## 1 Summary

Differential privacy allows quantifying privacy loss resulting from accessing sensitive personal data. Repeated accesses to underlying data incur increasing loss. Releasing data as privacy-preserving synthetic data would avoid this limitation, but would leave open the problem of

designing what kind of synthetic data. We propose formulating the problem of private data release through probabilistic modelling. This approach transforms the problem of designing the synthetic data into choosing a model for the data, allowing also including prior knowledge, which improves the quality of the synthetic data. We demonstrate empirically, in an epidemiological study, that statistical discoveries can be reliably reproduced from the synthetic data. We expect the method to have broad use in creating high-quality anonymized data twins of key data sets for research.

## 2 Introduction

Open release of data would be beneficial for research but is not feasible for sensitive data, for instance clinical and genomic data. Since reliably anonymizing individual data entries is hard, releasing synthetic microdata [30] has been proposed as an alternative. To maximize the utility of the data, the distribution of the released synthetic data should be as close as possible to that of the original data set, but should not contain synthetic examples that are too close to real individuals as their privacy could be compromised. Traditional methods of statistical disclosure limitation cannot provide rigorous guarantees on the risk [3]. However, differential privacy (DP) provides a natural means of obtaining such guarantees.

DP [13, 14] provides a statistical definition of privacy and anonymity. It gives strict controls on the risk that an individual can be identified from the result of an algorithm operating on personal data. Formally, a randomized algorithm  $\mathcal{M}$  is  $(\epsilon, \delta)$ -DP, if for all data sets X, X', where X and X' agree in all but one entry, and for all possible outputs S of  $\mathcal{M}$ , it satisfies

$$\Pr(\mathcal{M}(X) \in S) \le e^{\epsilon} \Pr(\mathcal{M}(X') \in S) + \delta, \tag{1}$$

where  $0 \le \delta < 1$ . The non-negative parameters  $\epsilon$ ,  $\delta$  define the strength of the guarantee, with smaller values indicating stronger guarantees. Privacy is usually achieved by introducing noise into the algorithms. DP has many desirable properties such as composability: combining results of several DP algorithms is still DP, with privacy guarantees depending on how the algorithms are applied [14, 16]. Another important property of DP is invariance to post-processing [12], which assures that the privacy guarantees of a DP result remain valid after any post-processing. Thus we can use the results of a DP algorithm to answer future queries and still have the same privacy guarantees.

Data sharing techniques under DP can be broadly separated into two categories as noted by Leoni [23]: input perturbation, where noise is added to the original data to mask individuals; and synthetic microdata, created from generative models learned under DP. The input perturbation techniques lack generality as they are often suitable for only very specific types of data, for example set-valued data [9]. From now on we will focus only on synthetic data based techniques. Using DP for releasing synthetic microdata provides a more generalisable solution and was first suggested by Blum et. al [6] for binary data sets. Since then, multiple privacy-preserving data release techniques have been proposed [5, 8, 10, 19, 27, 31, 32]. However, the methods have so far been limited to special cases such as discrete data [5, 10, 18, 19, 27, 31], or having to draw a synthetic data set from noisy histograms [31, 32]. More recent work has employed more powerful models [2, 4, 8]. These methods have been shown to be much more efficient and general compared to previous attempts. However, these methods as well as other data sharing works share a limitation: they are not able to use existing (prior) knowledge about the data set.

Typically the data sharing methods are build around a similar idea: learn a generative model from the sensitive data under privacy guarantees and then sample a synthetic data set from the trained model. These works differ mainly in the specific model used, and how the model is learned under DP. Now one might ask is this not sufficient, if the model is a universal

approximator (such as VAEs in [4]) and a sufficient amount of data is used to train it? The answer is yes in principle, but in practice the amount of data required may be completely infeasible, as the universal approximator would need to learn from data the structure of the problem, causality, and all parameters. All this is made more difficult by capacity of the models being more limited under DP, and the necessary tuning of hyperparameters coming with a privacy cost.

If the human modeller has knowledge of how the data have been generated, it is much more data-efficient to put this knowledge to the model structure than to learn everything from scratch with general-purpose data-driven models. For example, the data analyst might want to explicitly model structural zeros, i.e. zeros that corresponds to an impossible outcome due to other features of the data, e.g. alive subjects cannot have a cause of death. This is where the general purpose models fall short. Instead of building a new general purpose model for private data sharing, we propose a new essential component to private data sharing by augmenting the standard data sharing workflow with a modelling task. In this modelling task, the user can encode existing knowledge of the problem and the data into the model before the private learning, thus guiding the DP learning task without actually accessing any private data yet.

We propose to give the modeller the tools of probabilistic modelling that provide a natural language to describe existing knowledge about how the data have been generated. This includes any prior knowledge which can be seamlessly integrated. In a continuous or high-dimensional data space there is also another reason why probabilistic modelling is needed: finite data sets are often sparse and require smoothing that preserves the important properties of the data.

In this paper we formulate the principle of *Bayesian DP data release*, which employs a generative probabilistic model and hence turns synthetic data release into a modelling problem. We demonstrate how the modelling helps in data sharing by using a general purpose model as a starting point. We will increase the amount of prior knowledge encoded into the model and show empirically how the synthetic data set becomes more similar to the original one when we

guide it with more prior knowledge. We show how the modelling becomes pivotal in making correct statistical discoveries from the synthetic data. Code for applying the principle across model families and data sets is available at https://github.com/DPBayes/twinify<sup>1</sup>.

## **3** Results

#### **3.1** Overview of methods used in the experiments

Our aim is to release a new synthetic data set that preserves the statistical properties of the original data set while satisfying DP guarantees. Consider a data set X and a probabilistic model  $p(\mathbf{X} \mid \boldsymbol{\theta})$  with parameters  $\boldsymbol{\theta}$ . We use the posterior predictive distribution (PPD)  $p(\tilde{\mathbf{X}} \mid \mathbf{X})$ ,

$$p(\tilde{\mathbf{X}} \mid \mathbf{X}) = \int_{\text{Supp}(\boldsymbol{\theta})} p(\tilde{\mathbf{X}} \mid \boldsymbol{\theta}) \, p(\boldsymbol{\theta} \mid \mathbf{X}) \, \mathrm{d}\boldsymbol{\theta}, \tag{2}$$

to generate the synthetic data. PPD tells us the probability of observing a new sample conditioned on the data we have obtained thus far. Therefore, if our model sufficiently captures the generative process, the PPD is the natural choice for generating the synthetic data. We sample the synthetic data from the posterior predictive distribution, by first drawing  $\tilde{\theta}$  from the posterior distribution  $p(\theta \mid \mathbf{X})$  and then drawing new data point  $\tilde{\mathbf{x}}$  from the probabilistic model conditioned on  $\tilde{\theta}$ , and repeating for all points.

Many of the previous differentially private data sharing works share a common workflow, namely learn a specific generative model from the data and share samples drawn from this generator. This pipeline is depicted in Figure 1.

What we suggest is to augment this pipeline with domain knowledge of the data holder. This is possible through probabilistic modelling which gives a natural language for encoding

<sup>&</sup>lt;sup>1</sup>Code for experiments in the paper is available at https://github.com/DPBayes/ data-sharing-examples.

Figure 1: Standard differentially private data sharing workflow

such knowledge prior to learning. In out experiments, we have used the new improved pipeline, depicted in Figure 2.

Figure 2: Bayesian DP data release

#### 3.2 Reproducing statistical discoveries from the synthetic data

In order for private data sharing to be useful, we need to retain important statistical information in the synthetic data while preventing re-identification of data subjects. Next we will demonstrate how encoding prior knowledge becomes essential in making correct statistical discoveries from the synthetic data.

To test whether the same discoveries can be reproduced from the synthetic as from the original data set, we generated a synthetic replica of a data set used in an epidemiological study [7], using a general-purpose generative model family (mixture model). Prior to learning, we encoded experts' domain knowledge about the data into the probabilistic model.

The data have previously been used to study the association between diabetes and alcohol related deaths (ARD) using a Poisson regression model [28]. The study showed that males and

females exhibit different behaviour in terms of alcohol related mortalities. We encoded this prior knowledge into the model by learning independent mixture models for males and females. Another type of prior knowledge we had, comes from the nature of the study that produced the data: the data of each subject ends either on a specific date, or at death. Hence, the status at the endpoint is known to have a one-to-one correspondence on certain features such as duration of the follow-up and most importantly the binary indicator that tells if individual died of alcohol related causes. We encoded this prior knowledge into the probabilistic model as well. For details on the models we refer to the Materials and Methods.

After building the model, we learned the generative model under DP and generated the synthetic data. We fit the same Poisson regression model that was used in the earlier study [28] to the synthetic data as well, and compared the regression coefficients of the two models.

From the synthetic data, we make two key observations. (1) We can reproduce the discovery that the diabetics have a higher risk for ARD than the non-diabetics, which agrees with the previous results on the original data [28]. The bar dubbed "Stratified" in Figure 3 shows that we can reproduce the discoveries with high probability for males with relatively strict privacy guarantees ( $\epsilon = 1$ ). For females we need to loosen the privacy guarantees to  $\epsilon = 4$  in order to reproduce the statistical discovery with high probability. We discuss the difference between males and females in the next Section. (2) In order to reproduce the discovery, we need to have the correct model. Figure 3 shows results of three different models: "Stratified" equipped with prior knowledge on gender and outcome of the follow-up, "No alive/dead strat" with prior knowledge we encode into the model, the better reproducibility we get. For males, with strict privacy ( $\epsilon = 1$ ) we increase the rate of reproducibility almost by 40% by having the correct model. For females, the effect is even stronger, however best visible with larger  $\epsilon$ .

Figure 3: **ARD study: encoding prior knowledge into the generative model improves performance**. For both males (a) and females (b) we recover the correct statistical discovery with high probability when we guide the model sufficiently with prior knowledge. The prior knowledge is increased from right to left in both a and b. In "Stratified", we have independent mixture models for the genders and deterministic features due to studys outcome. In "No alive/dead strat." we have independent models for the genders, and in "Unstratified" we treat all features within a mixture component as independent. For a reproduced discovery, we required the association between ARD and medication type to be found for all medication types with significance (p < 0.05). The figures show results of 100 independent repeats of each method with three levels of privacy (parametrized by  $\epsilon$ ).

#### **3.3** Performance of DP data sharing

Next we will demonstrate the usability as well as the limitations of the proposed general DP data sharing solution.

**DP data sharing works best when data are plentiful.** As we saw in Figure 3, the utility is better for males than the females, especially for strict privacy guarantees. To understand the difference between the two cases (males, females) in the ARD study, we note the much smaller sample size for ARD incidences among females (520 vs 2 312). Since DP guarantees indistinguishability among individuals in the data set, it is plausible that the rarer a characteristic, the less well it can be preserved in DP-protected data. To assess whether this holds for the

regression coefficients in the ARD study, we divided the regression coefficients, both male and female, into four equal-sized bins based on how many cases exhibited the corresponding feature and computed the mean absolute error between the original and synthetic coefficients within these bins. Figure 4 shows that the regression coefficients with higher number of cases are more accurately discovered from the synthetic data.

Previously Heikkilä *et al.* [20] showed that the error of estimating parameter mean under  $(\epsilon, \delta)$ -DP decreases proportional to O(1/n), where *n* is the size of the data set. Figure 4 shows that the error in the ARD study follows closely the expected behaviour as the number of cases increases. In this experient, the inverse group size was estimated with the average of the inverse group sizes within a bin.

However, the data size is not the only determining factor for the utility of DP data sharing. Next we will show how more clear-cut characteristics of the data are easier to discover, even with fewer samples.

**Picking up a weak statistical signal is difficult for DP data sharing.** The ARD study stratifies individuals based on three types of diabetes treatment: Insulin only, orally administered drug (OAD) only and Insulin+OAD treatment. Each of these therapies is treated as an independent regressor. For a reproduced discovery, we require that all of the regressors are positive and have sufficient statistical significance (p < 0.05). From Figure 5a we see that the probability of reproducing the discoveries for each subgroup increases as  $\epsilon$  grows. However, we also see that for the "Insulin only" subgroup we recover the correct discovery with higher rate compared to the larger subgroup "OAD only". The reason, why the smaller subgroup "*Insulin only*" is more often captured with sufficient significance than the largest subgroup "*OAD only*", can be explained by the original regression coefficients shown in Table 1. The OAD only subgroup has a significantly smaller effect on the ARD than the Insulin only, thus making it more difficult for

Figure 4: Accuracy of findings from synthetic data as a function of their rarity, ARD study. Accuracy of regression coefficients learned from synthetic data rapidly improves as the number of relevant samples grows. The solid curves show mean absolute error within a prevalence bin between the regression coefficients learned from original and synthetic data. Figure shows average result over 100 independent runs of the algorithm. The dashed line is proportional to the expected behaviour of an optimal estimator (see text); note the different scale in the y-axis (shown on the right) Results are from the stratified model. Tickmarks on the x-axis are (min, max) number of relevant samples within the respective bin. Error bars denote the standard error of mean. Results shown for three values of the privacy parameter  $\epsilon$ .

the mixture model to capture it. However as we increase  $\epsilon$ , the correlation between OAD only and ARD is more often captured. Both of these effects are also visible in the male case, as we see from Figure 5b, however in a smaller scale.

Some of the regression coefficients learned from the synthetic data diverge from the ground truth, which seems to also persists without privacy (see Column  $\epsilon = \infty$  in Table 1). In our experiments we have used a small number of mixture components (k = 10) as a compromise between sufficiently high resolution (we can make correct statistical discoveries) and private learning that becomes more difficult as the number of parameters grow. Increasing the number of mixture components resolves this inconsistency by improving the fit in non-private case (See Table S1 in Supplemental Information)

To evaluate the strength of the statistical signals in the female ARD study, we ran the Poisson regression study with bootstrapped original female data. Figure 6 shows that under 100 bootstrap iterations,  $\approx 30\%$  of the repeats did not reach the required statistical signicance. This shows that the statistical signal in female data is weak to begin with, and therefore may be difficult for data sharing model to capture.

Figure 5: The statistical signal is weaker in female data (ARD study). (a) Likelihood of reproducing findings as a function of privacy guarantee. Female case. The statistical discoveries are reliably reproduced from the synthetic data for the strictest privacy requirements. Results for combined case and for each subgroup separately. Combined results: all subgroups are required to have the correct sign and p < 0.05 to call the discovery reproduced. The size of each subgroup is shown in parenthesis. Results are from stratified model. (b) Likelihood of reproducing findings from synthetic data. For males (226 372 samples), the discoveries can be reproduced with high probability from the synthetic data. For females (208 148 samples), the probability of reproducing discoveries is lower. Bars show discoveries for each type of diabetes medication separately, and for all combined. In the combined case, for a reproduced discovery, we required the association between ARD and medication type to be found for all medication types with significance (p < 0.05). Results of 100 independent repeats of the method with privacy level ( $\epsilon = 1.0, \delta = 10^{-6}$ ) using the stratified model.

Despite DP data sharing having difficulties with weak statistical signal and limited data, it provides an efficient solution for privacy-preserving learning, especially when we are not certain

	Female									
	Coefficient	Number of cases	Original coef. $\pm$ Std. Error	$\epsilon = 1.0$	$\epsilon = 2.0$	$\epsilon = 4.0$	$\epsilon = \infty$

Table 1: **ARD study**, **ABOVE** : Females, **BELOW** : Males. The magnitude of the statistical effect in the male case is well preserved in synthetic data. DP and synthetic non-DP ( $\epsilon = \infty$ ) results are average over 100 runs, error denoting the standard deviation. The error in original coefficients shows the standard error for the regression model.

Figure 6: **ARD study:** The statistical signal is weak in female data, and discoveries cannot be made with sufficient significance. On the left, the bars show results for private synthetic data with  $\epsilon = 1.0$  of 100 independent runs using the stratified model. On the right, the bars show results for 100 times bootstrapped original data.

about the future use of the data. Next we will discuss how DP-based synthetic data stands against traditional query based DP approaches.

**Performance against tailored mechanism.** As discussed, one of the greatest advantages of releasing a synthetic data set is that it can be used in arbitrary tasks without further privacy

concerns. Using traditional DP techniques, a data holder that wants to allow DP access to a sensitive data set needs to set a privacy budget at the desired level of privacy, and split this budget for each access that the data is subjected to. As soon as the privacy budget runs out, the data cannot be used in any additional analysis without unacceptable privacy risk.

We will next show that the data sharing methods can outperform traditional DP techniques, if the data are to be accessed multiple times. We evaluate the performance on two data sets, a mobile phone app data set [29] referred to as Carat, and the publicly available set of US Census data "UCI Adult" [11]. As data sharing methods we apply a mixture model based PPD sampling method ("Mixture model") and a Bayes networks based method PrivBayes [33] ("Bayes network").

Consider that the data holder splits the budget uniformly among T anticipated queries. Figure 7a illustrates how the number of anticipated queries will affect the accuracy. We compared the data sharing method against perturbing the covariance matrix with Gaussian noise, according to the Gaussian mechanism [13] ("tailored mechanism"). We measured the accuracy in terms of the Frobenius norm (see Equation 8) between the true and the DP covariance matrices. Already with T = 10 queries, releasing a synthetic data set outperforms the tailored mechanism for this high-dimensional data. We show results only for the mixture model because the difference in performance between the mixture model and the Bayes networks is small in this example (See Figure 8a)

As another example, we compared the synthetic data release on the Adult data against private logistic regression classifier [21]. Figure 7b shows that the Bayes network consistently outperforms the tailored mechanism, and for strict privacy requirement (small  $\epsilon$ ) also the mixture model performs better than the tailored mechanism given 20 or more queries.

Figure 7: Performance against tailored mechanisms (a) **Carat study**. The data sharing method outperforms the tailored mechanism as the number of anticipated future queries (T) grows, in terms of classification accuracy. Curves show the Frobenius norm between original and synthetic covariance matrices. Privacy budget was fixed to  $(1.0, 10^{-5})$ . Average of 10 runs. Errorbars denote the standard error of mean. (b) Adult study. Synthetic data from the Bayes network model outperforms the tailored mechanism. While a tailored mechanism is more accurate for loose privacy guarantees (large  $\epsilon$ ) and few queries (small T), also the mixture model based data release is more accurate for multiple queries and tighter privacy guarantees. Average classification accuracy over 10 independent runs. Error bars denote standard error of mean.

**Demonstration on two parametric families of distributions** Finally, we will demonstrate the results from two data sharing approaches using two very different universal probilistic models making different computational tradeoffs. We evaluate the performance between mixture models and Bayes networks on the ARD, Carat and Adult data sets.

For the Carat data, Figure 8a shows that the Bayes network is accurate when the dimensionality of the data is low, but as the dimensionality grows, synthetic data generated from the mixture model achieves higher accuracy than data from Bayes networks, which also becomes computationally exhausting as the dimension increases. From Figure 8a, we can see that learning the mixture model takes only a fraction of the Bayes networks computational time. Similarly, in

Figure 8: Comparing Mixture model and Bayes networks using two different data. (a) Accuracy and computation speed of two models in generating synthetic data (Carat study). For low-dimensional discrete data Bayes networks are good, but as dimensionality grows their computation time becomes intolerable and mixture models more accurate. The solid lines denote the mean Frobenius norm (8) between the original and synthetic covariance matrices, with error bars denoting standard error of the mean from 10 independent runs of the algorithm. The dashed lines show the runtimes. Privacy budget was fixed to ( $\epsilon = 1.0, \delta = 10^{-5}$ ). (b) Accuracy of data synthesized with two models (ARD study). Mixture models preserve regression coefficients better than the Bayes network. The curves show mean absolute error between the original and the learned coefficients. Average over 100 runs. Error bars: standard error of the mean.

the ARD study, the mixture models outperforms Bayes networks (Figure 8b).

As a final comparison between the Bayes networks and mixture model, we compared the two in the previously introduced classification task using the Adult data set, which has fewer samples compared to ARD and Carat data (Adult 30 162 samples, Carat 66 754 samples and ARD Females 208 148, ARD Males 226 372). After learning the generative model, we used the synthetic data obtained from the generative model to train a logistic regression classifier and demonstrated the performance by predicting income classes. Figure 7b illustrates that in this example, the Bayes networks outperforms the mixture model in terms of classification accuracy.

## 4 Discussion

Dwork et al. [15] showed theoretically that there is no computationally efficient DP method for data sharing that would preserve all properties of the data. They consider the problem from the learning theory perspective, where the aim is to accurately answer a set of queries. Accurate answers become infeasible as the size of this query set grows. However, if we only need to preserve the most important properties of the data, the set of queries we want to accurately answer stays bounded in size, giving a way out. We argue that it would already be highly useful to be able to answer questions of the important properties; and moreover, the bigger picture may be more relevant than all the unique characteristics in the data.

As we saw in the Adult example, the DP data release can perform as well as the tailored mechanism even when answering just one query, and progressively better for multiple queries. However, as our experiments exemplify, encoding of the prior knowledge has a significant impact on the results. In fact, what we are proposing is to transform the DP data release problem into a modelling problem, which includes as an essential part the selection of the model according to the data and task, and bringing in available prior knowledge.

We illustrated in Figure 4 how increasing the number of relevant samples improves the results. As is common with all differentially private methods, the data release works better when the original data set has a large number of samples. This is because of the nature of DP; it is easier to mask the contribution of one element of the data set when the number of samples is large.

Recently, Karwa et al. [22] showed that DP has a broadening effect on the confidence intervals of statistical quantities learned under DP. Their proof was for Gaussian mean estimation; however, intuitively this property should translate to other differentially private tasks as well. The width of the confidence intervals depends on both the required level of privacy and the number of samples. This suggests that we should not expect to necessarily reproduce all the same discoveries under DP.

In the past, there has been discussion on whether standard random number generators (RNG) can be used to assure DP [17]. In the actual data release setting we would need to consider using cryptographically secure RNGs to properly provide individuals in the data set the DP guarantees. Also, limited accuracy of floating point arithmetics make it possible for an attacker to break DP due to errors in approximation [26]. However, these problems are by no means specific to DP data release but apply to all DP methods.

One major question for all DP algorithms is how to set the privacy parameters  $\epsilon$  and  $\delta$ . While the parameters are in principle well-defined, their interpretation depends for example on the chosen neighbourhood relation. Furthermore, the parameters are worst-case bounds that do not fully capture for example the fact that we do not release the full generative model but only samples drawn from the posterior predictive distribution. Our use of  $\epsilon \approx 1$  is in line with widely accepted standards derived from observed feasibility of membership inference attacks. Given the complicated relationship between the released and original data, it seems unlikely that the privacy of specific data subjects could be compromised in this setting under this privacy level.

### **5** Conclusions

We have reformulated the standard differentially private data sharing by formulating it as a modelling task. Using probabilistic modelling, we can express prior knowledge about the data and processes that generated the data before the training, thus guiding the model towards right directions without additional privacy cost. This makes it possible to extend the DP data sharing solution to data sets that are of limited size, but for which there exists domain knowledge.

Differentially private data sharing shows great potential, and would be particularly useful for data sets which will be used in multiple analyses. Census data is a great example of such data.

Also, as private data sharing allows arbitrary downstream tasks with no further privacy cost, it is a good alternative for tasks for which there is no existing privacy-preserving counterpart.

Our results demonstrate the importance of guiding the data sharing task with prior knowledge about the data domain, and that when this prior knowledge is encoded into the probabilistic model, the synthetic data maintains the usability of the original data in non-trivial tasks.

## 6 Materials and methods

#### 6.1 Materials

For the ARD study [7], the data came from 208 148 females and 226 372 males and comprised of three continuous, five binary and two categorical features.

Carat data set: Carat [29] is a research project that maintains a mobile phone app that helps users understand their battery usage. We obtained a subset of Carat data from the research project. Our aim was to privately release a data set that consists of installed apps of 66 754 Carat users. In order to have some variance in the data, we dropped out the 100 most popular apps that were installed on almost every device and used the 96 next most popular apps to subsample in the experiments.

In the Adult study of the UCI machine learning repository [11], we trained the generative model with 30 162 samples with 13 features of both continuous and discrete types. Separate test set consisted of 15 060 instances, out of which 75.4% were labelled <50k\$.

#### 6.2 Differential privacy

In our experiments, we have used approximate differential privacy, definition given below.

**Definition 1** (Approximate differential privacy [13]). A randomized algorithm  $\mathcal{M} : \mathcal{X}^N \to \mathcal{I}$ satisfies  $(\epsilon, \delta)$  differential privacy, if for all adjacent datasets  $X, X' \in \mathcal{X}^N$  and for all measurable  $S \subset \mathcal{I}$  it holds that

$$\Pr(\mathcal{M}(X) \in S) \le e^{\epsilon} \Pr(\mathcal{M}(X') \in S) + \delta.$$
(3)

We consider data sets as adjacent in the substitute relation, i.e. if we get one by replacing a single element of the other and vice versa. The privacy parameter  $\delta$  used in the experiments was set to  $10^{-6}$  for the ARD study and  $10^{-5}$  for both Carat and Adult studies.

#### 6.3 Probabilistic models

**Mixture model** Mixture model is an universal approximator of densities. The probability density for mixture model with K mixture components is given as

$$p(\mathbf{X} \mid \boldsymbol{\theta}, \boldsymbol{\pi}) = \sum_{k=1}^{K} \boldsymbol{\pi}_{k} p(\mathbf{X} \mid \boldsymbol{\theta}^{(k)}).$$
(4)

It allows capturing complex dependency structures through the differences between less complex mixture components (the densities  $p(\mathbf{X} \mid \boldsymbol{\theta}^{(k)})$ ). There is no limitation on what kinds of distributions can be used for the mixture components, and thus a mixture model is suitable for arbitrary types of data. In this work we assume independence of features within each mixture component. This means that the component distribution factorizes over the features, and we can write

$$p(\mathbf{X} \mid \boldsymbol{\theta}, \boldsymbol{\pi}) = \sum_{k=1}^{K} \boldsymbol{\pi}_{k} \prod_{j=1}^{D} p(\mathbf{X}_{j} \mid \boldsymbol{\theta}_{j}^{(k)}),$$
(5)

where the  $\mathbf{X}_j$ , j = 1, ..., D denote the D features of the data and  $\boldsymbol{\theta}_j^{(k)}$  the parameters associated with the *j*th feature of the *k*th component distribution. Intuitively the problem can be seen as

finding clusters of features such that each cluster has a axis-aligned covariance structure. As the number of such clusters increases, we can cover the data more accurately.

In our experiments with mixture models, we used posterior predictive distribution as the generative model. The only access to data is through the posteriors of the model parameters, which we learned under DP using the DPVI method [21]. DPVI learns a mean field approximation for the posterior distributions of model parameters using DP-SGD [1]. The number of mixture components K was set to 10 for data with fewer dimensions (< 20) and to 20 for data with more dimensions ( $\geq$  20). If necessary, this number, along with hyperparameters of DPVI, could be optimized under DP [24], with potentially significant extra computational cost.

**Bayes networks** A Bayes network is a graphical model that presents the dependencies across random variables as a directed acyclic graph (DAG). In the graph, the nodes represent random variables and the edges dependencies between the variables. To learn the graphs privately and to sample the synthetic data, we used the PrivBayes method [33] which builds the graph between the features of the data, and no additional latent variables were assumed. The topology of the network is chosen under DP by using the exponential mechanism [25], and the conditional distributions that describe the probability mass function are released using Laplace mechanism [14].

#### 6.4 Model details

For the mixture model, we need to choose how to model each feature in the data sets. In all our experiments we used the following distributions: Continuous features were scaled to the unit interval and modelled as Beta distributed. The parameters for Beta-distributed variables were given a Gamma(1, 1) prior. Discrete features were modelled as either Bernoulli or Categorical random variables based on the domain. Both in Bernoulli and Categorical cases, the parameters

were given a uniform prior. Table 2 summarizes the mixture models used in the experiments.

Dataset	K	Variable types	Details		
ARD	10	Binary, Categorical, Beta	Separate mixture mod-		
			els for males and fe-		
			males and also separa-		
			tion based on outcome		
			of the follow-up.		
Carat	20	Binary	Within a mixture		
			component, the fea-		
			tures were treated as		
			independent.		
Adult	10	Binary, Categorical, Beta	Separate mixture mod-		
			els for high/low income.		
			"Hours per week", "Cap-		
			ital Loss" and "Capi-		
			tal Gain" features dis-		
			cretized into 16 bins.		

Table 2: Summary of mixture model details.

#### 6.4.1 Prior knowledge used in the ARD study

In the ARD study, we showed how incorporating prior knowledge into the model improves the utility of data sharing. Next we will describe in detail the type of knowledge we used to model the data. We will encode the prior knowledge into the mixture model given in Equation (5). This corresponds to the model referred to as "Unstratified" in Figure 3.

We start by splitting the probabilistic model based on gender of the subject. This yields the following likelihood function:

$$p(\mathbf{X} \mid \boldsymbol{\theta}, \boldsymbol{\pi}) = p(x_{\text{gender}} \mid \boldsymbol{\theta}_{\text{gender}}) \sum_{k=1}^{K} \boldsymbol{\pi}_{k} p(\mathbf{X}_{\{\text{gender}\}} \mid \boldsymbol{\theta}^{(k)}, x_{\text{gender}}).$$
(6)

We refer to this model as "No alive/dead strat.".

The ARD data is an aggregate of a follow-up study which ended either on 31 December 2012 or on the subject's death. In this study, we are interested if an individual dies due to alcohol related reasons. Since the subject cannot be dead due to alcohol related reasons while still continuing to the end of the follow-up, we separated the model according to subjects' status by the end of the follow-up. This leads to the final "Stratified" model used in our experiments, with likelihood given as

$$p(\mathbf{X} \mid \boldsymbol{\theta}, \boldsymbol{\pi}) = p(x_{\text{gender}} \mid \boldsymbol{\theta}_{\text{gender}}) p(x_{\text{dead}} \mid x_{\text{gender}}, \boldsymbol{\theta}_{\text{dead}}) \sum_{k=1}^{K} \boldsymbol{\pi}_{k} p(\mathbf{X}_{\{\text{dead, gender}\}} \mid \boldsymbol{\theta}^{(k)}, x_{\text{dead}}, x_{\text{gender}}).$$
(7)

Here,  $x_{dead}$  denotes the end of follow-up indicator and  $X_{\{dead\}}$  the features of the data excluding the end of follow-up indicator. Now we can learn two mixture models, one for alive and the other for dead subjects for both females and males. Since the alive subjects stay in the study until the end of the follow-up, we can model the feature pair ("start date", "duration of follow-up") using just either one of the features. In our experiments we used the "start date" feature. Similarly as the ARD death can only occur in dead subjects, we can remove this feature from the alive model.

#### 6.5 Similarity measures

In the Carat experiments, we measured the performance in terms of the similarity between the covariance matrices of the original and synthetic data. The Frobenius norm between two matrices A and B is given as:

$$||A - B||_F = \left(\sum_{i=1}^n \sum_{j=1}^d (a_{ij} - b_{ij})^2\right)^{1/2}.$$
(8)

#### Acknowledgements

This work was supported by the Academy of Finland; Grants 325573, 325572, 319264, 313124, 303816, 303815, 297741, 292334 and Flagship programme: Finnish Center for Artificial Intelligence, FCAI. We thank the Carat group for access to the Carat data (http://carat.cs.helsinki.fi/) and the CARING study group (https://www.caring-diabetes.eu/) for access to the ARD data.

#### **Author contributions**

J.J., S.K., and A.H. designed research; J.J., E.L., and J.H. analyzed data; J.J., E.L., J.H., S.T., S.K. and A.H. interpreted the results; and J.J., S.K., and A.H. wrote the paper.

#### **Competing interests**

The authors declare no conflict of interest.

#### Data and code availability

Code used in our experiments is available at https://github.com/DPBayes/data-sharing-exampl

The Adult data set is available from UCI machine learning repository (https://archive.

```
ics.uci.edu/ml/datasets/adult).
```

ARD and Carat data sets contain personal information and therefore are not publicly available.

Regarding the Carat data gathering process, the user is informed about the data gathering and the research usage of the data (including app data) when installing the application in the End-user License Agreement (EULA). The process complies with EU's General Data Protection Regulation (GDPR). The app requires user consent for the installation. The developers have IRB (ethical board) approval for the Carat data gathering and analysis. Anonymized subset of Carat data can be found here: https://www.cs.helsinki.fi/group/carat/data-sharing/.

The ARD data was a collection from multiple sources: SII (permission Kela 16/522/2012), the Finnish Cancer Registry, National Institute for Health and Welfare (THL/264/5.05.00/2012) and Statistics Finland (TK-53-214-12). This is a register-based study with pseudonymous data and no patient contact, thus no consents from pseudonymized patients were required according to Finnish law. The Ethical Committee of the Faculty of Medicine, University of Helsinki, Finland (02/2012) reviewed the protocol. Data permits were received from the Social Insurance Institute (SII) (16/522/2012), the National Institute for Health and Welfare (THL/264/5.05.00/2012) and Statistics Finland (TK-53-214-12). SII pseudonymized the data.
