(Dated: January 15, 2022)

We developed a versatile integrated control and readout instrument for experiments with superconducting quantum bits (qubits), based on a field-programmable gate array (FPGA) platform. Using this platform, we perform measurement-based, closed-loop feedback operations with 428 ns platform latency. The feedback capability is instrumental in realizing active reset initialization of the qubit into the ground state in a time much shorter than its energy relaxation time T_1 . We show experimental results demonstrating reset of a fluxonium qubit with 99.4 % fidelity, using a readout-and-drive pulse sequence approximately 1.5 μ s long. Compared to passive ground state initialization through thermalization, with the time constant given by $T_1 = 80 \mu$ s, the use of the FPGA-based platform allows us to improve both the fidelity and the time of the qubit initialization by an order of magnitude.

The control of superconducting quantum bits (qubits) [1–5] relies on the ability to read out their state with high precision and apply custom pulses, conditioned on the result of the readout, on a time scale much shorter than the qubit lifetime T_1 . For the same signal integration time, the readout fidelity can be increased significantly using Josephson parametric amplifiers (JPAs) [6–9]. The rapid signal processing and decision taking, on the other hand, requires custom hardware based on field-programmable gate arrays (FPGAs), as recently demonstrated in Refs. [10–12].

Here we present a versatile FPGA-based control and readout platform for experiments with superconducting qubits, which enables fast (compared to T_1) feedback loops to control qubits depending on their state. This type of dynamical and conditional control sequences provides the basis for experiments and algorithms relevant for quantum computation, such as active reset [10] or quantum error correction [12].

To perform such closed loops, we employ measurement-based feedback where the qubit, dispersively coupled to a readout resonator [13, 14], is first projected by an initial quantum non-demolition measurement [15–17] onto its ground or excited state, $|0\rangle$ or $|1\rangle$, respectively. The result of this measurement is evaluated in real-time on our platform, by separating the plane of the in-phase and quadrature (IQ) components of the readout resonator response signal in two semi-planes, one attributing the measurement outcome to state $|0\rangle$, the other to state $|1\rangle$. This is achieved by performing linear discriminant analysis which, in case of symmetric and state-independent noise on the response signal, represents also the optimal Bayesian classifier [18]. Based on the result, different pulse sequences can follow to further manipulate the qubit.

An important figure of merit is the response time or feedback latency of the platform. In the current state of development we report a platform latency of 428 ns. This starts to be advantageous in state preparation protocols for typical superconducting qubits, with energy relaxation times T_1 exceeding tens of microseconds. The response time is defined as the delay between the last sample of the readout pulse entering the platform and the first sample of the output pulse, which is conditioned on the acquired information. It is platform-specific and therefore does not include experimental parameters such as the propagation delay through the microwave lines connecting to the cryogenic setup, or the duration of the readout pulse. The response time is solely determined by internal delays of the electronics. The main contributions are given by the conversion from the analog to the digital domain and back, as well as by decimation and interpolation filters used to reduce the sample rate in the digital domain. We estimate that latencies as low as 150 ns are possible with an optimized platform design.

Currently, the platform consists of a Xilinx Zynq UltraScale+ RFSoc ZCU111 Evaluation Board with a XCZU28DR-2FFVG1517E chip. It integrates the FPGA, two processors, eight 6.554 GSPS 14 bit digital-to-analog and eight 4.096 GSPS 12 bit analog-to-digital converters. Our FPGA firmware runs at a clock speed of 125 MHz and handles signals at a sample rate of 500 MSPS. Input and output signals are decimated and interpolated from and to 4 GSPS, which is the sample rate at which the converters operate. The platform has four output channels, designed to operate as two IQ pairs, one intended for qubit manipulation pulses and one for the readout. The platform further provides two input channels to acquire the readout pulses which passed through the experimental setup. Here, we use them to digitize the signal and reference from an interferometer setup (see experimental

fidelity of the active reset operation. Histograms of the response in the IQ-plane of the cavity coupled to the fluxonium qubit, before and after the active reset operation, are shown in Fig. 2. Each histogram comprises one million single-shot measurements and was directly obtained by the platform. The dispersive frequency shift of the cavity makes the two states distinguishable and allows us to directly extract the qubit state population from the histograms.

In thermal equilibrium, right before the operation, a $|1\rangle$ state population of 11.7 % is obtained. Considering the transition frequency $f_{01} = 1.26$ GHz of the fluxonium qubit at the flux and T_1 sweet spot [26], this population corresponds to an effective temperature of 30.0 mK, comparable to the temperature of the cryostat mixing chamber. Directly after the reset operation, the $|1\rangle$ state population is only 0.6 %. We thereby achieved an effective cooling of the qubit to 11.9 mK. The achieved reset fidelity is limited by the experimental setup and choice of parameters, setting the state discrimination in the IQ-plane. The Bayesian error alone places an upper bound of 99.5 % fidelity.

To summarize, our FPGA-based platform enables qubit ground state initialization with 99.4 % fidelity, using a sequence approximately 1.5 μ s long, out of which only 428 ns account for the intrinsic platform latency. Future efforts will focus on reducing this platform latency down to 150 ns, and operating at larger readout powers, which should increase the

qubit state separation and decrease the readout pulse duration below 100 ns [29].
