planet and establish the weak formulation of the system with a separation of the essential spectrum. In Section 3, we discuss the hydrostatic equilibrium of a rotating fluid outer core in the presence of the gravitational and the centrifugal forces. In Section 4, we develop the matrix form of the resulting QEP and review various approaches to solve it. We then introduce our subspace method to reduce the dimension of the equivalent linear form of the QEP using extended Lanczos vectors. In Section 5, we illustrate the computational accuracy of our proposed method. We also show several computational experiments for different planetary models, including standard Earth and Mars models. In Section 6, we discuss the significance of our results.

2 THE ELASTIC-GRAVITATIONAL SYSTEM WITH ROTATION

In this section, we briefly discuss the weak formulation associated with the elastic-gravitational system of a rotating planet. In Subsection 2.1, we revisit the basic equations in the strong form. In Subsection 2.2, we illustrate the rotation and the centrifugal acceleration of a Mars model. In Subsection 2.3, we present the weak formulation to compute the normal modes associated with the seismic point spectrum.
Seismic normal modes with rotation

2.1 The basic equations

Given the reference density $\rho^0$ and the gravitational constant $G$, we let $\Phi^0$ denote the gravitational potential which satisfies,

$$\Delta \Phi^0 = 4\pi G \rho^0,$$

and $S(u)$ denote the Eulerian perturbation of the Newtonian potential associated with the displacement $u$,

$$\Delta S(u) = -4\pi G \nabla \cdot (\rho^0 u).$$

To include the centrifugal force, we introduce the centrifugal potential

$$\psi(x) = -\frac{1}{2} \left[ \Omega^2 x^2 - (\Omega \cdot x)^2 \right],$$

where $\Omega \in \mathbb{R}^3$ is the angular velocity of rotation. We form the geopotential and its gradient,

$$g' = -\nabla (\Phi^0 + \psi).$$

Under the hydrostatic assumption,

$$\omega^2 \rho^0 u - 2i \omega \rho^0 R\Omega u = -\nabla \cdot (c : \nabla u) - \nabla (\rho^0 u \cdot g') + \nabla \cdot (\rho^0 u g') + \rho^0 \nabla S(u),$$

where $\omega$ denotes the angular frequency and $c$ denotes the elastic stiffness tensor; $R\Omega u = \Omega \times u$. The boundary conditions for the system (5) governing a hydrostatic planet are summarized in (Dahlen & Tromp 1998, Table 3.4).

2.2 Illustration of the geometry and physics using a Mars model

We utilize a flexible, fully unstructured tetrahedral mesh to model multiple complicated discontinuities associated with different geological and geodynamical features. The major discontinuities are discretized

Figure 1. Illustration of (a) the topography and (b) the crust-mantle interface of the Mars using MOLA and gravity data. [Zuber et al. 1992, Smith et al. 1999, Goossens et al. 2017].

Figure 2. Illustration of (a) $V_P$, (b) $V_S$, and (c) $\rho^0$ of our Mars model with a three-dimensional crust shown in Fig. 1.
using triangulated surfaces that are generated via distmesh (Persson & Strang 2004). We then build up the planetary model using an unstructured tetrahedral mesh via TetGen (Si 2015). Here, we use a Mars model as an example to illustrate our construction of a terrestrial planet. The topography of Mars was measured by the Mars Orbiter Laser Altimeter (MOLA) (Zuber et al. 1992; Smith et al. 1999) with high accuracy. The thickness and density of the Martian crust from the topography and gravity data were constrained by works of Belleguic et al. (2005); Goossens et al. (2017). In Fig. 1 (a), we illustrate the topography of Mars using data from MOLA (Smith et al. 1999); in Fig. 1 (b), we show the crust-mantle interface of Mars using data provided by Goossens et al. (2017). In Figs. 2 (a)–(c), we illustrate $V_P$, $V_S$ and $\rho_0$ of Mars integrating a radial model (Khan et al. 2016) with a three-dimensional crust as shown in Fig. 1. In Figs. 3 (a) and (b), we illustrate the axial spin mode, $\Omega \times x$, and the centrifugal acceleration, $-\nabla \psi$, of the Mars model, respectively.

### 2.3 The weak formulation

Since we study a general planet with non-smooth coefficients, it is natural to utilize the weak form of the relevant system of equations. Following the notation in de Hoop et al. (2015), a bounded set $\tilde{X} \subset \mathbb{R}^3$ is used to represent the interior of the planet, with Lipschitz continuous exterior boundary $\partial \tilde{X}$. The exterior boundary $\partial \tilde{X}$ contains fluid (ocean) surfaces $\partial \tilde{X}^F$ and solid surfaces $\partial \tilde{X}^S$. We subdivide the set $\tilde{X}$ into solid regions $\Omega^S$ and fluid regions $\Omega^F$. We use $\Sigma$ to represent the interfaces between these subregions. In summary,

$$\tilde{X} = \Omega^S \cup \Omega^F \cup \Sigma \cup \partial \tilde{X}, \quad \partial \tilde{X} = \partial \tilde{X}^S \cup \partial \tilde{X}^F.$$  

The interior interfaces can further be subdivided into three categories: interfaces between two fluid regions $\Sigma^{FF}$, interfaces between two solid regions $\Sigma^{SS}$, and interfaces between fluid and solid regions $\Sigma^{FS}$. These regions, interfaces and boundaries are illustrated in Shi et al. (2019) Subsection 2.1.

In de Hoop et al. (2019) Shi et al. (2019), we discuss the decomposition of the function space, $H = L^2(\tilde{X}, \rho^0 \mathrm{d}x)$ into components $H_1$ and $H_2$, that is,

$$H = H_1 \oplus H_2.$$  

(6)

We let $u^s$ and $u^f$ be the displacements in the solid and fluid regions, respectively, and enforce that $u^f$ lies in $H_1$ by augmenting the system of equations and introducing an additional variable, $p$, according to

$$-p\kappa^{-1} = \nabla \cdot u^f + \rho^0 \kappa^{-1} g' \cdot u^f$$  

in $\Omega^F$.  

(7)

Here, $\kappa$ signifies the compressibility of the fluid. Imposing the fluid-solid boundary condition $\nu^{f \rightarrow s} \cdot u^f =$

---

Figure 3. Illustration of (a) the axial spin mode, $\Omega \times x$, and (b) the centrifugal acceleration, $-\nabla \psi$, of the Mars model shown in Fig. 2.
Seismic normal modes with rotation

Following standard theoretical analysis (de Hoop et al. 2019), we define which is consistent with (Dahlen & Tromp 1998, (4.82)).

\[
\nu^{r \rightarrow s} \cdot u^s \text{, we obtain the weak form for } \mathcal{A},
\]

\[
0 = -\int_{\Omega_F} \nabla^2 \rho^{-1} \ dx + \int_{\Omega_F} \left[ \nabla \left( \nabla^T \rho^{-1} \right) \cdot u^f - \nabla \left( g^f \cdot u^f \right) \rho^0 \mathbf{\kappa}^{-1} \right] \ dx - \int_{\Sigma_F} \nabla \left( \nu^{r \rightarrow s} \cdot u^s \right) \ d\Sigma
\]

\[
= c_g([u, p], v^p)
\]

(8)

for all the test functions \( v^p \) with \( v^p|_{\partial \Omega_F} = 0 \), where \( \nu^{r \rightarrow s} \) denotes the normal vector at the fluid-solid boundary pointing from the fluid to the solid side. The same short-hand notation, \( c_g([u, p], v^p) \) in (8), was introduced in Shi et al. (2019) (16)).

For the weak formulation, we let \( v^r \) and \( v^f \) be the test functions for the displacement fields in the solid and fluid regions, \( \Omega^s \) and \( \Omega^f \), respectively. To restrict the system to the computational domain, we obtain the complete formula for the rotating hydrostatic planetary model

\[
a_2([u, p, S(u)], v) = \int_{\Omega^f} (\nabla \phi^r) : (c : \nabla u^s) \ dx + \int_{\Sigma_F} \mathcal{G} \left( \left( \nabla^T \rho \right) \nu^{r \rightarrow f} \cdot u^s \right) \ d\Sigma
\]

\[
+ \int_{\Sigma_F} (\nabla \cdot \nu^{r \rightarrow f}) p \ d\Sigma + \int_{\Sigma_F} \mathcal{G} \left( \left( \nabla^T \rho \right) (g^f \cdot u^s) \rho^0 - u^s \cdot (\nabla g^f) \cdot \rho^0 - u^s \cdot (\nabla^T \rho) \cdot (g^f \rho^0) \right) \ dx
\]

\[
- \int_{\Omega^f} (\nabla \cdot (\rho^0 \mathbf{\tau}^s)) S(u) \ dx - \int_{\Sigma_{SSU} \cup \partial \Omega_X^s} \left( \nu \cdot \mathbf{\tau}^s \right) S(u) [\rho^0]_+ \ d\Sigma - \int_{\Sigma_{FS}} \left( \nu^{r \rightarrow s} \cdot \mathbf{\tau}^r \right) S(u) [\rho^0]_- \ d\Sigma
\]

\[
+ \int_{\Omega^f} \rho^0 N^2 \left( g^f \cdot u^s \right) \ d\Sigma + \int_{\Sigma_{FS}} \mathbf{\tau}^f \cdot (\nabla p - g^f \rho^0 \mathbf{\kappa}^{-1}) \ d\Sigma
\]

\[
- \int_{\Omega^f} [\nabla \cdot (\rho^0 \mathbf{\tau}^s)] S(u) \ dx - \int_{\Sigma_{FSU} \cup \partial \Omega_X^f} \left( \nu \cdot \mathbf{\tau}^f \right) S(u) [\rho^0]_+ \ d\Sigma - \int_{\Sigma_{FS}} \left( \nu^{r \rightarrow f} \cdot \mathbf{\tau}^r \right) S(u) [\rho^0]_- \ d\Sigma
\]

and

\[
b_H(u, v) = \int_{\Omega^s} (\nabla^T \cdot u^s) \rho^0 \ dx + \int_{\Omega^f} (\nabla^T \cdot u^f) \rho^0 \ dx,
\]

(10)

and

\[
c_r(u, v) = \int_{\Omega^s} \nabla^T \cdot (\Omega \times u^s) \rho^0 \ dx + \int_{\Omega^f} \nabla^T \cdot (\Omega \times u^f) \rho^0 \ dx,
\]

(11)

where \( N^2 = (\nabla^T \rho / \rho^0 - g^f \rho^0 / \kappa) \cdot g^f \) signifies the square of the Brunt-Väisälä frequency; \( \nu^{r \rightarrow f} \) denotes the normal vector at the fluid-solid boundary pointing from the solid to the fluid side; the symmetrization operation \( \mathcal{G} \) as in de Hoop et al. (2015) is defined as \( \mathcal{G} \{ L(u, v) \} := \frac{1}{2} \{ L(u, v) + L(v, u) \} \), for any bilinear \( L(u, v) \). We note that \( a_2 \) and \( b_H \) in (9) and (10) are analogue of Shi et al. (2019) (26) and (7)), respectively. We obtain the quadratic eigenvalue problem from (10), (11), (9) and (8):

\[
\begin{cases}
    a_2([u, p, S(u)], v) = \omega^2 b_H(u, v) - 2i \omega c_r(u, v), \\
    c_g([u, p], v^p) = 0.
\end{cases}
\]

(12)

A matrix representation can be derived from (12). In practice, we replace \( p \) in \( a_2 \) by \( p(u^f, u^s_{\Sigma FS}) \) via solving the constraint \( c_g([u, p], v^p) = 0 \) in (8) and obtain

\[
a_2([u, p(u^f), u^s_{\Sigma FS}], S(u), v) = \omega^2 b_H(u, v) - 2i \omega c_r(u, v).
\]

(13)

The corresponding orthonormality condition is that, for an eigenpair \( (\omega_{(i)}, u^{(i)}) \), any other eigenpair \( (\omega_{(j)}, u^{(j)}) \) satisfies

\[
b_H(u^{(i)}, u^{(j)}) - 2i (\omega_{(i)}^{-1} + \omega_{(j)}^{-1}) c_r(u^{(i)}, u^{(j)}) = \delta_{ij},
\]

(14)

which is consistent with Dahlen & Tromp (1998) (4.82)).

Following standard theoretical analysis (de Hoop et al. 2019), we define

\[
F(\omega) = -\omega^2 \mathbf{I} + 2i \omega R_{\Omega}.
\]

and consider the quadratic operator pencil

\[
L(\omega) = F(\omega) + A_2,
\]

and consider the quadratic operator pencil
Table 1. Bulk parameters of Earth and Mars; \( \dot{\epsilon}(r_e) \) denotes the derivative of \( \epsilon \) at \( a = r_e \), and \( \epsilon^{\text{hyd}}(r_e) \) and \( \epsilon^{\text{obs}}(r_e) \) denote the computed hydrostatic ellipticity and observed ellipticity, respectively.

where \( A_2 \) is defined as \( a_2(u, v) = \langle A_2 u, v \rangle \). The decomposition in (15) implies a decomposition of \( L(\omega) \),

\[
\begin{pmatrix}
L_{11}(\omega) & L_{12}(\omega) \\
L_{21}(\omega) & L_{22}(\omega)
\end{pmatrix},
\]

In the above, the matrix system corresponds with \( L_{11}(\omega) \), while the essential spectrum coincides with the essential spectrum of \( L_{22}(\omega) \). Asymptotically, the seismic point spectrum corresponds with the spectrum of \( L_{11}(\omega) \).

3 HYDROSTATIC EQUILIBRIUM OF THE LIQUID CORE WITH ROTATION

In this section, we discuss the hydrostatic equilibrium with rotation and how it constrains the shape of boundaries and density distribution in planets. Rotating fluids have been extensively studied (Greenspan 1968; Chandrasekhar 2013; Zhang & Liao 2017). The outer core's properties have been studied through seismic normal modes since the 1970s (Gilbert & Dziewonski 1975; Dziewonski et al. 1975; Dziewonski & Anderson 1981), but also with body waves (Morelli & Dziewonski 1993; Kennett et al. 1995). Much more recently, an alternative radial outer core model has been proposed using the parametrization of the equation of state for liquid iron alloys at high pressures and temperatures, inferred from eigenfrequency observations (Irving et al. 2018). We furthermore mention models for the outer core of the Moon (Weber et al. 2011) and the core of Mars (Rivoldini et al. 2011; Khan et al. 2016) albeit ignoring rotation.

To reach the hydrostatic equilibrium, the prepressure \( p^0 \) satisfies

\[
\nabla p^0 = \rho^0 g',
\]

where \( g' \) is defined in (11). Well-posedness requires that

\[
\nabla p^0 \parallel g' \parallel \nabla p^0 \text{ in } \Omega^p \text{ and } g' \parallel \nu \text{ along } \Sigma^{pS} \cup \partial X^p;
\]

see (de Hoop et al. 2015) Lemma 2.1) for details about the functional properties of \( \rho^0, p^0 \) and \( g' \). We provide various approaches enforcing (16) in general, in Appendix A, yielding the shapes of boundaries of rotating planets.

The computation greatly simplifies upon making an Ansatz for the density distribution, namely, that its level sets are spheroidal. The early study by Clairaut (1743) was based on this Ansatz. We briefly summarize Clairaut’s equation for determining the mentioned level sets assuming the ellipticity is small. We let \( a \) and \( \epsilon(a) \) be the mean radius and ellipticity of the density contours of \( \rho^0 = \hat{\rho}(a) \), where \( \hat{\rho}(a) \) is the value of the density of a spherically symmetric analogue. The ellipticity, \( \epsilon \), solves Clairaut’s equation,

\[
\frac{d^2 \epsilon}{da^2} + 8\pi G \rho^0 g_{(a)}^{-1} \left( \frac{de}{da} + a^{-1} \epsilon \right) - 6a^{-2} \epsilon = 0,
\]

supplemented with the boundary values

\[
\left. \frac{de}{da} \right|_{a=0} = 0, \quad \left. \frac{de}{da} \right|_{a=r_e} = r_e^{-1} \left( \frac{5\Omega^2 r_e}{2g(r_e)} - 2\epsilon(r_e) \right),
\]

where \( g_{(a)} \) is the value of the reference gravitational field in the radial direction, and \( r_e \) is the mean surface radius. The derivation of Clairaut’s equation, and the Radau approximation, are put in the context of a general scheme imposing (16) in Appendix A. The bulk parameters of Earth and Mars are listed in Table 1. While the hydrostatic assumption seems to apply to Earth with reasonable accuracy, \( \dot{\epsilon}(r_e) \) of the Mars appears to be negative, whence this assumption fails to hold (Dollfus 1972; Bills & Ferrari 1978).

In Appendix A2, we propose an optimization scheme to constrain the density distribution in the presence...

of rotation in accordance with (16). With the assumption that the level sets of the density distribution are spheroids, we will recover the solution of Clairaut’s equation. A refined model is the two-layer Maclaurin spheroid (Kong et al. 2010).

4 THE RESULTING QUADRATIC EIGENVALUE PROBLEMS

In this section, we present the matrix representation and solution of the QEP for a rotating planet. In Subsection 4.1, we derive the two matrix forms for a rotating planet with and without fluid regions. The fluid regions often indicate the fluid outer core or the entire core. In Subsection 4.2, we study various numerical approaches to solve the resulting QEP. In Subsection 4.3, we present two different subspace methods to provide solutions for the equivalent linear form of the resulting QEP.

4.1 The matrix forms

Following our previous work (Shi et al. 2019), we utilize the mixed finite-element method and FMM (Greengard & Rokhlin 1997; Gimbutas & Greengard 2011; Yokota 2013) to discretize the elastic-gravitational system. We use $u_h^s$, $u_h^f$ and $p_h$ to be the finite-element representation of the displacement for the solid regions, fluid regions and the pressure, $p$, respectively. Similarly, $v_h^s$, $v_h^f$ and $\tilde{p}$ are the finite-element representations of the corresponding test functions. Following the work of Shi et al. (2019), we write $\tilde{u}^s$, $\tilde{u}^f$ and $\tilde{p}$ for the vectors defining $u_h^s$, $u_h^f$ and $p_h$, and $\tilde{v}^s$, $\tilde{v}^f$ and $\tilde{\rho}$ for the vectors defining $v_h^s$, $v_h^f$ and $\rho_h$. In Tables 2 and 3, we list the implicit forms of the submatrices corresponding to the different terms in (12).

4.1.1 Planets with fluid regions

Following our previous work (Shi et al. 2019), for the planets with fluid regions, we have the matrix representation

$$\omega^2 M \tilde{u} - 2i \omega \tilde{R}_G \tilde{u} - (A_G - E_G A_p^{-1} E_G^T - C^T SC) \tilde{u} = 0,$$

(19)
We note that the actions of (19) simplify and we obtain the QEP,

\[ \omega^2 M \tilde{u}^s - 2i \omega R \tilde{u}^s - (A_{sg} - C_s^T S C_s) \tilde{u}^s = 0. \]  

We note that the actions of \( A_{sg}, C_s \) and \( C_s^T \) are shown in Tables 2 and 3 and do not include any terms related to the fluid-solid boundaries.

### 4.2 Solution of the quadratic eigenvalue problem

To simplify (19) and (20) without any loss of the generality, we let \( \tilde{u} \) be the solution vector \( \tilde{u}^s \) for (20) or \( \tilde{u} \) for (19) and derive a standard form for the QEP,

\[ \omega^2 M \tilde{u} - 2i \omega R \tilde{u} - A \tilde{u} = 0, \]  

where the implicit forms of all the submatrices are shown in Tables 2 and 3 and do not include any terms related to the fluid-solid boundaries.

Table 4. List of features of different linear forms.

where $A$ represents either $A_{sg} - C_s^T S_s C_s$ in (20) or $A_{G} - E_G A_p^{-1} E_G^T - C^T S C$ in (19). We also note that $\tilde R_\Omega = -\tilde R_\Omega^T$ and $2 i \tilde R_\Omega$ is Hermitian.

It is challenging to solve the resulting QEP directly; see Tisseur & Meerbergen (2001) for a review and Bai et al. (2000) for a practical guide. The standard QEP takes the form:

$$(\omega^2 M + \omega C + K)\tilde u = 0,$$

where $C = -2 i \tilde R_\Omega$ with $C = C^T$ and $K = -A$ with $K = K^H$ while comparing with our problem (21). The eigenfrequencies are real and come in pairs $(\omega, -\omega)$. To solve the QEP of the original form, the QEP is often projected onto a properly chosen low-dimensional subspace to facilitate the reduction to a QEP directly with lower dimension, such as in the Jacobi-Davidson method (Sleijpen et al. 1996a,b). The reduced QEP can then be solved by a standard dense matrix technique. Both Arnoldi- and Lanczos-type processes (Hoffnung et al. 2006) were developed to build projections of the QEP. Holz et al. (2004) presented a subspace approximation method applying perturbation theory to the QEP. Bai & Su (2005) developed a second-order Arnoldi procedure for generating an orthonormal basis for solving a large-scale QEP directly. We note that the above mentioned methods typically utilize a shift-and-invert scheme to solve for the interior eigenpairs. In practice, solving shifted linear systems often leads to a computational bottleneck, especially, on a highly parallel supercomputer with distributed memory using a direct solver. We exemplify this issue in Shi et al. (2018).

Alternatively, the QEP can be transformed into an equivalent linear problem. Possible options are the following (Saad 2011 Section 9.3)

\[
\begin{pmatrix}
0 & I \\
-A & -2\tilde R_\Omega
\end{pmatrix}
\begin{pmatrix}
\tilde u \\
i\omega \tilde u
\end{pmatrix}
= i\omega
\begin{pmatrix}
I & 0 \\
0 & M
\end{pmatrix}
\begin{pmatrix}
\tilde u \\
i\omega \tilde u
\end{pmatrix},
\]

\[
\begin{pmatrix}
0 & A \\
A & 2\tilde R_\Omega
\end{pmatrix}
\begin{pmatrix}
\tilde u \\
i\omega \tilde u
\end{pmatrix}
= i\omega
\begin{pmatrix}
A & 0 \\
0 & -M
\end{pmatrix}
\begin{pmatrix}
\tilde u \\
i\omega \tilde u
\end{pmatrix},
\]

\[
\begin{pmatrix}
0 & I \\
A & 2i \tilde R_\Omega
\end{pmatrix}
\begin{pmatrix}
\tilde u \\
\omega \tilde u
\end{pmatrix}
= \omega
\begin{pmatrix}
I & 0 \\
0 & M
\end{pmatrix}
\begin{pmatrix}
\tilde u \\
\omega \tilde u
\end{pmatrix},
\]

\[
\begin{pmatrix}
A & 0 \\
0 & M
\end{pmatrix}
\begin{pmatrix}
\tilde u \\
\omega \tilde u
\end{pmatrix}
= \omega
\begin{pmatrix}
-A & 0 \\
0 & M
\end{pmatrix}
\begin{pmatrix}
\tilde u \\
\omega \tilde u
\end{pmatrix},
\]

\[
\begin{pmatrix}
0 & A \\
A & 2i \tilde R_\Omega
\end{pmatrix}
\begin{pmatrix}
\tilde u \\
\omega \tilde u
\end{pmatrix}
= \omega
\begin{pmatrix}
A & 0 \\
0 & M
\end{pmatrix}
\begin{pmatrix}
\tilde u \\
\omega \tilde u
\end{pmatrix}.
\]

The orthonormality condition (cf. (14)) implies that

$$\tilde u^H(i) M \tilde u(j) - 2 i (\omega(i) + \omega(j))^{-1} \tilde u^H(i) \tilde R_\Omega \tilde u(j) = \delta_{ij},$$

where $(i), (j)$ label two eigenvectors. In Table we list the features of the different forms while solving the QEP. We will work with (26).
4.3 Subspace approximation

Following (Shi et al. 2018, 2019) using \( x \) as an alternative notation for the displacement vector of a non-rotating planet, we first solve for the eigenpairs in
\[
Ax = \omega_2^2 Mx,
\]
where \( \omega_2 \) denotes the eigenfrequency for the linear real Hermitian problem. Polynomial filtering techniques (Saad 2006; Fang & Saad 2012; Li et al. 2016) are appealing as they do not involve solving linear systems with highly indefinite shifted matrices. Instead, the bulk of the computations are carried out in the form of matrix-vector multiplications, which are generally much easier to implement on highly parallel platforms than solving the indefinite linear systems. For a generalized eigenvalue problem, \( Ax = \lambda Mx \) with both real Hermitian \( A \) and \( M \), the basic form of filtering is
\[
\rho(M^{-1}A)x = \rho(\lambda)x,
\]
where \( \rho(\cdot) \) denotes the filter function (Shi et al. 2018, 2019). Multiplying both sides by \( M \) yields the following problem
\[
K_2x = \rho(\lambda)Mx, \quad \text{with} \quad K_2 = M\rho(M^{-1}A).
\]
We apply the Lanczos algorithm to matrix pencil \((K_2, M)\). In the polynomial filtered non-restart Lanczos algorithm, each step of the iterative process consists of a Lanczos step with \( K_2 \),
\[
\beta_{i+1}z_{i+1} = K_2v_i - \alpha_i z_i - \beta_i z_{i-1},
\]
followed by a full reorthogonalization against all the previous vectors \( \{v\} \) using modified Gram-Schmidt iterations with \( z \) defined as \( z = Mv \). A test for convergence is implemented for every \( N_{\text{cycle}} \) steps after the first \( N_{\text{init}} \) iterations. We check if the sum of the Ritz values that are greater than the threshold \( \tau \) no longer vary. Finally, a computed Ritz pair \((\lambda_i, x_i)\) is accepted if \( \lambda_i \) is in the desired interval and its residual norm is smaller than a given tolerance. We note that vectors \( v \) and \( z \) are real and their inner product is \((v, z) = v^\top z\).

Since \( K_2 \) and \( M \) are real Hermitian, \( \alpha \) and \( \beta \), in the tridiagonal matrix \( T_{K2} \) say, are real. The details of the algorithm are provided in Algorithm 1 from line 1 to 12.

In the above, \( \{v\} \) contains the extended Lanczos vectors. These generate a large subspace, spanned by eigenvectors, associated with a target interval. In Subsections 4.3.1 and 4.3.2, we utilize the computed extended Lanczos vectors to reduce the dimension of the equivalent form \( (26) \) of the QEP.

4.3.1 Extended Lanczos vectors spanning the subspace

Instead of using the computed Ritz vectors directly, we utilize extended Lanczos vectors and obtain more Ritz vectors through the polynomial filtering method. We then approximate the solution \( \tilde{u} \) using the basis computed from
\[
AX_e = MX_e\Lambda_e,
\]
where \( X_e \) denotes the Ritz vectors of the linear system and \( \Lambda_e \) denotes a diagonal matrix whose diagonal is a collection of \( \omega_2^2 \). We take \( m_e \) eigenvectors spanning a subspace and let \( \tilde{u}_e = X_ey_e \) to approximate \( \tilde{u} \) in \( (21) \), where \( y_e \) is complex. Applying
\[
\begin{pmatrix}
X_e^T & 0 \\
0 & X_e^T
\end{pmatrix}
\]
to both sides of \( (26) \) and making use of \( X_e^TAX_e = \Lambda_e \), we can then rewrite \( (26) \) as
\[
\begin{pmatrix}
0 & \Lambda_e \\
\Lambda_e & 2iX_e^T\tilde{R}_QX_e
\end{pmatrix}
\begin{pmatrix}
y_e \\
\omega_e y_e
\end{pmatrix} = \omega_e \begin{pmatrix}
\Lambda_e & 0 \\
0 & I
\end{pmatrix} \begin{pmatrix}
y_e \\
\omega_e y_e
\end{pmatrix}.
\]
We note that \( 2iX_e^T\tilde{R}_QX_e \) is dense of size \( m_e \times m_e \) and complex Hermitian. We can further simplify \( (30) \) to a standard eigenvalue problem,
\[
\begin{pmatrix}
0 & \Lambda_e^{1/2} \\
\Lambda_e^{1/2} & 2iX_e^T\tilde{R}_QX_e
\end{pmatrix}
\begin{pmatrix}
\Lambda_e^{1/2} y_e \\
\omega_e y_e
\end{pmatrix} = \omega_e \begin{pmatrix}
\Lambda_e^{1/2} y_e \\
\omega_e y_e
\end{pmatrix}.
\]

\[\text{Algorithm 1}\]
We collect all the computed Lanczos vectors and obtain \( V \) for an entirely solid planet (cf. (20)), while \( \omega \) for a planet containing fluid regions (cf. (19)) and \( X \) computed Lanczos vectors. We calculate the extended Ritz vectors where \( \tilde{X}_c \) denotes the eigenfrequencies in the Cowling approximation. Then we solve the generalized eigenvalue problem

\[
A^c x = \omega_c M x,
\]

where

\[
A^c = A + C^T S C,
\]

for a planet containing fluid regions (cf. (19)) and

\[
A^c = A + C^T S_c C_s,
\]

for an entirely solid planet (cf. (20)), while \( \omega_c \) denotes the eigenfrequencies in the Cowling approximation. We collect all the computed Lanczos vectors and obtain \( V_C = [v_1, \ldots, v_{m_C}] \), where \( m_C \) is the number of computed Lanczos vectors. We calculate the extended Ritz vectors \( X_c = [x_1, \ldots, x_{m_c}] \), where \( m_c \) is the number of Ritz vectors, for the original system without rotation via

\[
A X_c = M X_c \Lambda_c,
\]

It is apparent that if \( \tilde{R}_\Omega = 0 \), we have \( \omega = \omega_c = \Lambda_c^{1/2} \). The system (31) can be solved with a standard eigensolver such as the one implemented in \textsc{Lapack} \cite{Anderson99}. The details are provided in lines 13 to 20 in Algorithm 1.

\begin{figure}[h]
\begin{center}
\includegraphics[width=\textwidth]{algorithm.png}
\end{center}
\caption{Algorithm 1 A subspace method for the resulting QEP}
\end{figure}

4.3.2 Extended Lanczos vectors in the Cowling approximation spanning the subspace

The computation of the incremental gravitational potential using the FMM is quite costly. To avoid this computation one may invoke the Cowling approximation. Then we solve the generalized eigenvalue problem

\[
A^c x = \omega_c M x,
\]

where

\[
A^c = A + C^T S C,
\]

for a planet containing fluid regions (cf. (19)) and

\[
A^c = A + C^T S_c C_s,
\]

for an entirely solid planet (cf. (20)), while \( \omega_c \) denotes the eigenfrequencies in the Cowling approximation. We collect all the computed Lanczos vectors and obtain \( V_C = [v_1, \ldots, v_{m_C}] \), where \( m_C \) is the number of computed Lanczos vectors. We calculate the extended Ritz vectors \( X_c = [x_1, \ldots, x_{m_c}] \), where \( m_c \) is the number of Ritz vectors, for the original system without rotation via

\[
A X_c = M X_c \Lambda_c,
\]

In Algorithm 2, we provide the details of our proposed algorithm. As an aside, our approach allows high rotation rates. Nonetheless, our approach based on extended Lanczos vectors is not entirely dissimilar from a full-mode coupling concept.

**Algorithm 2** A subspace method using Lanczos vectors of Cowling approximation

1. **Input:** $A_C$, $A$ and $M$, filter function $\rho$, $K_C = \rho(A_C)$ and target interval $[f_1, f_2]$
2. **Initialization:** $z_0 := 0$, initial vector $v_1$ with $\|v_1\|_M = 1$, and $z_1 := Mv_1$
3. Perform filtered Lanczos algorithm $\beta_{i+1}z_{i+1} = K_cv_i - \alpha_i z_i - \beta_i z_{i-1}$ (cf. Algorithm 1)
4. Obtain all the Lanczos vectors $V_C = [v_1, ..., v_{m_{lc}}]$
5. $[\Theta_C, Q_C] = \text{eig}(T_C)$, where $T_C = V_C^T A_C V_C$
6. for $i = 1, ..., m_{lc}$ do
   7. $x_i = VQ_C(:, i)$, $x_i := x_i/\|x_i\|_M$ and $\lambda_i := (Ax_i, x_i)$
   8. if $(\lambda_i \geq \xi_{cut}$ and $\|Ax_i - \lambda_i Mx_i\|/|\lambda_i| < tol_3)$ Accept $(\lambda_i, x_i)$; **end if**

10. Obtain $X_c = [x_1, ..., x_{m_{lc}}]$ and $\Lambda_c = [\lambda_1, ..., \lambda_{m_{lc}}]$
11. $[\omega_c, Y_c] = \text{eig}(A_c)$, where $A_c = \begin{pmatrix} 0 & \Lambda_1^{1/2} \\ \Lambda_1^{1/2} & 2iX_c^T \hat{R}_0 X_c \end{pmatrix}$
12. Collect all the eigenfrequencies in $[f_1, f_2]$ as well as the corresponding eigenvectors

5 COMPUTATIONAL EXPERIMENTS

In this section, we first show the computational accuracy of our proposed approach on different small planetary models when the computation of the full mode expansion is feasible. We then illustrate computational experiments yielding planetary normal modes with the use of two supercomputers, Stampede2 (an Intel cluster) at the Texas Advanced Computing Center and Abel (a Cray XC30 cluster) at Petroleum Geo-Services. We study the spectra of two models: Earth 1066A (Gilbert & Dziewonski 1975) and a Mars model (Khan et al. 2016). We use 23.9345 hours (Allen 1973) and 24.6229 hours (Lodders & Fegley 1998) as Earth’s and Mars’ rotation periods, respectively.

5.1 Computational accuracy

For small models, we are able to compute the full mode expansion associated with the point spectrum using (31). In Table 5, we list the numerical parameter values pertaining to the testing of computational accuracy.
and estimating the cost in different models: The number of elements (labeled as # of elm.), size of $A$, size of $S$ and the target frequency interval in milliHertz (labeled as $[f_1, f_2]$ (mHz)).

In Figs. 4 (a)–(c), we illustrate the computational accuracy of tests in three different models, C3kp1, E3kp1 and M2kp1, respectively, on the lowest seismic eigenfrequencies using P1 elements. We compare the differences in the eigenfrequencies between the full mode expansion and a 200 mode expansion using Algorithm 1. The differences are about $5 \times 10^{-6}$ mHz, which is two digits below the accuracy of common normal mode measurements.

In Figs. 5 (a) and (b), we show the computational accuracy of M8kp1 on $[0.4, 1.14]$ mHz as well as the error distribution. In Fig. 5 (a), we show that even with a 100 mode expansion, the differences are as low as $1 \times 10^{-5}$ mHz. In Fig. 5 (b), we show that with a 1000 mode expansion, the differences are further reduced to about $1 \times 10^{-6}$ mHz.

5.2 Computational cost

Here, we compare the computational costs of Algorithms 1 and 2. In Table 6 we list the parameters used in running the two algorithms on experiment E40kp1: Polynomial degree (labeled as pol. deg.), number of iterations (labeled as # of iter.), average time of one $M$ multiplication with a vector (labeled as t-$Mv$), average time of one FMM operation (labeled as t-FMM), total time and relative error that are calculated via $\|\omega^2 M \tilde{u} - 2i\omega \tilde{R} \tilde{u} - A \tilde{u}\|/\|\omega\|$. Both tests are performed on 4 Intel Knights Landing nodes using P1 elements.

We note that the computational cost of one FMM operation is much more than this of a single sparse matrix-vector multiplication. In this test, Algorithms 1 and 2 perform $167 \times 831 = 138,777$ FMM operations and 771 FMM operations, respectively. The cost savings in the Cowling approximation are significant indeed.
Table 6. Comparison between two methods on experiment E40kp1 in Table 5 on 4 computing nodes.

5.3 Benchmark experiments for Earth models

Over the past two decades, a significant number of observational studies have been carried out to understand the Earth's interior [Zürn et al. (2000); Millot-Langet et al. (2003); Park et al. (2005); Roult et al. (2010); Nader et al. (2015); Schimmel et al. (2018)]. Our computational approach allows such studies to be complemented with accurate and consistent simulations even at relatively high eigenfrequencies. Here, we perform a benchmark experiment of Earth model 1066A [Gilbert & Dziewonski 1975] against a perturbation calculation [Dahlen & Sailor 1979]. In the perturbation calculation, the eigenfrequency perturbations $\delta\omega_m$ have the following form

$$\delta\omega_m = \omega_0(a + bm + cm^2), \quad -l \leq m \leq l,$$

(33)

where $\omega_0$ denotes the eigenfrequency of the unperturbed spherically symmetric model, $l$ denotes the angular order in the spherical harmonic expansion, and $a$, $b$ and $c$ are the relevant coefficients. The values of $a$, $b$ and $c$ for different radial modes can be found in [Dahlen & Tromp 1998, Table 14.1]. In Table 7, we list the numerical parameters of the Earth models in the benchmark test. Models E1Mp1 and E2Mp2 used to compute $\omega_0$ represent spherically symmetric Earth models without rotation. Experiments EE1Mp1 and EE2Mp2 represent elliptic Earth models and are used to compute eigenfrequencies of our proposed method via Algorithm 2. The ellipticity of the Earth models are computed by solving Clairaut’s equation in Section 3. Since the eigenfrequencies of the Slichter modes [Slichter 1961] are close to the upper bound of the essential spectrum and the convergence of the proposed algorithm is relatively slow, we set $f_1 = 0.04$ mHz and use experiments E1Mp1 and EE1Mp1 to compute the Slichter modes using P1 elements. Experiments E2Mp2 and EE2Mp2 are used to compute other modes using P2 elements. In Fig. 6, we show the comparison between the perturbation and our proposed method. The values of the computed eigenfrequencies of the proposed method agree with the perturbation results in as much as that the relative differences are commonly less than 0.3 µHz. The degree of agreement is, of course, model dependent. The eccentricity in the Earth model is so small that the second-order perturbation is accurate within the typical error of our numerical computations. Higher rotation rates would increase the eccentricity and presumably let the second-order perturbation become less accurate.

5.4 Mars models

Here, we present our computational results for Mars models. The interiors of the Mars models are based on mineral physics calculations [Khan et al. 2016]. In Table 8, we list three Mars models labeled as M2Mp2, EM2Mp2 and TM2Mp2 which represent a spherically symmetric Mars model without rotation, a spheroidal Mars model with rotation, and a spheroidal Mars model with a three-dimensional crust and rotation using P2 elements. The shape of the spheroidal Mars model’s core-mantle boundary is computed by solving Clairaut’s equation. Since Mars presumably is not hydrostatic as discussed in Section 3, its solid region is estimated via a linear interpolation using the ellipticities of the core-mantle boundary ($\varepsilon = 4.19 \times 10^{-3}$) and the surface ($\varepsilon = 5.89 \times 10^{-3}$). Model TM2Mp2 is illustrated in Fig. 2.

In Fig. 7, we show eigenfrequencies computed in different Mars models listed in Table 8. Symbols •, ◦ and □ represent the computed eigenfrequencies for Earth and Mars models, respectively.

Table 7. Numerical parameters of the Earth models used in the benchmark experiments.
Seismic normal modes with rotation

Figure 6. Comparison of the results from a perturbation calculation and our proposed method, which are shown using symbols • and ×, respectively. (a), (b) and (c) present comparisons of $0_{S_l}$, $0_{T_l}$ and $1_{S_l}$ modes, respectively.

× represent the eigenfrequencies computed in Mars models M2Mp2, EM2Mp2 and TM2Mp2 (cf. Table 5). The horizontal dashed lines represent the eigenfrequencies of a spherically symmetric Mars model computed with a one-dimensional solver (Masters et al. 2011; Ye 2018). Mode splitting is apparent due to ellipticity, rotation and heterogeneity in three dimensions. The three-dimensional crust does not have a clear influence on the lowest eigenfrequencies associated with $0_{S_2}$, $0_{T_2}$, $1_{S_1}$, $0_{S_3}$, $0_{T_3}$, $1_{S_2}$ and $0_{S_4}$ in Fig. 7(a). The three-dimensional crust has a noticeable effect on the surface wave modes, such as $0_{T_6}$, $0_{T_7}$, $0_{T_8}$, $0_{S_6}$, $0_{S_7}$ and $0_{S_8}$, as expected. In Fig. 8 we show the eigenfrequencies in a subinterval of the interval used in Fig. 7(d). Here, we note the splitting of modes $2_{S_4}$, $0_{S_8}$ and $0_{T_8}$ and highlight the effects of the three-dimensional crust. The maximum difference among the eigenfrequencies in Fig. 8 is 5.2 µHz, which, in principle, can be detected. There is no mode-coupling observed in these experiments.

In Fig. 9 we plot the branch $1_{S_l}$ as well as the corresponding incremental gravitational fields $\nabla S(u)$.

**Figure 7.** Eigenfrequencies of different Mars models. (a), (b), (c) and (d) illustrate eigenfrequencies in different frequency windows. Symbols •, ◦ and × represent the eigenfrequencies computed from Mars models M2Mp2, EM2Mp2 and TM2Mp2 in Table 8, respectively. The x-axis indicates the indexes of eigenfrequencies with ascending order. The horizontal dashed lines represent the eigenfrequencies of a spherically symmetric Mars model computed with a one-dimensional solver.
Seismic normal modes with rotation

Figure 8. Illustration of a subinterval in Fig. 7(d). The x-axis indicates the indexes of eigenfrequencies with ascending order. Splitting of modes $2S_4$, $0S_8$, and $0T_8$ due to the three-dimensional crust. The maximum difference among the eigenfrequencies is $5.2 \mu$Hz.

The superconducting gravimeters are expected to contribute to normal mode seismology (Crossley et al. 1999; Van Camp 1999; Widmer-Schnidrig 2003; Rosat et al. 2003; Häfner & Widmer-Schnidrig 2012). We anticipate that both the seismic and gravity measurements of these modes could help to estimate the size of Martian core.

6 CONCLUSION

In this work, we propose a method to compute the normal modes of a fully heterogeneous rotating planet. We apply the mixed finite-element method to the elastic-gravitational system of a rotating planet and utilize the FMM to calculate the self-gravitation. We successfully separate out the essential spectrum by introducing an additional constraint equation. Thus, we are able to compute the normal modes associated with seismic point spectrum. To solve the relevant QEP, we utilize extended Lanczos vectors computed in a non-rotating planet – with the shape of boundaries of a rotating planet and accounting for the centrifugal potential – spanning a subspace to reduce the dimension of an equivalent linear form of the QEP. The reduced system can be solved with a standard eigensolver. We demonstrate our ability to compute the seismic normal modes with rotation accurately. We then study the computational accuracy and cost of our proposed method and use a standard Earth model to perform a benchmark test against a perturbation calculation. We carry out computational experiments on various Mars models and illustrate mode splitting due to rotation, ellipticity and heterogeneity of the crust. The use of modern supercomputers enables us to capture normal modes associated with the seismic point spectrum of a fully heterogeneous planet accurately. The computational cost can further be reduced using accelerating techniques.

ACKNOWLEDGEMENT

APPENDIX A: SHAPES OF A ROTATING PLANET

In this appendix, we revisit the derivation of Clairaut’s equation in the context of condition (16) associated with the well-posedness and hydrostatic equilibrium (15).

A1 Spheroidal density profiles and Clairaut’s equation

We start with the equation (15) in the co-rotating frame,

\[ \nabla \rho = \rho^0 g' = -\rho^0 \nabla (\Phi^0 + \Psi), \]

where \( \Phi^0, \Psi \) and \( g' \) are defined in (1), (3) and (4), respectively. Upon transforming (3) into spherical polar coordinates, the centrifugal potential takes form of

\[ \Psi(r, \theta) = \frac{\Omega^2 r^2}{3} [-1 + P_2(\cos \theta)], \quad (A.1) \]

where \( P_2(\cos \theta) = (3\cos^2 \theta - 1)/2 \) denotes the second-order Legendre polynomial. Equation (16) directly implies

\[ \nabla \rho^0 \times g' = -\nabla \rho^0 \times \nabla (\Phi^0 + \Psi) = 0. \]

We now assume that the level sets of the density \( \rho^0 \) are spheroidal with mean radii, \( a \), and ellipticities, \( \epsilon \). Condition (16) will imply that \( \epsilon \) depends on \( a \). The level sets can be written in spherical polar coordinates as

\[ r = r_a(\theta) = a \left[ 1 - \frac{2}{3} \epsilon(a) P_2(\cos \theta) \right]. \quad (A.2) \]

To first order in \( |\epsilon| \), the inverse relation,

\[ a = a_r(\theta) = r \left[ 1 + \frac{2}{3} \epsilon(r) P_2(\cos \theta) \right], \]

follows. Since \( \rho^0 \) is independent of the azimuth angle, the level sets of the density \( \rho^0 \) can be described as

\[ \rho^0(r_a(\theta), \theta) = \text{const}_a =: \hat{\rho}^0(a). \]

To first order in \( |\epsilon| \), we have the elliptical density:

\[ \hat{\rho}^0(r, \theta) = \hat{\rho}^0(a_r(\theta)) \approx \rho^0(r) + \frac{2r}{3} \frac{d\rho^0}{da} \bigg|_{a=r} \epsilon(r) P_2(\cos \theta). \quad (A.3) \]

While solving Poisson’s equation (1) in spherical polar coordinates, we obtain

\[ \Phi^0(r, \theta) = -G \int_0^\infty \int_0^\pi \int_0^{2\pi} \frac{\rho^0(r', \theta') r'^2 \sin \theta'}{\sqrt{r^2 - 2rr' \sin \theta \sin \theta' \cos \psi' + \cos \theta \cos \theta' + r'^2}} \psi' \sin \theta' \sin \theta \, dr' \, d\theta' \, d\psi'. \quad (A.4) \]

Since \( \rho^0 \) is independent of the azimuth angle \( \psi \), we let

\[ \Theta(r, r', \theta, \theta') := \int_0^{2\pi} \left[ r^2 - 2rr' \sin \theta \sin \theta' \cos \psi' + \cos \theta \cos \theta' + r'^2 \right]^{-\frac{3}{2}} \, d\psi', \]

and, after some algebra, obtain that

\[ \Theta(r, r', \theta, \theta') = \begin{cases} \frac{1}{r} \sum_{n=0}^\infty \left( \frac{r'}{r} \right)^n P_n(\cos \theta) P_n(\cos \theta') & r > r', \\ 1 & r < r', \end{cases} \]

where \( P_n(\cos \theta) \) denotes the Legendre polynomials, see (Morse & Feshbach 1953 Chapter 6) and (Abramowitz & Stegun 1965 Chapter 8). Substituting \( \Theta(r, r', \theta, \theta') \) in (A.4), we obtain

\[ \Phi^0(r, \theta) = \sum_{n=0}^\infty \Phi_n(r) P_n(\cos \theta), \]
where

\[ \Phi_0(r) = \frac{2\pi G}{r^{n+1}} \int_0^r \int_0^{\theta'} r^{n+2} \rho^0(r', \theta') P_n(\cos \theta') \sin \theta' \, d\theta' \, dr' - 2\pi G r^n \int_r^\infty \int_0^{\theta'} r^{n+2} \rho^0(r', \theta') P_n(\cos \theta') \sin \theta' \, d\theta' \, dr'. \]

Substituting the density \( \rho^0 \) in (A.3), we obtain the expansion

\[ \Phi^0(r, \theta) = -4\pi G \left[ \frac{1}{r} \int_0^r \rho^0(r') r^2 \, dr' + \int_r^\infty \rho^0(r') r' \, dr' \right] \]
\[ - \frac{8\pi G}{15} \left[ \int_0^\infty \frac{\rho^0(\theta') - \epsilon(\theta') r^{n+5} \, dr'}{r} \right] P_2(\cos \theta). \]

To match the level sets of \( \rho^0(\alpha) \), condition (A.6) also implies

\[ \Psi(r, \alpha, \theta) + \Phi^0(r, \alpha, \theta) = \text{const}. \]  

Hence, we need to evaluate the potentials at the level sets of the density profiles. To first order in \(|\epsilon|\), using the relation (A.2) and (A.3), we rewrite \( \Phi^0(r, \theta) \) and obtain

\[ \Phi^0(r, \theta) \approx \Phi_0(a) + \Phi_2(a) P_2(\cos \theta), \]

where

\[ \Phi_0(a) = -4\pi G \left[ \frac{1}{a} \int_0^a \rho^0(a') a^2 \, da' + \int_a^\infty \rho^0(a') a' \, da' \right], \]
\[ \Phi_2(a) = -\frac{8\pi G}{3} \left[ \epsilon(a) \int_0^a \rho^0(a') a^2 \, da' - \frac{1}{5} \int_0^a \rho^0(a') P_2(\cos \theta) \, da' \right]. \]

We also rewrite (A.1) using (A.2) to the same order in \(|\epsilon|\), and obtain

\[ \Psi(r, \alpha, \theta) \approx -\frac{\Omega^2 a^2}{3} (-1 + P_2(\cos \theta)). \]  

To match the level sets of \( \rho^0(\alpha) \) and (A.5), to the same order in \(|\epsilon|\), while adding the two potentials (A.6) and (A.7) together, we simply must have the cancellation,

\[ \Phi_2(a) + \frac{\Omega^2 a^2}{3} = 0. \]  

Equation (A.8) implies

\[ \epsilon(a) a^2 \int_0^a \rho^0(a') a^2 \, da' - \frac{1}{5} \int_0^a \rho^0(a') \frac{d[\epsilon(a')]}{da'} \, da' \]
\[ \approx \frac{3}{5} \int_0^a \rho^0(a') \frac{d[\epsilon(a')]}{da'} \, da' = \frac{\Omega^2 a^5}{8\pi G}. \]

Differentiating (A.8) with respect to \( a \), we obtain

\[ \left( a \frac{de}{da} + 2\epsilon \right) \rho^0(a) - 3 \int_a^\infty \frac{dP(a')}{da'} \, da' = \frac{15\Omega^2}{8\pi G}, \]

where the average density is given by

\[ \bar{\rho}^0 = \frac{3}{3a} \int_0^1 \rho^0(a') a^2 \, da' = \frac{3g(a)}{4\pi G a}. \]

The derivation of the boundary conditions (cf. (18) can be obtained from taking the limit of (A.9); see (Dahlen & Tromp 1998) (14.12) for details. Differentiating (A.8) with respect to \( a \) twice, we obtain

\[ a^2 \frac{d^2 \epsilon}{da^2} - 6\epsilon + \frac{6\bar{\rho}^0}{\rho^0} \left( a \frac{de}{da} + \epsilon \right) = 0. \]  

Equation (A.10) is exactly the Clairaut’s equation (17). Clairaut’s equation determines the ellipticities of the level sets. Through the hydrostatic equilibrium, we automatically guarantee that the level sets of \( \rho^0 \) coincide with the ones of the geopotential. More details about hydrostatic ellipticity and Clairaut’s equation can be found in (Dahlen & Tromp 1998 Section 14.1).
A2 More general density profiles

To overcome the limitation of ellipsoidal assumption, we model the density of the fully heterogeneous planet and the shape of the fluid core due to the effects of the centrifugal force. Since $g'$ needs to be parallel to $\nabla \rho^0$, to find the satisfactory $\rho^0$ in (16), we form a related optimization

$$\min \mathcal{E}(\rho) = \frac{1}{2} \int_\Omega [(g')^2 (\nabla \rho)^2 - (g' \cdot \nabla \rho)^2] \, dx + \frac{1}{2} \int_{\Sigma^{FS\cup\partial X_F}} [(g')^2 \nu^2 - (g' \cdot \nu)^2] \, d\Sigma,$$

(A.11)

subjects to constraints on conservation of mass,

$$\int_{\tilde{X}} \rho \, dx = M^e,$$

(A.12)

and conservation of the moment of inertia,

$$\int_{\tilde{X}} |\Omega|^{-2}[\Omega^2 x^2 - (\Omega \cdot x)^2] \rho \, dx = \int_{\tilde{X}} -2|\Omega|^{-2}\psi \rho \, dx = I^e.$$

(A.13)

where $M^e$ and $I^e$ denote mass and moment of inertia, respectively; $g'$ is a function of the density $\rho$. We note that $g'$ depends on $\rho$ through Poisson’s equation (cf. (1)) while we need to align the gradient of $\rho$ and $g'$ at the same time.

We note that if $\rho^*$ is a local solution,

$$\frac{d}{d\rho} \mathcal{E}(\rho^*) = 0.$$

(A.14)

where

$$\frac{d}{d\rho} \mathcal{E}(\rho)(\cdot) = \int_{\tilde{X}^F} \left[(g' \cdot \frac{dg'}{d\rho}(\cdot)) (\nabla \rho)^2 + (g')^2 \nabla \rho \cdot \nabla (\cdot)\right] \, dx$$

$$- \int_{\tilde{X}^F} \left[(g' \cdot \nabla \rho) \left(\frac{dg'}{d\rho}(\cdot) \cdot \nabla \rho + g' \cdot \nabla (\cdot)\right)\right] \, dx + \int_{\Sigma^{FS\cup\partial X_F}} \left[(g' \cdot \frac{dg'}{d\rho}(\cdot)) \nu^2 - (g' \cdot \nu) \left(\frac{dg'}{d\rho}(\cdot) \cdot \nu\right)\right] \, d\Sigma.$$

The combination of (A.12), (A.13) and (A.14) yields the Karush-Kuhn-Tucker conditions, or KKT conditions for short (Nocedal & Wright 2006). Given that a perturbation $\delta \rho^*$ near $\rho^*$ satisfies

$$\int_{\tilde{X}} \delta \rho^* \, dx = 0, \quad \text{and} \quad \int_{\tilde{X}} -2|\Omega|^{-2}\psi \delta \rho^* \, dx,$$

the fact that

$$\frac{d}{d\rho} \mathcal{E}(\rho^*) \delta \rho^* = 0,$$

implies that

$$g'(\rho^*) \times \nabla \rho^* = 0, \quad \text{and} \quad |g'(\rho^*) \times \nu|_{\Sigma^{FS\cup\partial X_F}} = 0.$$

Equation (16) is then satisfied.
