Abstract

We present a new method for formulating closures that learn from kinetic simulation data. We apply this method to phase mixing in a simple gyrokinetic turbulent system—temperature gradient driven turbulence in an unsheared slab. The closure is motivated by the observation that in a turbulent system the nonlinearity continually perturbs the system away from the linear solution, thus demanding versatility in the closure scheme. The closure, called the learned multi-mode (LMM) closure, is constructed by, first, extracting an optimal basis from a nonlinear kinetic simulation using singular value decomposition (SVD). Subsequent nonlinear fluid simulations are projected onto this basis and the results are used to formulate the closure. We compare the closure with several other closures schemes over a broad range of the relevant 2D parameter space (collisionality and gradient drive). We find that the turbulent kinetic system produces phase mixing rates much lower than the linear expectations. In contrast with the other closures, the LMM closure is able to capture this reduction. In comparisons of heat fluxes, the LMM closure performs comparably to other closure schemes when trained at a single parameter point. When trained at three points (in a 35 point parameter grid), the LMM closure exhibits errors substantially lower than the other closures.

1 Introduction

The gyrokinetic model [1, 2, 3], in which the fast gyration of particles around the magnetic field is averaged out, has proven to be a useful description of strongly magnetized plasmas. The system is reduced from 6D to 5D (3 spatial dimensions and 2 velocity dimensions) and and the fast cyclotron timescale is eliminated. The kinetic system is thus greatly simplified for both analysis and simulation.

Gyrokinetics has become the standard tool for describing turbulent transport in magnetic fusion devices, and more broadly, has found fruitful applications ranging from basic plasma physics to space / astro systems [4, 5, 6, 7]. In fusion applications, in particular, gyrokinetic simulations have demonstrated increasing explanatory power with respect to experimental observations [8, 9, 10]. Despite these developments, nonlinear gyrokinetics remains too expensive to be routinely used to predict confinement (i.e., to evolve profiles) or broadly explore parameter space for optimal confinement configurations. Consequently, further reductions in complexity remain highly desirable.

One such approach to further reducing the gyrokinetic system, the gyrofluid framework, was introduced in Ref. [11, 12]. A critical component of gyrofluid models is closures that model important kinetic effects within a fluid treatment. A prototypical example is the Hammett-Perkins (HP)[11] closure. The HP procedure closes a fluid system in collisionless regimes using the linear kinetic response. The HP closure was a major breakthrough, providing a much more rigorous treatment of collisionless plasmas than conventional fluid theory. It effectively models phase mixing / Landau damping rates resulting in linear growth rates and frequencies in quite good agreement with the true (kinetic)
values. Its utility is evidenced by continued vigorous development and application to broad-ranging plasma systems such as turbulent transport in tokamaks [13, 14], tokamak edge turbulence [15, 16, 17], and space plasma turbulence [18, 19].

However, its validity is perhaps not as well established in turbulent systems where nonlinearity can alter phase mixing dynamics. As will be shown for a simple turbulent system, the standard gyrofluid closures appear to over-estimate the phase mixing rate in comparison with nonlinear kinetic simulations. This is consistent with several recent papers that have noted that Landau damping rates can be greatly modified from linear expectations in turbulent systems (see, e.g. Refs. [20, 21, 22, 23, 24, 25]).

In this paper we present a method for formulating closures from nonlinear kinetic simulation data. This method, which we call the learned multi-mode (LMM) closure, is motivated by the notion that a closure for a turbulent system may benefit from the versatility to capture aspects of the nonlinear state. Our closure procedure first extracts, from a single nonlinear kinetic simulation, an optimal basis using singular value decomposition (SVD). Subsequent nonlinear kinetic simulations are projected onto the “fluid” components of this basis and the projection is used to formulate the closure. We apply this method to the problem of phase mixing in a gradient-driven turbulent system in slab geometry. We test it broadly throughout the 2D parameter space (gradient drive and collision frequency) of the turbulence in an unsheared slab. The underlying model is a reduction of gyrokinetics to one dimension (parallel to the magnetic field) in velocity space and retaining rudimentary finite Larmor radius (FLR) effects. As a starting point, we consider the gyrokinetic equations for a single kinetic species s in a triply periodic Fourier representation of an unsheared slab:

\[
\frac{\partial f_s}{\partial t} = - \left[ \omega_n + \omega_T \left( \frac{v_n^2}{\mu} + \mu \frac{3}{2} \right) \right] F_{0s} k_y \bar{\phi}_s \\
- \sqrt{2} v_T k_x \left( f_s + F_{0s} \bar{\phi}_s \right) + C(f_s) \\
+ \sum_{k'_{\perp}} (k'_s k_y - k_s k'_y) \bar{\phi}_s, k'_{\parallel} f_s, k_{\perp} = k'_{\perp},
\]

where the overbar denotes a gyroaverage (i.e. multiplication by the zeroth order Bessel function \( J_0(\sqrt{2} k_{\perp} a) \)), \( k_s(\rho_s) \) is the radial wavenumber (in the direction of the background gradients) and \( \rho_s \) is the species gyroradius, \( k_y(\rho_s) \) is the parallel (to the magnetic field) wavenumber, \( v_{\parallel}(1/v_{th,s}) \) is the parallel (to the magnetic field) velocity, \( \mu = \frac{m_s v_T^2}{2 T_0} (B_0/T_0) \) is the magnetic moment, \( t(\sqrt{F_{r,s}/m_s}) \) is time, \( C \rightarrow C(\frac{L_{ref}}{\tau_{th,s}}) \) is a collision operator (defined below for our system), \( f_s(\frac{L_{ref}}{\rho_s} \frac{T_{th,s}}{T_0}) \) is the perturbed distribution function, \( F_{0s}(\frac{\rho_s}{\tau_{th,s}}) \) is the background Maxwellian distribution function, \( \phi(\frac{L_{ref}}{\rho_s} \frac{T_{th,s}}{T_0}) \) is the electrostatic potential, \( \omega_n = L_{ref} / \tau_n \) is the inverse normalized density gradient scale length, \( \omega_T = L_{ref} / L_T \) is the inverse normalized temperature gradient scale length, and \( L_{ref} \) is

2 Reduced Gyrokinetic Equations in a Hermite Representation

In order to explore various closure ideas, we study a relatively simple kinetic turbulent system—gradient driven electrostatic instabilities and turbulence in an unsheared slab. The underlying model is a reduction of gyrokinetics to one dimension (parallel to the magnetic field) in velocity space and retaining rudimentary finite Larmor radius (FLR) effects. As a starting point, we consider the gyrokinetic equations for a single kinetic species s in a triply periodic Fourier representation of an unsheared slab:
the conventional fluid moments (see Appendix C). The gyrocenter distribution function, \( f_{k_x,k_y,k_z}(v) \), is a function of the three spatial wavenumbers and two velocity coordinates.

The field equation for the electrostatic potential is

\[
\phi_{k_x,k_y} = \frac{\int \int \int dv \int d\mu}{\tau + [1 - \Gamma_0(b)]} \int \phi_{FS} \delta_{k_x,0},
\]

where \( \tau \) is the ratio of ion to electron temperature, \( \Gamma_0(x) = I_0(x)e^{-x} \) with \( I_0(x) \) the zeroth order modified Bessel function, \( b = k_x^2 \), and the flux-surface averaged potential is,

\[
\langle \phi \rangle_{FS} = \frac{\pi \int \int \int dv \int d\mu}{[1 - \Gamma_0(b)]}.
\]  

The inclusion of the flux-surface averaged potential in Eq. 2 is appropriate for an ion species driven by the ion-temperature gradient (ITG). Such a system favors strong zonal flow production. In this unsheared slab system, this results in strongly suppressed turbulence [26]. Consequently, we neglect this term in our simulations below, which is appropriate for an electron species with adiabatic ions.

The gradient drive is now due to the electron-temperature gradient (ETG). In the following, the species labels are dropped with the understanding that all quantities should be considered to be electrons.

The reduced system studied in this work is derived by first integrating over the \( \mu \) coordinate and retaining rudimentary FLR effects of the form \( e^{-k_x^2/2} \). This approximation is exact only when integrating over a Maxwellian distribution function, as is done for all gyroaverages of the electrostatic potential. More sophisticated treatments are noted in the literature [12], but this rudimentary treatment is sufficient for our purposes, namely to stabilize the instabilities at \( k \perp \rho_s \gtrsim 1 \).

The parallel velocity dimension is then decomposed on a basis of Hermite polynomials \( f(v) = \sum_{n=0}^{\infty} f_n H_n(v)e^{-v^2/2} \), where \( n \) denotes now the order of the Hermite polynomial. The Hermite representation employed here facilitates analysis of the system in both fluid (truncation at low \( n \)) and kinetic (truncation at high \( n \)) limits and is thus well suited for studying closures. There is a simple connection between these Hermite moments, \( f_n \), and the conventional fluid moments (see Appendix C for details). The Hermite-based equations are as follows [26, 27]:

\[
\frac{df_{k,n}}{dt} = \frac{\omega_T ik_y k_x^2}{\pi^{1/4}} \phi_{k,n,2} - \frac{\omega_T ik_y}{\pi^{1/4}} \phi_{k,n,1} - \frac{ik_z}{\pi^{1/4}} \phi_{k,n,1} - ik_z [\sqrt{n}f_{k,n-1} + \sqrt{n+1}f_{k,n+1}] - \nu \bar{f}_{k,n} - \frac{\pi^{1/4} e^{-k_x^2/2}}{\Gamma + \tau - \Gamma_0(b)} \mathcal{I}_{k,0} - \frac{\pi^{1/4} e^{-k_x^2/2}}{\Gamma + \tau - \Gamma_0(b)} \mathcal{I}_{k,0}
\]

The electrostatic potential is directly proportional to the zeroth-order Hermite polynomial:

\[
\phi_k = \frac{\pi^{1/4} e^{-k_x^2/2}}{\Gamma + \tau - \Gamma_0(b)} \mathcal{I}_{k,0}.
\]
2.1 Free Energy Equations

In order to understand the effects and limitations of various closures, it is useful to conceptualize the turbulent dynamics in the context of an energy equation. The free energy [27] is given by:

$$\varepsilon_{k,n} = \varepsilon_k^{(f)} \delta_{n,0} + \varepsilon_k^{(f)}$$

(5)

with electrostatic component:

$$\varepsilon_k^{(f)} = \frac{1}{2} (\tau + 1 - \Gamma_0 (k_1^2)^{-1}) |\phi_k|^2$$

(6)

and entropy component

$$\varepsilon_k^{(f)} = \frac{1}{2} \pi^{1/2} |\phi_k|^2$$

(7)

The free energy evolution equation can be obtained from 3 and 4:

$$\frac{\partial \varepsilon_k^{(f)}}{\partial t} = J_k^{(f)} \delta_{n,0} + N_k^{(f)}$$

(8)

and

$$\frac{\partial \varepsilon_k^{(f)}}{\partial t} = \omega T Q_k \delta_{n,2} - C_k^{(f)} \delta_{n,1} + J_k^{(f)} \delta_{n,0}^{(f)} + J_k^{(f)} \delta_{n,0}^{(f)}$$

(9)

The terms on the RHS of 8 and 9 represent various energy injection, dissipation, and transfer channels. The only energy sink—collisional dissipation $C_k^{(f)}$—is directly proportional to the Hermite number $n$ multiplied by the free energy. The energy source $\omega T Q_k$ is proportional to the perpendicular heat flux $Q_k$.

There are also two conservative energy transfer channels. The nonlinear energy transfer $N_k^{(f)}$ redistributes energy in $k$ space but does not transfer energy between different $n$ and is not a net source or sink (it vanishes under summation in $k$-space).

$$J_k^{(f)} = \text{Re} \left[ -ik_\perp \phi_k^{1/4} \phi_k^{*} f_k^{(f)} \right]$$

is the energy transferred between the electrostatic component at $n = 0$ and the entropy component (i.e., Landau damping).

For our purposes of studying closures, the most important terms are the linear phase mixing terms $J_{k,n-1/2} = \text{Re} \left[ -\pi^{1/2} ik_\perp \sqrt{\pi} f_{k,n} f_{k,n-1} \right]$ and $J_{k,n+1/2} = \text{Re} \left[ \pi^{1/2} ik_\perp \sqrt{\pi} f_{k,n} f_{k,n+1} \right]$. These terms also represent a conservative energy transfer channel, albeit in velocity space. They conservatively transfer energy between $n$ and $n-1, n+1$ respectively but do not transfer energy in $k$-space.

One way to characterize the closure problem is determining the proper value of $f_{n+1}$ so that $J_{k,n+1/2}$ sends the proper amount of energy to higher order moments—or, as the case may be, receives the proper amount of energy from higher order moments. Below, in Sec. 4, we will analyze several closures in terms of their capacity to recover the proper (turbulent, kinetic) rates of energy transfer in phase space.

3 Closures

In this section, we will describe several closure schemes as applied to our reduced gyrokinetic system. All closure schemes are of the same class: $f_k = \sum_{n=0}^{\infty} A_{k,n} f_{k,n}$, i.e., closures that express the last moment in terms of a linear combination of the lower moments. Some closures will have coefficients $A_{k,n}$ that are specific to the wave-vector, $k$ but others will not, instead having $A_{k,n} = A_{n}$ for all $k$.

In a kinetic model where a large number of moments is retained, truncation, which entails setting $f_{k,n+n+1} = 0$, can be used. Alternatively, a simple high-$n$ closure as described in Ref. [29] can be applied. However, our goal in this work is to formulate a fluid model that captures the relevant kinetic physics while retaining only the most thermodynamically-relevant quantities, namely the first four moments. To achieve this, we require a closure for $f_{k,4}$ that is more intelligent than simple truncation. The following subsections describe HP-style closures as well as our new closure scheme.

3.1 HP-style closures

Here we provide a brief description of HP-style closures. Derivations and verification of these closures can be found in Appendix A. The HP closure [11, 30] is designed so that the dispersion relation, also referred to as the kinetic response function, arising from the hierarchy of closed moment equations matches the linear kinetic dispersion relation arising from the Vlasov-Poisson kinetic system. The exact kinetic response function, which...
involves the plasma dispersion function, $Z(\omega)$, is
\[ R_{00}(\omega) = -iZ(\omega). \] (10)

The HP closure for the $N^{th}$ moment takes the form $f_N = \sum_{i=0}^{N-1} A_i f_i(\omega)$. Combining this closure ansatz with the hierarchy of moment equations results in an approximate response function $R_{00}^a(\omega)$, a polynomial in $\omega$ involving the closure coefficients, $A_i$.

The HP closure chooses to do the matching in the low frequency limit, $\omega \to 0$, so the Taylor expansion for plasma dispersion function can be used, which turns Eq. 10 into a polynomial in $\omega$. The closure coefficients $A_i$ can then be chosen so that $R_{00}^a(\omega) = R_{00}(\omega)$. A detailed derivation of the HP closure can be found in A.

The HP closure for the $4^{th}$ moment in our system is
\[ f_{k,4} = -i\text{sgn}(k_z)A_3 f_{k,3} + A_2 f_{k,2} \] (11)
where the coefficients are $A_3 = -1.759i$ and $A_2 = 0.755$. These coefficients are the same for all $k$, so the only $k$-dependence for this closure comes from the $\text{sgn}(k_z)$.

A generalization of the HP closure, the Snyder closure [31], also includes the effects of collisionality. The procedure for arriving at the Snyder closure for the $N^{th}$ moment, $f_{k,N}$ is as follows. First, use the HP method to determine the closure for the $N+1^{th}$ moment, then substitute this expression for $f_{k,N+1}$ into the linearized time evolution equation for $f_{k,N}$ and take the low frequency limit of this equation ($\partial f_{k,N}/\partial t = 0$). The resulting equation can be solved for $f_{k,N}$ in terms of $f_{k,N-1}$.

The Snyder closure for the $4^{th}$ moment in our system is
\[ f_{k,4} = \frac{-ik_z(2 + \sqrt{5}A_3)}{ik_z\text{sgn}(k_z)\sqrt{5}A_4 + 4\nu} f_{k,3}. \] (12)
where $A_4 = -1.805i$ and $A_3 = 0.803$. A detailed derivation of this closure and its coefficients can be found in B.

Both the Snyder and HP closures were initially designed for models based on the conventional fluid moments in which the $n^{th}$ fluid moment is calculated by integrating the kinetic distribution times velocity to the $n^{th}$ power. Subsequent work generalized the procedure for Hermite-based systems [30]. The relationship between the Hermite moments and the fluid moments is very simple and is shown in C.

### 3.2 The Learned Multi-Mode Closure

We now ask the question of how a closure may be generalized for a nonlinear system in which the turbulent dynamics continually perturb the relationships between the low order moments retained in the system.

This is motivated, in part, by several recent contributions to the literature. Refs. [20, 21] investigate the effect of a stochastic forcing term on Landau damping rates, demonstrating large deviations from the linear expectations for some parameters. Refs. [22, 24, 25] demonstrate a ‘fluidization’ of collisionless plasma turbulence—i.e., a large reduction of Landau damping rates due to the cancellation of the forward velocity space cascade due to turbulence. Likewise, Ref. [23] observes Landau damping rates far smaller than the linear predictions in a turbulent system (see Fig. 10 of that paper). We thus posit that in order to capture the phase mixing rates appropriate for a turbulent, kinetic system, a closure should be endowed with the versatility to adapt to the nonlinear state. To this end, we propose a closure scheme that learns directly from the turbulent kinetic system.

To illustrate our closure strategy, consider the Hermite-based system described in Sec. 2 at two different truncation levels: (1) a four-moment fluid system, and (2) a kinetic system of $N$ Hermite moments, where $N$ is large enough that the system is effectively kinetic (in our simulations we opt for $N = 48$). For a given wavevector, $k$, the eigenvector of the linear operator is simply a vector with the complex values of each moment—i.e., a 4D vector in the fluid system and an ND vector in the kinetic system.

The following closure approach is conceptually similar to the HP approach. For a given set of physical parameters (gradient drive, collisionality), solve for the linear eigenvectors of the kinetic system. Then use the relationship between $g_4$ and $g_3$ from this kinetic eigenvector to close the fluid system. If the linear eigenvector persists unmodified in the nonlinear state, this approach would be sufficient. However, as described above, important nonlinear modifications are observed in turbulent
systems. Consequently, our strategy is to ‘learn’ an appropriate closure directly from the turbulent kinetic system.

We do so by extracting from a nonlinear kinetic simulation an ‘optimal’ basis for the nonlinear turbulent state at each wave vector. For a four-field fluid model, we extract this optimal basis from the first five moments of the kinetic system in order to retain the information necessary to close the system. The turbulent fluid state is then projected onto these basis vectors (with the fifth moment of each removed). Since these basis vectors are attached also to the kinetic information (i.e. the fifth moment), this projection can be used to close the system. Mathematical details are described in the next subsection.

Since an optimal basis was extracted from a kinetic simulation, we would expect this procedure to be effective at the parameter point of the kinetic ‘training’ simulation. The utility of this method, however, will depend on the procedure retaining efficacy in some non-negligible parameter domain surrounding the training point. We demonstrate below that this is the case.

We call this closure strategy the ‘Learned multi-mode’ (LMM) closure because (1) it ‘learns’ the closure coefficients from the full turbulent kinetic system, and (2) it employs multiple modes (basis vectors) in order to better capture the dynamical variations in the turbulent state.

We end this section by noting some connections with other lines of research. First, this closure approach is related to various strategies for projection-based model reduction [32, 33, 34, 35, 36, 37], wherein basis vectors are extracted (often via SVD) from data describing a complex system to reduce the complexity of the underlying models.

We also note some connections with the closure proposed in Refs. [38, 39]. This closure scheme employs two modes (the ITG mode and its complex conjugate) in order to enforce a ‘non-dissipative’ closure—i.e., it eliminates any energy transfer between the fluid moments and higher order moments. Consequently, it produces damping rates that are far below (i.e., zero) the linear values in qualitative agreement with the nonlinear results cited above. However, the true turbulent system allows energy to shift dynamically between lower and higher order moments. Consequently, we view this closure as a compelling idea, but one that is perhaps too restrictive.

We also note the connection between the LMM closure and the line of research exploring the role of damped eigenmodes in plasma microturbulence [40, 41, 42, 23, 43], which shows multiple modes coexisting at a single wavevector play a crucial role in turbulent energetics. Our ‘multi-mode’ closure also acknowledges the activity of multiple eigenmodes per wavevector and defines the closure coefficients in terms of the relative amplitude of these modes in the nonlinear state.

### 3.3 Implementation of the LMM Closure

Here we describe the mathematical details of the approach outlined in the previous section. The closure requires a nonlinear kinetic simulation to formulate a set of basis vectors. In our case, we use 48 Hermite moments for the full kinetic simulation. Any number of subsequent fast fluid simulations can then be run requiring explicit computation of only $f_0$, $f_1$, $f_2$, and $f_3$. In this section we will use bold uppercase letters to denote matrices and bold lowercase letters to refer to vectors.

The full kinetic simulation is used as follows. Let $F_{M \times M}$ ($M$ is the number of time points and $N$ is number of moments retained in the fluid model plus one) be the matrix created from the simulated distribution function at a single wave vector. The distribution function at a single wavevector is written $f_i(t)$, where $i = 0, 1, ..., N - 1$ denotes the Hermite number and $t$ takes on discrete values $t_j$ with $j = 0, 1, ..., M - 1$ (the wave vector is suppressed for clarity), so that element $ij$ of $F$ is $F_{ij} = f_i(t_j)$:

$$F = \begin{bmatrix} f_0(t_0) & f_0(t_1) & \cdots & f_0(t_{M-1}) \\ f_1(t_0) & f_1(t_1) & \cdots & f_1(t_{M-1}) \\ \vdots & \vdots & \ddots & \vdots \\ f_{N-1}(t_0) & f_{N-1}(t_1) & \cdots & f_{N-1}(t_{M-1}) \end{bmatrix}$$

The SVD of $F$ is given by

$$F_{M \times M} = U_{N \times N} \Sigma_{N \times N} V_{N \times M}^H$$

where $U$ and $V$ are unitary and $\Sigma$ is diagonal with real entries. General background information about this extremely useful matrix decomposition and be found in Ref. [44] and a review on its application to turbulence as proper orthogonal decomposition (POD) can be found in Ref. [45].
columns of the matrix $\mathbf{U}$ are called the left singular vectors. In our application, they define $N$ basis vectors for the distribution function. The rows of $\mathbf{V}^H$ are the time traces of the amplitude of each of these vectors. The diagonal entries in $\Sigma$ define the singular values, which encompass all the amplitude information. The utility of the SVD lies in the property that the outer product between the first basis vector and the first time trace (weighted by the corresponding singular value) reproduces more of the fluctuation data (as measured by the Frobenius norm) than any other possible decomposition of this form. Likewise the superposition of the first two $(n)$ outer products captures more of the fluctuation data than any other rank two $(n)$ decomposition and so forth. For convenience, we define a matrix $\mathbf{B}$, which weights the basis vectors by their corresponding singular values so that they include the amplitude information: $\mathbf{B} = \mathbf{U}\Sigma$.

For the purposes of our desired four moment model, we select $N = 5$ (i.e. only a small subset of the 48 total Hermite moments). Since different Hermite moments are only connected to their direct neighbors, this is sufficient to fully exploit the information in the simulation defining the natural (kinetic, turbulent) relations between $f_3$ and $f_4$.

Let $\mathbf{f}$ represent the column vector of the first four moments at a single time step: $\mathbf{f} = [f_0 \ f_1 \ f_2 \ f_3]^T$. In each time step of a subsequent fluid simulation, we numerically advance $\mathbf{f}$ explicitly via Eq. 3. The truncated moment, $\mathbf{f}_5$, is calculated as follows. First, we project the state vector $\mathbf{f}$ onto the basis formed by the columns of $\mathbf{B}$. This entails finding the projection coefficients that define the amount of each SVD mode in the turbulent state at a given point in time. We will call the column vector containing these projection coefficients $\mathbf{c}$. We can do this by removing the row corresponding to the unknown $N^{th}$ moment (the $5^{th}$ row) from $\mathbf{B}$ and extracting $\mathbf{c}$ from the following equation:

$$\mathbf{f} = \mathbf{Mc}$$

where $\mathbf{M}$ denotes the submatrix of $\mathbf{B}$ consisting of the first 4 rows and all 5 columns of $\mathbf{B}$, i.e., $\mathbf{M}$ is the submatrix produced by removing the last $(5^{th})$ row of $\mathbf{B}$. This gives

$$\mathbf{c} = \mathbf{M}^\dagger \mathbf{f}$$

where $\dagger$ denotes the pseudo-inverse. Now that we have $\mathbf{c}$, a length $N$ vector of the inferred mode amplitudes, we can predict $f_4$ by applying these mode strengths to the previously removed row of $\mathbf{B}$, $b_5$. This gives

$$f_4 = b_5 \mathbf{c} = b_5 \mathbf{M}^\dagger \mathbf{f} = \mathbf{c}_{LMM} \mathbf{f}$$

(17)

where $b_5$ is the $5^{th}$ row of $\mathbf{B}$ and $\mathbf{c}_{LMM} = b_5 \mathbf{M}^\dagger$ is the vector containing the 4 LMM closure coefficients. This procedure is repeated at each wavevector $\mathbf{k}$ to obtain a full set of coefficients that can be used to conduct an LMM-closed simulation - $\mathbf{c}_{LMM}$ is different for each wavevector.

This procedure results in a closure that reflects the natural relations between moments in the turbulent kinetic system and adapts to the relative amplitude of each basis vector in the nonlinear state.

Regarding computational cost, the LMM closure comes down to the dot product between two length 4 vectors: the closure coefficients, $\mathbf{c}_{LMM}$, and the lower order moments, $\mathbf{f}$. The closure coefficients are computed ahead of time and saved to a file, which is loaded at the beginning of the simulation. During the simulation, the computational expense of the LMM closure is very similar to that of the HP closure: the HP closure requires two complex multiplications per wavevector per time step (one for each of the two HP closure coefficients), and the LMM closure requires four complex multiplications per wavevector per time step. This is much less demanding than the pseudo-spectral computation of the nonlinearity, so the increased expense is negligible. The main additional expense is in running nonlinear kinetic simulations for training. If this can be done sparsely, we expect the LMM closure to be a valuable tool.

4 Linear Evaluation of Closures

In this section we probe the properties of several closures in comparison with the kinetic system in both linear and nonlinear scenarios.

The HP closure has been shown to faithfully reproduce kinetic Landau damping rates and linear growth rates. We reproduce this result for our system: simulations exhibit good agreement between kinetic linear growth rates and fluid growth rates
using the HP closure. A representative example is shown in Fig. 1 (top panel), where it is seen that the HP closure, the Snyder closure, and the LMM closure all reproduce the growth rates of the linear kinetic system. Growth rates are produced by solving the linearized eigenvalue problem given by Eq. 3 for the 48-moment (kinetic system) and the 4-moment fluid system with each of the closures.

Fig. 1 (lower panels) also shows a simple test of the eigenmode structures by plotting the 4th moment, $f_4$, normalized to the zeroth moment. These plots are highly relevant since ratios of moments are closely connected to the closure problem. We plot this quantity for the 48-moment (kinetic) linear system, the 48-moment nonlinear system, as well as all of the 4-moment systems closed by the HP, Snyder, and LMM closures. For this example, the LMM closure was trained and tested at the same parameter point: $\omega_T = 12, \nu = 0.01$.

While the growth rates produced by all the closed systems match the linear kinetic growth rates very closely, there is much less agreement in the plots of these moment ratios. $f_4$ produced by the HP and Snyder closures, which are both based on the linear system, exhibit a similar shape to the linear kinetic $f_4$. However, $f_4$ of the nonlinear kinetic system exhibits a significantly different shape in $k_y$: the ratio is much smaller. This is closely mirrored by $f_4$ produced by the LMM closure. The capacity of the LMM closure to reproduce the nonlinear result is perhaps unsurprising, as it is based on the nonlinear system.

This is an initial indication that dynamics of the linear and nonlinear systems are quite different, consistent with the literature discussed above [20, 21, 23, 25]. In fact, agreement with the linear system may not be ideal since the nonlinear dynamics are the ones we ultimately wish to model.

5 Nonlinear Closure Tests

In order to more thoroughly examine closure performance, simulations covering a wide range of temperature gradients, $\omega_T$, and collision frequencies, $\nu$, were conducted with a fully (reduced gyro-) kinetic model (48 moments : $n_{\text{max}} = 48$), simply truncated model (4 moments, 5th is set to 0), the standard Hammett-Perkins (HP) closure retaining 4 moments, Snyder’s collisional version of the HP closure, and three different LMM closures.

The scan covers $\omega_T = 5, 6, 7, 8, 9, 12, 15$, and $\nu = 0.01, 0.05, 0.1, 0.2, 0.5$. All closures perform very poorly in the completely collisionless regime, $\nu = 0$. This is currently under investigation and

![Figure 1](image_url)
may require a more careful treatment of the dissipation in the kinetic system, which is left for future work (collisionless results are shown in Appendix X). Other simulation parameters used are $\omega_\nu = 1$ and $\tau = 1$.

The grids used in $k$-space are $k_x, min = 0.05$, $k_x, max = 1.5$, $k_y, min = 0.05$, $k_y, max = 1.5$, and $k_z, min = 0.1$, $k_z, max = 3.6$. Hyper-collisions of the form $\nu_h (n/n_{max})^nf_n$ are included in order to enforce decaying moments at high $n$ and hyper-diffusion of the form $\nu_h (k_x/k_x^{max})^8$ is included as a small scale dissipation mechanism (intended to roughly account for, e.g., nonlinear perpendicular phase mixing). We use $\nu_h = 0.1$ and $\nu_z = 1$ in our simulations. In addition, a Krook term is applied to the $k_y, 0, k_z = 0$ mode to prevent long-term secular growth of this mode. Refs. [26, 27] describe such numerical considerations in more detail.

For reference, the exact HP closure used was $f_3 = 0.755f_3 - i(1.759sgn(k_z)f_3$. The Snyder closure used was

$$f_{k,4} = \frac{-ik_z(2+\sqrt{5}(0.803))}{ik_zsgn(k_z)\sqrt{5}(-1.805i)+4\nu}f_{k,3}. \quad (18)$$

The derivation of these coefficients is described in Appendices A and B.

A key question for the LMM closure is the parameter domain over which the closure remains viable. We would expect the applicability of a set of LMM closure coefficients to deteriorate as the distance in parameter space from the training simulation increases. Of course, the computational expense of kinetic simulations requires that the number of training simulations be kept minimal in order for the closure to be useful. In order to probe the question of how far the closure applies throughout parameter space, we selected 3 kinetic training simulations spread throughout our grid.

The three different LMM closures are obtained by applying the method described in Sec. 3.3 to extract coefficients from kinetic simulations at $\omega_T, \nu = 6, 0.01$, $\omega_T, \nu = 9, 0.1$, at $\omega_T, \nu = 12, 0.5$. We refer to these three LMM closures as LMM-Left, LMM-Middle, and LMM-Right respectively, indicating the region of the scanned parameter space within which their training simulation lies.

6 Tests of Energy Dissipation

In order to gain insight into the nonlinear dynamics and their effect on the closure problem, we investigate the energy evolution equation, Eq. 9. In Eq. 9, the contribution from phase mixing defines the energy flux to higher order moments [27]. More specifically, $J_{n+1/2}$, the rate at which energy is transferred to/from higher order moments, is defined by a correlation between two neighboring moments. The linear physics defines a fixed, dissipative, relationship between $f_n$ and $f_{n+1}$. In the presence of turbulence, however, the various moments are continually perturbed by the nonlinearity, resulting in correlations that can differ substantially from the linear expectation.

These considerations are illustrated in Fig. 2, which shows the distribution (accumulated over time) of the energy transfer between the 3rd and 4th moments, $J_{4+1/2}$, for kinetic, LMM-closed, and HP-closed simulations. The average dissipation, $J_{4+1/2}$ resulting from the HP closure is much larger than the dissipation present in the kinetic system. We note that the HP closure would likely perform better by this metric with the inclusion of more moments, which may be explored in future work. The LMM-closure, being based on the nonlinear system, produces dissipation that matches the kinetic level quite closely. We note that the LMM closure coefficients used are extracted from a training simulation with different parameters than the simulation being examined (both parameter points are noted in the title of the figure), which indicates the effectiveness of the LMM closure even in simulations with parameters different from the training parameters.

Fig. 3 shows the ratio of the average value of $J_{Closed}$ to the average value of $J_{Kinetic}$ for both the HP and LMM closures for every point in the extended parameter scan. Three different sets of LMM closure coefficients are used to produce this plot: one set is extracted from the kinetic simulation at $\omega_T, \nu = 6, 0.01$, one from $\omega_T, \nu = 9, 0.1$, and one from $\omega_T, \nu = 12, 0.5$. These three LMM closures are detailed in sec. 5 and are referred to as the LMM-Left, LMM-Middle, and LMM-Right closures respectively. They are named as such to indicate the region of our parameter space in which they were trained. At each point in
our parameter grid, we use the LMM closure that was trained closest to that grid point to produce the values of \( J_{3+1/2}^{LMM} \) shown in this plot. Table 1 in Appendix D shows which of these closures (LMM-Left, Right, or Middle) was used at each grid point. The HP closure produces dissipation levels that are too large almost everywhere. It performs best at low gradient drive \( (\omega_T) \) with deteriorating performance as gradient drive is increased. The LMM closure matches kinetic dissipation levels significantly better than the HP closure throughout the space.

Figure 2: Probability distribution functions (a) and box and whisker plots (b) showing the distribution of \( J_{3+1/2} \), the energy transferred between the 3rd and 4th moments, in the Kinetic, LMM-closed, and HP-closed systems for \( \omega_T = 7 \) and \( \nu = 0.05 \) at the most unstable wavevector, \( k_x = 0, k_y = 0.75, k_z = 0.4 \). The LMM coefficients used to produce this plot were extracted from the kinetic simulation at \( \omega_T, \nu = 6, 0.01 \). Red dashed lines show the average value of each distribution, \( \bar{J}_{3+1/2} \).
Figure 3: Ratios of the average value of $J_{3+1}/J_{Kinetic}^{3+1}/2$ throughout parameter space for both the HP and LMM closures. Values below 1 indicate not enough dissipation and values above 1 indicate too much dissipation. This heatmap is set up such that fractions far from 1 in either direction are penalized the same way. For example, ratios of 0.5 and 2 will be the same color. As shown here, the LMM closure matches kinetic dissipation levels much better than the HP closure at almost every point on our parameter grid.

6.1 Comparison of Heat Fluxes

Ultimately, we would like closed simulations to reproduce the macroscopic behavior of gyrokinetic simulations, so the performance of the closures was evaluated primarily by comparing the saturated value of the total radial heat flux, $Q = \sum_{k_x,k_y,k_z} Q_k$, where $Q_k$ is defined in the discussion surrounding Eq. 9.

Time traces of the heat flux produced by all seven types of simulation are shown for each combination of input parameters, $\omega_T$ and $\nu$, in Fig. 4.

The simplest metric for the performance of the closure is the proximity of the saturated heat flux for a given closure scheme to that of the kinetic simulation. The final saturation levels of each simulation type at each set of input parameters were calculated by averaging over the last 30% of the time trace—this was determined to be a cutoff point after which the heat fluxes from all simulations had saturated to their final levels. Each plot in Fig. 5 shows the percent error in saturated heat flux, $(Q_{Closed} - Q_{Kinetic})/Q_{Kinetic}$, for all parameter combinations for each closure scheme. Versions of figures 4 and 5 including $\nu = 0$ can be found in Appendix D.

As expected, truncation performs poorly at low values of collisionality, but improves at high collisionality where the simulations become more fluid-like. Truncation still performs relatively poorly at high collisionality for low gradient drive, but performs well when both collisionality and gradient drive are large—i.e., for parameters at which other effects (gradient drive or collisions) dominate phase mixing.

The HP closure works well in the low collisionality regime for which it was designed (note the small errors at $\nu = 0.01$). However, its performance deteriorates as collisionality is increased.

The Snyder Closure is designed to simultaneously include the effects of collisions and phase mixing in the appropriate limits. It performs well in the high collisionality regime but produces substantial errors at low collisionality. This is similar to the trend exhibited by simple truncation with one major difference—the Snyder closure is superior at low gradient drive and good performance extends to lower collisionality.

The LMM-Middle closure based on the kinetic simulation at $\omega_T, \nu = 9, 0.1$ surprisingly performs poorly in the simulation at its training parameter point but performs well in nearby regions (in the middle of our scanned parameter space). In fact, this closure extends throughout parameter space quite well, displaying low errors everywhere except in the top left corner (low collisionality and gradient drive).

The LMM-Right closure based on the kinetic simulation at $\omega_T, \nu = 12, 0.5$ produces very low errors at high collisionality and gradient drive, in the middle of the parameter region, and even at low gradient drive if collisionality is high. As one would expect, it starts to deteriorate as one ventures farther from the training point—low collisionality and gradient drive.

The LMM-Left closure based on the kinetic simulation at $\omega_T, \nu = 6, 0.01$ works well at low gradient drive regardless of collisionality. At high values of gradient drive however, its performance is poor. Specifically at the highest value of gradient drive, $\omega_T = 15$, this closure has extremely large errors. Inspecting Fig. 4, one can see the reason for this.
Figure 4: Time traces of the total radial heat flux ($Q$) for Kinetic (blue), HP (orange), Snyder (green), truncated (red), LMM-Middle (purple), LMM-Right (brown), and LMM-Left (pink) simulations for temperature gradient drives ($\omega_T$) ranging from 5 to 15 (increasing downward by panel) and collision frequencies ($\nu$) ranging from 0.01 to 0.5 (increasing to the right by panel). The metric of performance is the final saturation level. The vertical blue lines show the cutoff point - 70% of the simulation time - after which each heat flux curve is averaged to get the final saturation level.

The LMM-Left heat flux initially appears to saturate at an appropriate level, but partway through the simulation, it jumps to a higher level and re-saturates. This behavior can also be seen in kinetic simulations at $\omega_T, \nu = 15, 0.2$ and $\omega_T, \nu = 15, 0.5$. When this jump occurs in the closed simulation but not the kinetic, it results in very large errors. These simulations illustrate the potential hazard of applying an LMM closure in a regime too far removed from its training point.

We note that the LMM-Left and LMM-Middle closures are slightly more accurate than the HP closure throughout the parameter space, even taking into account the simulations far removed from the training point. The LMM-left closure exhibits the worst performance of all the closures due to the large late-time jumps in saturation levels at high gradient drive.

Ultimately, we envision the LMM closure applied in scenarios where kinetic training simulations can be supplied sparsely throughout parameter space. Consequently, we show in Fig. 5 the closure called \textit{LMM-Optimal}, which is defined by selecting the LMM-closure that is trained at the nearest point in parameter space. For example, at $\omega_T, \nu = 5, 0.05$, the LMM-Left closure with coefficients extracted from the $\omega_T, \nu = 6, 0.01$ kinetic simulation is used and at $\omega_T, \nu = 15, 0.5$, the LMM-Right closure with coefficients extracted from the $\omega_T, \nu = 12, 0.5$ kinetic simulation is used. In Fig. 5, we include an LMM-Optimal closure that makes use of all three training points and another that uses only the left and right training points. Using two training points instead of three only slightly reduces performance; using three training points results in an average error of 7% and using two yields an average error of 8%. Tables 1 and 2 in Appendix D show which training simulation was used to run the LMM-closed simulation at each grid point for the LMM-Optimal (3 Point) and LMM-Optimal (2 Point) plots in Figure 5. Choosing the coefficients this way—using the LMM coefficients extracted from the nearest kinetic simulation to each grid point—results in excellent performance.
Figure 5: Percent error in saturated heat flux for each closure (HP, Snyder, Truncation, LMM-Middle, LMM-Right, LMM-Left, LMM-Optimal) as compared against the kinetic simulation throughout parameter space. The circles on the 4th, 5th, and 6th figures indicate which simulations from which the LMM coefficients were extracted. Percent errors are calculated as $(Q_{\text{Closed}} - Q_{\text{Kinetic}})/Q_{\text{Kinetic}} \times 100$ where $Q_{\text{Closed}}$ is calculated by averaging the last 30% of the time trace of the heat flux from the closed simulation and $Q_{\text{Kinetic}}$ is calculated by averaging the last 30% of the time trace of the heat flux from the kinetic simulation. The average error in for each closure is calculated by averaging the absolute value of the errors. The 7th plot, LMM-Optimal (3 Points), displays error of the LMM closure trained at the nearest parameter point using three training points. The 8th plot, LMM-Optimal (2 Points), displays the error of the LMM closure trained at the nearest parameter point using only the left and right training points.

Only three parameter points exhibit errors above 20% and the average error is only 7% when three training points are used.

7 Summary and Conclusions

We have introduced the LMM closure—a new method for formulating closures based on kinetic simulation data. Here it is applied to the problem of phase mixing in a relatively simple turbulent system—gradient driven turbulence in an unsheared slab. The LMM closure utilizes an optimal set of basis vectors from a nonlinear kinetic simulation to formulate closure coefficients in a fluid system. We have compared this method to several closure methods from the literature throughout the relevant 2D parameter space (collisionality and gradient drive).

First, we demonstrate that the LMM closure addresses the observation in several recent papers that phase mixing rates are substantially decreased in a
turbulent system from the linear expectations. The HP closure is observed to be too dissipative, over-estimating nonlinear values. We demonstrate that the LMM closure reproduces phase mixing rates quite accurately.

Comparisons between heat fluxes for four-moment fluid systems and the kinetic system demonstrate that simple truncation performs rather poorly. The HP and Snyder closures perform much better than simple truncation, with errors similar to the LMM closures that are trained at a single parameter point and applied throughout the parameter space. When the LMM closure uses three training points (out of 35 parameter points) the closure is quite accurate, producing errors $\sim 40\%$ smaller than any other closure examined.

Our results suggest that the LMM closure has various advantages as well as drawbacks, which we summarize here. Advantages:

- Capacity to capture the reduced phase mixing rates observed in turbulent systems.
- Accuracy throughout parameter space when trained sparsely.
- Generalizable to more comprehensive systems (e.g., that described in Ref. [46]) and closure problems (e.g. curvature terms).
- Applicable to scenarios where analytic closures have not been formulated or are inaccurate.

Drawbacks:

- Requirement for kinetic training simulations.
- Uncertain extrapolation throughout parameter space.

We expect these drawbacks can be mitigated by statistical frameworks (e.g., Bayesian optimization) designed to track and optimally minimize uncertainties throughout a parameter space.

Various generalizations can be imagined. For example, suitable basis vectors could be formulated without the need for a nonlinear kinetic simulation by, e.g., taking inspiration from (multiple) linear eigenmodes or conducting a deeper study of nonlinear modifications to the linear eigenmodes.

A  HP Closure

As introduced in [11] and derived formally in [30], the HP/Smith-style closure coefficients are chosen by matching the approximate response $R_{00}(\omega)$ to the exact response $R_{00}(\omega)$, which is given by

$$R_{00}(\omega) = -iZ(\omega)$$

(19)

where $Z$ is the plasma dispersion function.

The HP closure for the $N^{th}$ moment, $f_N(\omega)$ takes the form $f_N = \sum_{n=0}^{N-1} A_n f_n(\omega)$. When the first $p$ closure coefficients, $A_i$ are set to zero, the approximate response in terms of the orthogonal polynomials, $P_i(\omega)$, and conjugate polynomials, $Q_i(\omega)$, becomes

$$P_0(\omega) = \frac{Q_n(\omega) - A_n Q_{n-1}(\omega)}{P_n(\omega) - A_n P_{n-1}(\omega) - i A_p Q_p(\omega)}$$

(20)

and matches the exact response to order ($O(\omega^{n+1+p})$). The orthogonal and conjugate polynomials are expressed as

$$P_j(\omega) = P_{j,0} + P_{j,1} \omega + \cdots + P_{j,j} \omega^j$$

$$Q_j(\omega) = Q_{j,0} + Q_{j,1} \omega + \cdots + Q_{j,j} \omega^j$$

(21)

This becomes the $[n,q,\omega = 0]$ Pade approximant to the exact response for $q = n - p$ if the $q$ remaining coefficients are chosen to match the first $q$ terms of the Taylor series

$$R_{00}(\omega) = r_0 + r_1 \omega + r_2 \omega^2 + \cdots$$

(23)

Since we are matching in the $\omega \to 0$ limit, we can substitute

$$Z(\zeta) = i \sqrt{\pi} e^{-\zeta^2} - 2\zeta \left(1 - \frac{2\zeta}{3} + \frac{4\zeta}{15} - \frac{8\zeta}{105} + \cdots \right),$$

(24)

the Taylor expansion for the plasma dispersion function in the low frequency limit, into 19 to define $r_i$ in 23.

Setting $R_{00}(\omega) = R_{00}(\omega)$ results in the following equation

$$r_0 + \cdots + r_{q-1} \omega^{q-1} \left( A_{n-1} P_{n-1}(\omega) + \cdots + A_p P_p(\omega) \right)$$

$$- i \left( A_{n-1} Q_{n-1}(\omega) + \cdots + A_p Q_p(\omega) \right)$$

(25)

Choosing the coefficients $A_{n-1}, \ldots, A_p$ so that the coefficients of the different powers of $\omega$ on the RHS and LHS match results in the closure.

This matching can be done by solving the following matrix equation

$$\begin{bmatrix}
  r_0 & 0 & \cdots & 0 \\
  r_1 & r_0 & \cdots & 0 \\
  \vdots & \vdots & \ddots & \vdots \\
  r_{q-1} & r_{q-2} & \cdots & r_0
\end{bmatrix}
\begin{bmatrix}
  P_{n-1,0} \\
  P_{n-1,1} \\
  P_{n-2,0} \\
  P_{n-2,1} \\
  \vdots \\
  P_{n-q-1,0} \\
  P_{n-q-1,1}
\end{bmatrix}
= \begin{bmatrix}
  A_{n-1} \\
  A_{n-2} \\
  \vdots \\
  A_p
\end{bmatrix}$$

(26)

for the closure coefficients $A_{n-1}, \ldots, A_p$.

We use $P_n(\omega) = H_n(\omega)$ defined by

$$H_n(\omega) = \left( -1 \right)^n \frac{e^{x^2}}{\sqrt{2^{2n} n! \pi}} e^{-\omega^2}$$

(27)

satisfying the recurrence relation

$$H_n(\omega) = \sqrt{\frac{2}{n}} x H_{n-1}(\omega) - \sqrt{\frac{n-1}{n}} H_{n-2}(\omega)$$

(28)

and conjugate polynomials $Q_n(x)$ constructed by requiring that they satisfy the same recurrence relation as our Hermite polynomials and the conditions

$$Q_0(x) = 0, Q_1(x) = \pi^{-1/4} \sqrt{2} \theta(x).$$

(29)

The orthogonal polynomial moments, our Hermite moments, are defined with respect to the Hermite polynomials as

$$f_n = \int_{-\infty}^{\infty} f(x) H_n(x) dx.$$
These are the Hermite polynomials and Hermite decomposition used in our model as described in Sec. 2.

A.1 Verification of HP Coefficients

The HP closure that we focus on closes at the 4th moment with the N,q = 4,2 HP closure. For this closure we have A_3 = -1.759i, A_2 = 0.755. This gives the following HP closure for our system in DNA

\[ f_{k,4} = -1.759i \, sgn(k_z) f_{k,3} + 0.755 f_{k,2} \]  \hspace{1cm} (31)

The \( sgn(k_z) \) is present in the \( f_{k,3} \) term to ensure damping for both positive and negative \( k_z \). As shown in Fig. 6, this closure produces an excellent match to the response function.

To construct the Snyder closure we instead need the coefficients for a closure at the 5th moment. The N,q = 5,3 closure which takes the form \( f_{k,5} = A_4 f_{k,4} + A_3 f_{k,3} + A_2 f_{k,2} \) has coefficients \( A_4 = -0.714i, A_3 = -1.118, \) and \( A_2 = -0.824i \).

The N,q=5,3 closure does not produce an approximate response function that closely matches the exact response function as shown in Fig. 6. The N,q=5,2 closure which takes the form \( f_{k,5} = A_4 f_{k,4} + A_3 f_{k,3} \) produces a better match (see Fig. 6), so we choose to use the N,q=5,2 closure coefficients \( A_4 = -1.805j, A_3 = 0.803 \) for the Snyder closure.

![Figure 6: Real and imaginary parts of the exact response function and the approximate response functions for the N,q=4,2, N,q=5,2, and N,q=5,3 HP closures.](image)

B Snyder’sCollisional Closure

The HP closure is designed for a collisionless regime. However, there is a method for modifying the HP closure to include the effects of collisions developed in [31]. In order to derive the collisional closure for our system, we start by using Smith’s method to determine the optimal closure for \( f_{k,5} \) with N,q=5,2 as described above. We then plug this expression for \( f_{k,5} \) into the linearized time evolution equation for \( f_{k,4} \), take the low frequency limit \( (\partial f_{k,4}/\partial t = 0) \), and solve the resulting equation for \( f_{k,4} \) in terms of \( f_{k,3} \).

The closure used for \( f_{k,5} \) is

\[ f_{k,5} = sgn(k_z) A_4 f_{k,4} + A_3 f_{k,3} \]  \hspace{1cm} (32)

with coefficients \( A_4 = -1.805j, A_3 = 0.803 \). Notice the \( sgn(k_z) \) in the \( f_{k,4} \) term. This is included to ensure damping at both positive and negative \( k_z \).

Taking \( n = 4 \) and \( \partial f_{k,4}/\partial t = 0 \) in 3 gives

\[ \frac{\partial f_{k,4}}{\partial t} = 0 = -i k_z [2 f_{k,3} + \sqrt{5} f_{k,5}] - 4 \nu f_{k,4} \]  \hspace{1cm} (33)

Plugging in 32 gives

\[ 0 = -i k_z (2 + \sqrt{5}) f_{k,3} - (i k_z sgn(k_z) \sqrt{5} A_4 + 4 \nu) f_{k,4} \]

\[ \rightarrow f_{k,4} = \frac{-i k_z (2 + \sqrt{5}) A_3}{i k_z sgn(k_z) \sqrt{5} A_4 + 4 \nu} f_{k,3} \]  \hspace{1cm} (34)

This is the Snyder closure we choose to use.

B.1 Verification of Snyder Closure

In order to verify the correctness of our choice of coefficients in the Snyder closure we plot the growth rates as well as \( f_{k,4} \) given by the linear kinetic system, the N,q=4,2 HP-closed system, and the Snyder-closed system against \( k_y \) and \( k_z \).

We expect to see better agreement between the kinetic and HP-closed system at low \( \nu/k_y \) and then better agreement between the kinetic and Snyder-closed system at higher \( \nu/k_z \).

In Fig. 7 and Fig. 8 we show plots of the growth rates and \( f_{k,4} \) from the kinetic problem as well as growth rates and \( f_{k,4} \) reconstructed from the eigenvectors of the kinetic problem using the closure coefficients. The eigenvector elements \( f_{k,4} \) are normalized to \( f_{k,0} \). The expected results are confirmed.
in these figures, the Snyder closure seems to produce better matching at high collisionality than the HP closure.

In Fig. 9 and Fig. 10 we show the same plots but for a lower gradient drive \( \omega_T = 6 \). Fig. 10 highlights a potential issue: the real part of \( f_{k,4} \) from the Snyder closure deviates strongly from the kinetic \( f_{k,4} \) at high \( k_z \) even at high collisionality.

Figure 8: Plots of the growth rates and real and imaginary parts of \( f_{k,4} \) produced by the linear kinetic problem, the \( N, q = 4, 2 \) HP-closed system, and the Snyder closed system against \( k_y \). Shown for low collisionality and then high collisionality.

Figure 7: Plots of the growth rates and real and imaginary parts of \( f_{k,4} \) produced by the linear kinetic problem, the \( N, q = 4, 2 \) HP-closed system, and the Snyder closed system against \( k_y \). Shown for low collisionality and then high collisionality.
Figure 9: Plots of the growth rates and real and imaginary parts of $f_{k,4}$ produced by the linear kinetic problem, the N,q=4,2 HP-closed system, and the Snyder closed system against $k_y$. Shown for low collisionality and then high collisionality.

Figure 10: Plots of the growth rates and real and imaginary parts of $f_{k,4}$ produced by the linear kinetic problem, the N,q=4,2 HP-closed system, and the Snyder closed system against $k_z$. Shown for low collisionality and then high collisionality.

C Hermite and Fluid Moments

In a fluid or gyrofluid model, the $n^{th}$ moment is calculated as $\int v^n fdv$ where $f$ is the kinetic or gyrokinetic distribution function respectively. The first four moments are physically meaningful: $n$ is density, $u$ is mean velocity, $p$ is pressure, and $q$ is heat flux. Moments beyond $q$ are not physically meaningful but may need to be calculated to ensure the accuracy of the model.

The Hermite moments in our system are calculated as $f_n = \int f(v)H_n(v)dv$ where $f(v)$ is the gyrokinetic distribution function. Since the Hermite polynomials contain only powers of $v$, the fluid mo-
ments are simply linear combinations of the Hermite moments. The relationship between the first 5 fluid moments and the first 5 Hermite moments is shown below.

\[ n = \int dv f(v) = \pi^{1/4} f_0 \]  
\[ u = \int dv f(v)v = \frac{\pi^{1/4}}{\sqrt{2}} f_1 \]  
\[ p = \int dv f(v)v^2 = \frac{\pi^{1/4}}{\sqrt{2}} f_2 + \frac{\pi^{1/4}}{2} f_0 \]  
\[ q = \int dv f(v)v^3 = \frac{\sqrt{3} \pi^{1/4}}{2} f_3 + \frac{3\pi^{1/4}}{2\sqrt{2}} f_1 \]  
\[ r = \int dv f(v)v^4 = \frac{\sqrt{3} \pi^{1/4}}{\sqrt{2}} f_4 + \frac{3\pi^{1/4}}{\sqrt{2}} f_2 + \frac{3\pi^{1/4}}{4} f_0 \]

D Additional Heat Flux plots
Figure 11: Time traces of the total radial heat flux \((Q)\) for Kinetic (blue), HP (orange), Snyder (green), truncated (red), LMM-Middle (purple), LMM-Right (brown), and LMM-Left (pink) simulations for temperature gradient drives \((\omega_T)\) ranging from 5 to 15 (increasing downward by panel) and collision frequency \(\nu = 0\). The vertical blue lines show the cutoff point - 70% of the simulation time - after which each heat flux curve is averaged to get the final saturation level.

Table 1: This table shows which training simulation, equivalently which set of LMM-closure coefficients, was used to produce the LMM-Optimal (3 Point) error plot in Figures 5 and 12. At each grid point in parameter space, the set of coefficient from the training simulation that lies closest to that grid point is used. For example, at \(\omega_T, \nu = 5, 0.05\), the LMM-Left closure with coefficients extracted from the \(\omega_T, \nu = 6, 0.01\) kinetic simulation is used and at \(\omega_T, \nu = 15, 0.5\), the LMM-Right closure with coefficients extracted from the \(\omega_T, \nu = 12, 0.5\) kinetic simulation is used.
Figure 12: Percent error in saturated heat flux for each closure (HP, Snyder, Truncation, LMM-Middle, LMM-Right, LMM-Left, LMM-Optimal (3 Point), LMM-Optimal (2 Point)) as compared against the kinetic simulation for temperature gradient drives ($\omega T$) ranging from 5 to 15 (increasing downward) and collision frequency $\nu = 0$. Percent errors are calculated as $(Q_{\text{Closed}} - Q_{\text{Kinetic}})/Q_{\text{Kinetic}} \times 100$ where $Q_{\text{Closed}}$ is calculated by averaging the last 30% of the time trace of the heat flux from the closed simulation and $Q_{\text{Kinetic}}$ is calculated by averaging the last 30% of the time trace of the heat flux from the kinetic simulation. Average errors are calculated by averaging the absolute value of the errors.
Table 2: This table shows which training simulation, equivalently which set of LMM-closure coefficients, was used to produce the LMM-Optimal (2 Point) error plot in Figures 5 and 12. At each grid point in parameter space, the set of coefficient from the training simulation that lies closest to that grid point is used. For example, at $\omega_T, \nu = 5, 0.05$, the LMM-Left closure with coefficients extracted from the $\omega_T, \nu = 6, 0.01$ kinetic simulation is used and at $\omega_T, \nu = 15, 0.5$, the LMM-Right closure with coefficients extracted from the $\omega_T, \nu = 12, 0.5$ kinetic simulation is used.
