## Abstract

Solving linear systems and computing eigenvalues are two fundamental problems in linear algebra. For solving linear systems, many efficient quantum algorithms have been discovered. For computing eigenvalues, currently, we have efficient quantum algorithms for Hermitian and unitary matrices. However, the general case is far from fully understood. Combining quantum phase estimation, quantum algorithm to solve linear differential equations and quantum singular value estimation, we propose two quantum algorithms to compute the eigenvalues of diagonalizable matrices that only have real eigenvalues and normal matrices. The output of the quantum algorithms is a superposition of the eigenvalues and the corresponding eigenvectors. The complexities are dominated by solving a linear system of ODEs and performing quantum singular value estimation, which usually can be solved efficiently in a quantum computer. In the special case when the matrix  $M$  is  $s$ -sparse, the complexity is  $\tilde{O}(s\rho^2\kappa^2/\epsilon^2)$  for diagonalizable matrices that only have real eigenvalues, and  $\tilde{O}(s\rho\|M\|_{\max}/\epsilon^2)$  for normal matrices. Here  $\rho$  is an upper bound of the eigenvalues,  $\kappa$  is the conditioning of the eigenvalue problem, and  $\epsilon$  is the precision to approximate the eigenvalues. We also extend the quantum algorithm to diagonalizable matrices with complex eigenvalues under an extra assumption.

## 1 Introduction

Solving linear systems and computing eigenvalues are two fundamental problems in linear algebra. These are two problems of major importance in many scientific and engineering applications [3, 17, 31]. Many classical algorithms were discovered in the past decades. Except for some special cases, the theoretical complexities of these algorithms to solve linear systems of size  $n$  or to estimate the eigenvalues of  $n \times n$  matrices range from  $O(n^2)$  to  $O(n^3)$ . On the other hand, recent developments on quantum algorithms [1, 9–13, 19, 24] verify the fact that quantum computers can solve many linear algebraic problems much faster than classical computers. For instance, under certain conditions we can efficiently estimate the eigenvalues of unitary matrices [25] and Hermitian matrices [1], the singular values of general matrices [11, 24]. For solving linear systems in the quantum version, people have already found many efficient quantum algorithms (e.g. see [11, 12, 19]).

Currently, the solving of linear systems in a quantum computer is almost optimal, especially by the recently discovered block-encoding method [11]. For computing eigenvalues, there are some attempts [14, 33] to estimate the eigenvalues of non-Hermitian and non-unitary matrices. However,

---

\*changpeng.shao@bristol.ac.uk

this problem is still far from well understood. In this paper, we focus on the eigenvalue problem of diagonalizable matrices.

The classical eigenvalue algorithms are mainly iterative. Based on quantum linear algebraic techniques, we may generalize them into quantum algorithms. However, in this paper, we choose to follow the idea of quantum phase estimation (QPE) [25], a method that is different from any classical algorithms to estimate eigenvalues. Following the idea of QPE, the problem we want to solve in this paper is stated as follows:

**Problem 1.** *Let  $M$  be an  $n$ -by- $n$  diagonalizable matrix,  $\epsilon \in (0, 1)$ . Assume that the eigen-pairs of  $M$  are  $\{(\lambda_j, |E_j\rangle) : j = 1, \dots, n\}$ . Given access to copies of the state of the form  $\sum_{j=1}^n \beta_j |E_j\rangle$ , find a quantum algorithm that outputs a state proportional to  $\sum_{j=1}^n \beta_j |\tilde{\lambda}_j\rangle |E_j\rangle$  such that  $|\lambda_j - \tilde{\lambda}_j| \leq \epsilon$ .*

The diagonalizability assumption implies that any vector is a linear combination of the eigenvectors, so we can choose any desired vector as the initial state. Usually, the decomposition is not known for us, so the quantum algorithm we construct should be independent of this decomposition.

The eigenvalue problem we solve here is a little different from the classical sense. In Problem 1, we only obtain a superposition of the eigen-pairs. We may view it as a quantum version of eigenvalue decomposition. There are two reasons for us to solve this problem. First, similar to solve linear systems in a quantum computer, it is better to obtain a quantum result for the eigenvalue problem. For us, this should be a quantum state that contains the information of the eigenvalues and the corresponding eigenvectors. Second, by measuring the first register, we can obtain all the eigenvalues. This needs at least  $\Omega(n)$  measurements. We can also obtain the quantum states of the corresponding eigenvectors. However, we may hope the quantum eigenvalue decomposition has other applications. For instance, implementing functions of matrices. Let  $f$  be a function,  $M = E\Lambda E^{-1}$  be the eigenvalue decomposition of  $M$ . In many cases (e.g. see [20]),  $f(M) = Ef(\Lambda)E^{-1}$ . In a quantum computer, by implementing a function of  $M$ , we mean to implement  $f(M)|\mathbf{b}\rangle$  for any given state  $|\mathbf{b}\rangle$ . Since  $E$  is non-singular, we have a decomposition  $|\mathbf{b}\rangle = \sum_{j=1}^n \beta_j |E_j\rangle$ . Thus  $f(M)|\mathbf{b}\rangle = \sum_{j=1}^n \beta_j f(\lambda_j) |E_j\rangle$ . If we can solve Problem 1, then we can construct the state  $f(M)|\mathbf{b}\rangle$ .

## 1.1 Our results

In this paper, we mainly focus on two types of matrices: diagonalizable matrices that only have real eigenvalues and normal matrices. We also consider the case that the diagonalizable matrices can have complex eigenvalues. In this case, we need to make an extra assumption in Problem 1.

Our quantum algorithm is inspired by QPE and recent works in quantum algorithms to solve ordinary differential equations [9, 10, 13]. In QPE, an important step is to perform Hamiltonian simulation to implement  $e^{iHt}$  for some Hermitian matrix  $H$ . For example, suppose the input state is  $|E_j\rangle$ , then after Hamiltonian simulation, we obtain a state of the form  $(1/\sqrt{m}) \sum_{l=0}^{m-1} e^{i\lambda_j l} |l\rangle |E_j\rangle$ . Then  $\lambda_j$  is recovered by applying quantum Fourier inverse transform to  $|l\rangle$ . When  $M$  is not Hermitian,  $e^{iMt}$  is not unitary, so we cannot apply Hamiltonian simulation. One alternative method we can use is ordinary differential equations. Just like Hamiltonian simulation, which arises from Schrödinger equation, we can consider the ODE  $d\mathbf{x}(t)/dt = iM\mathbf{x}(t)$  as a source to implement  $e^{iMt}$ . It is easy to show that the solution is  $\mathbf{x}(t) = e^{iMt} |E_j\rangle$ . In a quantum computer, to solve this ODE, we usually use the discretization method to change it into a linear system. Then solve the linear system by quantum linear algebraic techniques. An interesting point of this idea is that the solution of the linear system is a superposition of the solutions at differential times  $t_l = l\Delta t$ , i.e.,  $\sum_{l=0}^{m-1} |l\rangle |\mathbf{x}(t_l)\rangle = \sum_{l=0}^{m-1} e^{i\lambda_j t_l} |l\rangle |E_j\rangle$ . This state is exactly what we need in QPE. Consequently, we

can obtain the state  $|\lambda_j\rangle|E_j\rangle$  by applying quantum Fourier inverse transform to  $|l\rangle$ . This idea also works when the input state is a linear combinations of the eigenvectors  $|\phi\rangle = \sum_j \beta_j |E_j\rangle$ . Moreover, in this algorithm, we do not need to know how  $|\phi\rangle$  is decomposed.

With the above idea, for the first type of matrices, our main result is

**Theorem 1** (Informal of Theorem 9). *Let  $M$  be an  $n \times n$  diagonalizable matrix which only has real eigenvalues,  $\rho \geq 1$  be a upper bounded of the eigenvalues. Then Problem 1 can be solved in time*

$$O\left(T\left(\frac{\rho\kappa(E)\log(\rho/\epsilon)}{\epsilon}, \frac{\epsilon}{\rho}, \frac{n\rho\log(\rho/\epsilon)}{\epsilon}\right) \times \frac{\rho\kappa(E)\sqrt{\log(\rho/\epsilon)}}{\epsilon}\right), \quad (1)$$

where  $T(\cdot, \cdot, \cdot)$  is the complexity to solve certain linear systems, and  $\kappa(E)$  is the condition number of the matrix generated by the eigenvectors.

In a quantum computer, to solve an  $n \times n$  linear system, the complexity  $T(\kappa, \epsilon, n)$  depends on the condition number  $\kappa$  of the coefficient matrix, the precision  $\epsilon$  to approximate the solution, the size  $n$  of the linear system and some other parameters about the linear system. In many case,  $T$  is linear at  $\kappa$  and logarithmic at  $\epsilon$  and  $n$ . For instance, if the linear system is  $s$ -sparse, then  $T = O(s\kappa \text{poly}(\log \kappa, \log s, \log 1/\epsilon, \log n)) = \tilde{O}(s\kappa)$  [12]. Consequently, we have the following result.

**Theorem 2** (Informal of Theorem 13). *Assume that  $M$  is diagonalizable and  $s$  sparse,  $\rho \geq 1$  is a upper bounded of the eigenvalues. Then Problem 1 can be solved in time  $\tilde{O}(s\rho^2\kappa(E)^2/\epsilon^2)$ .*

As discussed above, when we have the state  $\sum_{j=1}^n \beta_j |\tilde{\lambda}_j\rangle|E_j\rangle$ , we can obtain all the eigenvalues by measurements. It is not hard to show that  $O(n \log n)$  measurements are enough. Thus for sparse matrices, the complexity to obtain all the eigenvalues is  $\tilde{O}(sn\rho^2\kappa(E)^2/\epsilon^2)$ . However, the current classical algorithms cost at least  $O(n^2)$  to obtain all the eigenvalues, even if all the eigenvalues are real [6, 21]. So quantum computers still have the possibility to beat classical computers when the eigenvalue problem is well-conditioned.

The algorithm above also works when  $M$  only has purely imaginary eigenvalues. However, when  $M$  has complex eigenvalues, it may not work in a straightforward way. One simple reason is that we cannot estimate the real and imaginary parts of the eigenvalues at the same time in QPE. An alternative approach is to consider the ODE  $d\mathbf{x}(t)/dt = i(M \otimes I + I \otimes \bar{M})\mathbf{x}(t)$  with initial state  $\sum_j \beta_j |E_j\rangle|\bar{E}_j\rangle$ . Here  $\bar{M}, |\bar{E}_j\rangle$  refer to the complex conjugate of  $M, |E_j\rangle$  respectively. The solution of this ODE is  $\mathbf{x}(t) = \sum_j \beta_j e^{2it\text{Re}(\lambda_j)} |E_j\rangle|\bar{E}_j\rangle$ . Then a similar idea to above shows that we can create the state proportional to  $\sum_j \beta_j |\text{Re}(\lambda_j)\rangle|E_j\rangle|\bar{E}_j\rangle$ . If this state is further viewed as the initial state of the ODE  $d\mathbf{x}(t)/dt = (M \otimes I - I \otimes \bar{M})\mathbf{x}(t)$ , then we will end up with a state proportional to  $\sum_j \beta_j |\text{Re}(\lambda_j)\rangle|\text{Im}(\lambda_j)\rangle|E_j\rangle|\bar{E}_j\rangle$ . Conclude the above analysis, we obtain the following theorem.

**Theorem 3** (Informal of Theorem 18). *Let  $M$  be an  $n \times n$  diagonalizable matrix,  $\rho \geq 1$  be a upper bound of the eigenvalues. Assume that the initial state of Problem 1 is  $\sum_{j=1}^n \beta_j |E_j\rangle|\bar{E}_j\rangle$ , then Problem 1 can be solved in time*

$$O\left(T\left(\frac{\rho\kappa(E)^2\log(\rho/\epsilon)}{\epsilon}, \frac{\epsilon}{\rho}, \frac{n\rho\log(\rho/\epsilon)}{\epsilon}\right) \times \frac{\rho^2\kappa(E)^4\log(\rho/\epsilon)}{\epsilon^2}\right), \quad (2)$$

*Especially, if  $M$  has sparsity  $s$ , then the complexity is  $\tilde{O}(s\rho^3\kappa(E)^6/\epsilon^3)$ .*

As for normal matrices, the quantum algorithm is much simpler than above. Since normal matrices are unitarily diagonalizable, the eigenvalue decomposition and singular value decomposition

are closely related. For this kind of matrices, we can directly use quantum singular value estimation (QSVE) to solve Problem 1. Suppose the eigenvalues are  $\sigma_j e^{i\theta_j}$ ,  $j \in \{1, 2, \dots, n\}$ . Since we know how to do QSVE in a quantum computer [11, 24], we can estimate  $\sigma_j$  through QSVE. As for  $\theta_j$ , by considering the QSVE of  $\begin{pmatrix} 0 & M \\ M^\dagger & 0 \end{pmatrix}$ , we can construct a unitary  $U$  to perform  $|E_j\rangle \mapsto e^{-i\theta_j}|E_j\rangle$ . Hence,  $\theta_j$  can be estimated by applying QPE to  $U$ .

For normal matrices, our main result is stated as follows.

**Theorem 4** (Informal of Theorems 19, 20). *Let  $M$  be an  $n \times n$  normal matrix. Then Problem 1 can be solved in time  $O(T/\epsilon^2)$ , where  $O(T/\epsilon)$  is the complexity to do quantum singular value estimation of  $M$  to precision  $\epsilon$ . Especially, if  $M$  is  $s$  sparse, then the complexity is  $\tilde{O}(s\rho\|M\|_{\max}/\epsilon^2)$ .*

In the above theorem, if  $M = (m_{ij})$ , then  $\|M\|_{\max} = \max_{i,j} |m_{ij}|$ . Quantum singular value estimation can be solved efficiently in many situations in a quantum computer, so we can think  $T = O(\text{polylog}(n))$ .

## 1.2 Related works

The most related work is quantum phase estimation to estimate eigenvalues of Hermitian and unitary matrices [1, 25]. It is the starting point of our research. For estimating the eigenvalues of non-unitary (non-Hermitian) matrices, as far as we know, there are two papers [14, 33]. One difficulty behind this might be the result in complexity theory [22, 34], which suggesting that many eigenvalue problems are QMA-complete, i.e., they are hard to solve even for quantum computers. In [14], Daskin et al. use the idea of iterative phase estimation algorithm to estimate the complex eigenvalues of non-unitary matrices. This idea works when the input state is  $|E_j\rangle$ . The complexity of their quantum algorithm is  $O(n^2/\epsilon)$ . In [33], Wang et al. propose a measurement-based quantum phase estimation algorithm. This kind of idea is similar to the power method. So it usually recovers the largest eigenvalue. In [27], Low and Chuang studied the qubitization of normal operators. This result might be helpful to improve Theorem 4.

There are many results in the classical case. For example, in a recent paper [4], Banks et al. proposed a random classical algorithm that can find an invertible matrix  $V$  and a diagonal matrix  $D$  such that  $\|M - VDV^{-1}\| \leq \epsilon$  in time  $O(n^\omega \log^2(n/\epsilon))$ , where  $2 \leq \omega < 2.373$  is the exponent of matrix multiplication. This algorithm is optimal up to polylogarithmic factors, in the sense that verifying that a given similarity diagonalizes a matrix requires at least matrix multiplication time. As a result,  $VDV^{-1}$  can be viewed as an approximated eigenvalue decomposition of  $M$ .

In physics, eigenvalues of Hamiltonian describe the energy levels of the quantum system. It is one of the most important tasks in chemistry as they are required to predict reaction rates and electronic structures. The  $\mathcal{PT}$ -symmetric matrices refer to a type of Hamiltonians that are not Hermitian but have real eigenvalues [8]. These new kinds of Hamiltonians describe a new class of complex quantum theories having positive probabilities and unitary time evolution, and play crucial roles in quantum mechanics and many other areas of physics [7, 29]. Our algorithm may provide a method to perform this kind of Hamiltonian simulations in a quantum computer.

## 1.3 Organizations of the paper

In section 2, we consider Problem 1 for diagonalizable matrices that only have real eigenvalues. Then in section 3, we generalize the quantum algorithm to the case when the matrix has complex eigenvalues under an extra assumption. Finally, in section 4, we studies Problem 1 for normal

matrices. Since QPE is an important idea for our quantum algorithms, in Appendix A, we briefly introduce this method and review some quantum linear algebraic techniques that will be used in this paper.

## 2 Diagonalizable matrices that only have real eigenvalues

In this section, we study Problem 1 in the case that all the eigenvalues are real. These kind of matrices are closely related to Hermitian matrices. A simple fact is that a diagonalizable matrix  $M$  only has real eigenvalues if and only if there is a Hermitian matrix  $H$  and an invertible matrix  $P$  such that  $M = PHP^{-1}$  [15]. So if  $H_1, H_2$  are Hermitian and  $H_1$  or  $H_2$  is positive definite, then  $M = H_1 H_2$  only have real eigenvalues. Indeed, this is the only possibility such that a diagonalizable matrix only has real eigenvalues. Note that if we know the decomposition  $M = H_1 H_2$ , then we can solve Problem 1 by QPE directly. More precisely, assume that  $H_1$  is positive definite, then there is a positive definite Hermitian matrix  $H_3$  such that  $H_1 = H_3^2$ . Thus  $H_3^{-1} M H_3 = H_3 H_2 H_3$  is Hermitian. In a quantum computer,  $H_3$  can be created efficiently, such as by the technique of block-encoding [11]. Now it suffices to find the eigenvalues of the Hermitian matrix  $H_3 H_2 H_3$ . This can be solved by QPE. In this paper, we will not consider this case.

In the following, we first state the main idea of our quantum algorithm based on the Euler method. Then we show the detailed analysis of solving ODEs based on [10]. As an illustration, we will apply our quantum algorithm to compute the eigenvalues of sparse matrices. Finally, we analyze the difficulties of the quantum algorithm in estimating complex eigenvalues.

### 2.1 Main idea

Assume that  $M$  is an  $n \times n$  diagonalizable matrix with real eigenvalues  $\{\lambda_1, \dots, \lambda_n\}$  and eigenvectors  $\{|E_1\rangle, \dots, |E_n\rangle\}$  of unit norm. For simplicity, we first assume that the input state is  $|E_j\rangle$  in Problem 1. Now let us start from the following linear system of differential equations

$$\begin{cases} \frac{d\mathbf{x}(t)}{dt} = 2\pi i M \mathbf{x}(t), \\ \mathbf{x}(0) = |E_j\rangle. \end{cases} \quad (3)$$

It is easy to see that the solution of this differential equation is

$$\mathbf{x}(t) = e^{2\pi i M t} |E_j\rangle = e^{2\pi i \lambda_j t} |E_j\rangle. \quad (4)$$

Since  $M$  is not Hermitian, it may not easy to apply  $e^{2\pi i M t}$  directly to  $|E_j\rangle$  to obtain the solution. Fortunately, there are some quantum algorithms [9, 10, 13] to solve ordinary differential equations. These algorithms are mainly based on the discretization method.

One of the simplest discretization method is Euler method:

$$\frac{d\mathbf{x}(t)}{dt} \approx \frac{\mathbf{x}(t) - \mathbf{x}(t - \Delta t)}{\Delta t}. \quad (5)$$

In the following, we briefly show how Euler method is used to solve (3). First, we discrete the time interval  $[0, t]$  into  $m$  short intervals by setting  $t_0 = 0, t_1 = \Delta t, t_2 = 2\Delta t, \dots, t_m = m\Delta t = t$ . After discretization by Euler method (5), we obtain a linear system

$$(A \otimes I_n - 2\pi i \Delta t I_m \otimes M) \tilde{\mathbf{x}} = \mathbf{b}, \quad (6)$$

where

$$A = \begin{pmatrix} 1 & & & \\ -1 & 1 & & \\ & \ddots & \ddots & \\ & & -1 & 1 \end{pmatrix}_{m \times m}, \quad \tilde{\mathbf{x}} = \begin{pmatrix} \mathbf{x}(t_1) \\ \mathbf{x}(t_2) \\ \vdots \\ \mathbf{x}(t_m) \end{pmatrix}, \quad \mathbf{b} = \begin{pmatrix} \mathbf{x}(t_0) \\ 0 \\ \vdots \\ 0 \end{pmatrix}.$$

Solve this linear system in a quantum computer, then we obtain the quantum state of  $\tilde{\mathbf{x}}$

$$\frac{1}{\sqrt{m}} \sum_{l=1}^m |l\rangle |\mathbf{x}(t_l)\rangle = \frac{1}{\sqrt{m}} \sum_{l=1}^m e^{2\pi i l \lambda_j \Delta t} |l\rangle |E_j\rangle. \quad (7)$$

This is a quantum state similar to the one required in the quantum phase estimation (see (77) in Appendix A). Thus we can obtain  $|\tilde{\lambda}_j\rangle |E_j\rangle$  by applying quantum Fourier inverse transform to  $|l\rangle$ .

If the initial state of (3) is a linear combination of the eigenvectors  $\mathbf{x}(0) = \sum_{j=1}^n \beta_j |E_j\rangle$ , then the quantum state of the linear system (6) is proportional to

$$\sum_{j=1}^n \sum_{l=0}^m \beta_j e^{2\pi i l \lambda_j \Delta t} |l\rangle |E_j\rangle. \quad (8)$$

Similarly, when quantum Fourier inverse transform is applied to  $|l\rangle$ , we obtain

$$\sum_{j=1}^n \beta_j |\tilde{\lambda}_j\rangle |E_j\rangle. \quad (9)$$

In the next section, we will give more details. However, we will not use the Euler method as it has worse dependence on the precision [9]. Instead, we shall use the quantum algorithm proposed in [10] to solve the ODE (3). It is poly-log at the precision.

## 2.2 Error analysis

Following the idea discussed above, we need to solve the differential equation (3). It is interesting to see that the ODE (3) satisfies the assumptions<sup>1</sup> of the quantum algorithm proposed in [10]. Thus we can apply this algorithm directly.

In the discretization method, we choose  $t = \Theta(1/\rho\epsilon)$ , where  $\epsilon$  is the precision to approximate the eigenvalues, and  $\rho \geq \max\{1, \max_j |\lambda_j|\}$  is an upper bound of the eigenvalues. The integer  $m = \Theta(1/\epsilon)$  and  $\Delta t = \Theta(1/\rho)$ . The choices of the parameters here are inspired by the quantum phase estimation, which will become clear later.

For any integer  $k$  and any  $z \in \mathbb{C}$ , denote the  $(k+1)$ -terms truncation of exponential function  $e^z$  as

$$T_k(z) = \sum_{j=0}^k \frac{z^j}{j!}. \quad (10)$$

If  $r \in \mathbb{R}$  and  $|r| < 1$ , then it is easy to show that  $|T_k(ir) - e^{ir}| \leq e/(k+1)!$ .

Set  $d = m(k+1)$ , define the  $(d+1)n \times (d+1)n$  matrix  $C_{m,k}$  by

$$C_{m,k}(2\pi i M \Delta t) = \sum_{p=0}^d |p\rangle \langle p| \otimes I - \sum_{p=0}^{m-1} \sum_{q=1}^k |p(k+1)+q\rangle \langle p(k+1)+q-1| \otimes \frac{2\pi i M \Delta t}{q} \quad (11)$$

---

<sup>1</sup> The assumptions are:  $2\pi i M$  is diagonalizable, the eigenvalues have non-positive real parts.

$$- \sum_{p=0}^{m-1} \sum_{q=0}^k |(p+1)(k+1)\rangle \langle p(k+1)+q| \otimes I. \quad (12)$$

The goal of this matrix is to implement  $T_k(2\pi i M \Delta t)$  without computing matrix powers. For an illustration,  $C_{2,2}(A)$  is of the following form:

$$C_{2,2}(A) = \begin{pmatrix} I & & & & & & & \\ -A & I & & & & & & \\ & -\frac{A}{2} & I & & & & & \\ -I & -I & -I & I & & & & \\ & & & -A & I & & & \\ & & & & -\frac{A}{2} & I & & \\ & & & -I & -I & -I & I & \end{pmatrix}.$$

The definition of the matrix  $C_{m,k}$  is a little different from the one defined in [10]. We deleted their fourth summation term. This is caused by different goals. In [10], the authors aim to compute the quantum state of the solution at time  $t_m$ . The fourth term is introduced to improve the probability of this state. However, in this paper, we need the superposition of the quantum state of the solution at time  $t_0, t_1, \dots, t_m$ . Thus, the solution at time  $t_m$  is not special for us.

Now we consider the following linear system

$$C_{m,k}(2\pi i M \Delta t) \tilde{\mathbf{x}} = |0..0\rangle |E_j\rangle. \quad (13)$$

In the right hand side,  $|0..0\rangle$  is added to make sure both sides have the same dimension. Here  $\tilde{\mathbf{x}}$  refers to the approximated solution of the differential equation (3). We can formally write the solution as

$$\tilde{\mathbf{x}} = \sum_{p=0}^{m-1} \sum_{q=0}^k |p(k+1)+q\rangle |\mathbf{x}_{p,q}\rangle + |m(k+1)\rangle |\mathbf{x}_{m,0}\rangle. \quad (14)$$

In the above expression, we use the ket notation to simplify the expression of  $\tilde{\mathbf{x}}$ , but  $|\mathbf{x}_{p,q}\rangle$  may not a unit vector.

We can check that (see Appendix B)

$$|\mathbf{x}_{0,0}\rangle = |E_j\rangle, \quad (15)$$

$$|\mathbf{x}_{0,q}\rangle = \frac{(2\pi i M \Delta t)^q}{q!} |E_j\rangle = \frac{(2\pi i \lambda_j \Delta t)^q}{q!} |E_j\rangle, \quad (q = 1, \dots, k). \quad (16)$$

If  $p > 0$ , then

$$|\mathbf{x}_{p,0}\rangle = T_k(2\pi i M \Delta t) |x_{p-1,0}\rangle = T_k(2\pi i \lambda_j \Delta t) |x_{p-1,0}\rangle, \quad (17)$$

$$|\mathbf{x}_{p,q}\rangle = \frac{(2\pi i M \Delta t)^q}{q!} |x_{p,0}\rangle = \frac{(2\pi i \lambda_j \Delta t)^q}{q!} |x_{p,0}\rangle, \quad (q = 1, \dots, k). \quad (18)$$

**Lemma 5.** Assume that  $2\pi \Delta t |\lambda_j| < 1$ , then for any  $p \in \{1, 2, \dots, m\}$ , we have

$$\| |\mathbf{x}(t_p)\rangle - |\mathbf{x}_{p,0}\rangle \|_2 \leq \left( 1 + \frac{e}{(k+1)!} \right)^p - 1. \quad (19)$$

Moreover,

$$\left| \| |\mathbf{x}_{p,0}\rangle \|_2 - 1 \right| \leq \left( 1 + \frac{e}{(k+1)!} \right)^p - 1. \quad (20)$$

*Proof.* By equations (4), (17),

$$\begin{aligned}
\| |\mathbf{x}(t_p)\rangle - |\mathbf{x}_{p,0}\rangle \|_2 &= \| e^{2\pi i \lambda_j \Delta t} |\mathbf{x}(t_{p-1})\rangle - T_k(2\pi i \lambda_j \Delta t) |\mathbf{x}_{p-1,0}\rangle \|_2 \\
&\leq |e^{2\pi i \lambda_j \Delta t} - T_k(2\pi i \lambda_j \Delta t)| \| |\mathbf{x}(t_{p-1})\rangle - |\mathbf{x}_{p-1,0}\rangle \|_2 \\
&\leq \frac{e}{(k+1)!} + \left(1 + \frac{e}{(k+1)!}\right) \| |\mathbf{x}(t_{p-1})\rangle - |\mathbf{x}_{p-1,0}\rangle \|_2 \\
&\leq \frac{e}{(k+1)!} \sum_{r=0}^{p-1} \left(1 + \frac{e}{(k+1)!}\right)^r \\
&= \frac{e}{(k+1)!} \frac{(1 + \frac{e}{(k+1)!})^p - 1}{(1 + \frac{e}{(k+1)!}) - 1} \\
&= \left(1 + \frac{e}{(k+1)!}\right)^p - 1.
\end{aligned}$$

This proves the first claim. Since  $|\mathbf{x}(t_p)\rangle$  is unit, the second result comes naturally.  $\square$

**Proposition 6.** Let  $|\mathbf{x}\rangle = \frac{1}{\sqrt{m+1}} \sum_{p=0}^m |p\rangle |\mathbf{x}(t_p)\rangle$  be the superposition of the exact solution of the differential equation (3). Denote the quantum state of  $\sum_{p=0}^m |p\rangle |\mathbf{x}_{p,0}\rangle$  as  $|\hat{\mathbf{x}}\rangle$ , then

$$\| |\mathbf{x}\rangle - |\hat{\mathbf{x}}\rangle \|_2 \leq 2\sqrt{m+1} \left( \left(1 + \frac{e}{(k+1)!}\right)^m - 1 \right) \left( 2 - \left(1 + \frac{e}{(k+1)!}\right)^m \right)^{-1/2}. \quad (21)$$

*Proof.* Denote the  $l_2$ -norm of  $\sum_{p=0}^m |p\rangle |\mathbf{x}_{p,0}\rangle$  as  $\sqrt{L}$ . Then

$$\begin{aligned}
\| |\mathbf{x}\rangle - |\hat{\mathbf{x}}\rangle \|_2 &= \sum_{p=0}^m \left\| \frac{|\mathbf{x}(t_p)\rangle}{\sqrt{m+1}} - \frac{|\mathbf{x}_{p,0}\rangle}{\sqrt{L}} \right\|_2 \\
&\leq \sum_{p=0}^m \left| \frac{1}{\sqrt{m+1}} - \frac{1}{\sqrt{L}} \right| + \frac{1}{\sqrt{L}} \sum_{p=0}^m \| |\mathbf{x}(t_p)\rangle - |\mathbf{x}_{p,0}\rangle \|_2.
\end{aligned} \quad (22)$$

By Lemma 5,

$$|L - m - 1| \leq (m+1) \left( \left(1 + \frac{e}{(k+1)!}\right)^m - 1 \right) =: (m+1)A,$$

so

$$\left| \frac{1}{\sqrt{m+1}} - \frac{1}{\sqrt{L}} \right| = \frac{|L - m - 1|}{\sqrt{L(m+1)}(\sqrt{m+1} + \sqrt{L})} \leq \frac{A}{\sqrt{(m+1)(1-A)}}.$$

Thus the first term of (22) is bounded by  $A\sqrt{m+1}/\sqrt{1-A}$ . Again by Lemma 5, the second term of (22) is also bounded by  $A\sqrt{m+1}/\sqrt{1-A}$ . This completes the proof.  $\square$

Proposition 6 states that if we choose  $k$  such that  $(k+1)! \gg m$ , then the quantum state of the solution of the differential equation (3) is approximated by the part of the quantum state of the solution of the linear system (13) with  $q = 0$ . The following lemma further enhances this by showing that this part occupies a constant amplitude. If we perform amplitude amplification, then we can enlarge the amplitude of this state close to 1 with  $O(1)$  repetitions.

**Lemma 7.** Assume that  $|2\pi\lambda_j\Delta t| < 1$ , then the  $l_2$ -norm of the solution  $\tilde{\mathbf{x}}$  of the linear system (13) satisfies

$$\left| \|\tilde{\mathbf{x}}\|_2^2 - e^{2\pi\lambda_j\Delta t} \sum_{p=0}^{m-1} \|\mathbf{x}_{p,0}\|_2^2 - \|\mathbf{x}_{m,0}\|_2^2 \right| \leq \frac{e}{(k+1)!}. \quad (23)$$

*Proof.* By equation (14)

$$\begin{aligned}
\|\tilde{\mathbf{x}}\|_2^2 &= \sum_{p=0}^{m-1} \sum_{q=0}^k \|\mathbf{x}_{p,q}\|_2^2 + \|\mathbf{x}_{m,0}\|_2^2 \\
&= \sum_{p=0}^{m-1} \sum_{q=0}^k \frac{(2\pi\lambda_j\Delta t)^q}{q!} \|\mathbf{x}_{p,0}\|_2^2 + \|\mathbf{x}_{m,0}\|_2^2 \\
&= T_k(2\pi\lambda_j\Delta t) \sum_{p=0}^{m-1} \|\mathbf{x}_{p,0}\|_2^2 + \|\mathbf{x}_{m,0}\|_2^2.
\end{aligned}$$

It is easy to prove that  $|T_k(2\pi\lambda_j\Delta t) - e^{2\pi\lambda_j\Delta t}| \leq e/(k+1)!$ . This completes the proof.  $\square$

## 2.3 Main results

In this paper, for solving an  $n$ -by- $n$  linear system  $A\mathbf{x} = \mathbf{b}$  in a quantum computer, we shall use  $T(\kappa(A), \epsilon, n)$  to denote the complexity. Here  $\kappa(A)$  is the condition number of the  $A$  and  $\epsilon$  is the precision to approximate the solution state. The cost  $T$  may depend on other parameters, like the sparsity or the norm of  $A$ , but we concern more about  $\kappa(A)$ ,  $\epsilon$  and  $n$  in this paper. In many cases, for a quantum linear solver, the complexity  $T$  is linear at  $\kappa(A)$  and poly-log at  $\epsilon, n$ .

The following theorem concludes the result of solving the ODE (3) in the special case when  $\mathbf{x}(0) = |E_j\rangle$  for some  $j$ .

**Proposition 8.** *Let  $M$  be an  $n \times n$  diagonalizable matrix which only has real eigenvalues,  $\rho \geq 1$  be a upper bound of the eigenvalues. Suppose that the linear system (12) can be solved in time  $T(\kappa(C_{m,k}), \epsilon, m(k+1)n)$  to precision  $\epsilon$ . Given access to copies of one of the eigenvectors, then there is a quantum algorithm that estimates the corresponding eigenvalue up to precision  $\rho\epsilon$  in time  $T(\kappa(E)\epsilon^{-1}(\log(1/\epsilon)), \epsilon, n\epsilon^{-1}\log(1/\epsilon))$ , where  $\kappa(E)$  is the condition number of the matrix generated by the eigenvectors.*

*Proof.* By Proposition 6, to make sure the error between  $|\mathbf{x}\rangle$  and  $|\hat{\mathbf{x}}\rangle$  is smaller than  $\epsilon$ , we can choose  $k$  such that  $(k+1)! \geq m^2/\epsilon$ . That is  $k \geq \log(m/\epsilon)$ . Thus, we can set  $k = O(\log(m/\epsilon)) = O(\log(1/\epsilon))$  as  $m = O(1/\epsilon)$ .

Let  $|\bar{\mathbf{x}}\rangle$  be the quantum state obtained by the quantum linear solver to solve the linear system (12). Since  $2\pi\Delta t|\lambda_j| < 1$ , Lemma 7 shows that in  $|\bar{\mathbf{x}}\rangle$  the amplitude of  $|\hat{\mathbf{x}}\rangle$  is close to  $e^{-2\pi\Delta t|\lambda_j|} > e^{-1} > 0.36$ . Applying amplitude amplification with  $O(1)$  repetitions, we can increase the amplitude of  $|\hat{\mathbf{x}}\rangle$  close to 1 in  $|\bar{\mathbf{x}}\rangle$ . Since

$$|\mathbf{x}\rangle = \frac{1}{\sqrt{m+1}} \sum_{l=0}^m |l\rangle |\mathbf{x}(t_l)\rangle = \frac{1}{\sqrt{m+1}} \sum_{l=0}^m e^{2\pi i \lambda_j l \Delta t} |l\rangle |E_j\rangle. \quad (24)$$

If we apply quantum Fourier inverse transform to the first register of  $|\hat{\mathbf{x}}\rangle$ , then we can obtain an  $\epsilon$  approximation of

$$\frac{1}{m+1} \sum_{k=0}^m \left( \sum_{l=0}^m e^{2\pi i l (\lambda_j \Delta t - \frac{k}{m+1})} \right) |k\rangle |E_j\rangle. \quad (25)$$

Based on the analysis of QPE, we are left with a  $k$  such that  $k/(m+1)$  is an  $\epsilon$  approximation of  $\lambda_j \Delta t$  with probability close to 1.

The complexity is dominated by the solving the linear system (12). As proved in Theorem 5 of [10], the condition number of  $C_{m,k}$  is bounded by  $O(\kappa(E)km)$ . For the linear system (12), the dimension is  $m(k+1)n$ . Finally, based on the choices of  $k$  and  $m$ , we obtain the claimed complexity of the above procedure.  $\square$

In a quantum computer, under certain conditions (e.g. block-encoding, sparse), the complexity to solve a linear system is linear at the condition number, logarithm on the precision, and the dimension. Thus, under these conditions, the complexity of Proposition 8 can be simplified into  $\tilde{O}(\kappa(E)/\epsilon)$ .

In the general case, the eigenvalue problem can be solved similarly. Before we state the algorithm, we remark that in the proof of Proposition 8, we approximate  $\lambda_j \Delta t$  up to error  $\epsilon$ . This gives an  $\epsilon/\Delta t = \rho\epsilon$  approximation of  $\lambda_j$ . If we choose  $\epsilon = \epsilon'/\rho$ , then we obtain an  $\epsilon'$ -approximation of  $\lambda_j$ . The parameters  $k, m$ , and complexity should be changed accordingly.

---

**Algorithm 1** Quantum algorithm for computing the real eigenvalues

---

- Input:** (1). An  $n \times n$  diagonalizable matrix  $M$  that only with real eigenvalues. Suppose the eigenvalues are  $\{\lambda_1, \dots, \lambda_n\}$  and the unit eigenvectors are  $\{|E_1\rangle, \dots, |E_n\rangle\}$ .  
(2). A upper bound  $\rho \geq 1$  of the eigenvalues.  
(3). Quantum access to copies of the state  $|\phi\rangle$ , which formally equals  $\sum_{j=1}^n \beta_j |E_j\rangle$ .  
(4). The precision  $\epsilon \in (0, 1)$ ,  $\Delta t = 1/2\rho$ ,  $m = \lceil \rho/\epsilon \rceil$ ,  $k = \lceil \log(\rho/\epsilon) \rceil$ .

**Output:** The quantum state

$$\sum_{j=1}^n \beta_j |\tilde{\lambda}_j\rangle |E_j\rangle \quad (26)$$

up to a normaliation, where  $|\tilde{\lambda}_j - \lambda_j| \leq \epsilon$  for all  $j$ .

- 1: Construct the matrix  $C_{m,k}$  based on equation (12).
  - 2: Use quantum linear algebraic technique to create the state  $C_{m,k}^{-1}|0..0\rangle|\phi\rangle$ .
  - 3: Apply quantum Fourier inverse transform to the first register of  $C_{m,k}^{-1}|0..0\rangle|\phi\rangle$ .
  - 4: Perform measurements on the last register, return the post-selected state if the output is  $|0\rangle$ .
- 

**Theorem 9.** Let  $M$  be an  $n \times n$  diagonalizable matrix which only has real eigenvalues  $\{\lambda_1, \dots, \lambda_n\}$ . Assume that the corresponding unit eigenvectors are  $\{|E_1\rangle, \dots, |E_n\rangle\}$ . Let  $\rho \geq 1$  be a upper bound of the eigenvalues. Suppose that  $C_{m,k}^{-1}$  can be implemented in a quantum computer in time  $T(\kappa(C_{m,k}), \epsilon, m(k+1)n)$  to precision  $\epsilon$ . Given access to copies of the state  $|\phi\rangle = \sum_{j=1}^n \beta_j |E_j\rangle$ , then with probability close to 1, Algorithm 1 returns

$$\frac{1}{Z} \sum_{j=1}^n \beta_j |\tilde{\lambda}_j\rangle |E_j\rangle \quad (27)$$

in time

$$O\left(T_0 \times T\left(\frac{\rho\kappa(E)\log(\rho/\epsilon)}{\epsilon}, \frac{\epsilon}{\rho}, \frac{n\rho\log(\rho/\epsilon)}{\epsilon}\right) \times \frac{\rho\kappa(E)\sqrt{\log(\rho/\epsilon)}}{\epsilon}\right), \quad (28)$$

where  $Z$  is the normalization factor,  $T_0$  is the complexity to prepare the initial state,  $\kappa(E)$  is the condition number of the matrix generated by the eigenvectors, and  $|\lambda_j - \tilde{\lambda}_j| \leq \epsilon$  for all  $j$ .

*Proof.* By equation (14), up to a normalization

$$\begin{aligned} C_{m,k}^{-1}|0..0\rangle|\phi\rangle &= \sum_{j=1}^n \beta_j C_{m,k}^{-1}|0..0\rangle|E_j\rangle \\ &= \sum_{j=1}^n \beta_j \left( \sum_{p=0}^m |p(k+1)\rangle|\mathbf{x}_{p,0}\rangle + \sum_{p=0}^{m-1} \sum_{q=1}^k |p(k+1)+q\rangle|\mathbf{x}_{p,q}\rangle \right). \end{aligned}$$

We will consider the normalization constant later. Since  $k+1$  is invertible modulo  $m(k+1)+1$ , we can find  $(k+1)^{-1}$  and multiple it on the first register. As a result, we obtain

$$\sum_{j=1}^n \beta_j \left( \sum_{p=0}^m |p\rangle|\mathbf{x}_{p,0}\rangle|0\rangle + |0\rangle^\perp \right). \quad (29)$$

In the above state, we added a new ancilla qubit  $|0\rangle$  to separate the two summation terms. This is feasible as the base states in the first register are orthogonal to each other.

By equation (4), Proposition 6 and Lemma 7, the state (29) is  $\epsilon$ -close to the state

$$\sum_{j=1}^n \sum_{p=0}^m \beta_j e^{2\pi i \lambda_j p \Delta t} |p\rangle|E_j\rangle|0\rangle + |0\rangle^\perp. \quad (30)$$

If we apply quantum Fourier inverse transform to  $|p\rangle$ , then we obtain

$$\frac{1}{\sqrt{m+1}} \sum_{j=1}^n \sum_{q=0}^m \sum_{p=0}^m \beta_j e^{2\pi i p(\lambda_j \Delta t - \frac{q}{m+1})} |q\rangle|E_j\rangle|0\rangle + |0\rangle^\perp = \sqrt{m+1} \sum_{j=1}^n \beta_j |\tilde{\lambda}_j \Delta t\rangle|E_j\rangle|0\rangle + |0\rangle^\perp. \quad (31)$$

The above equality is caused by a similar reason to the QPE, see (82) in Appendix A.

Note that the state (30) is not normalized. By [10, Lemma 3],  $\|C_{m,k}^{-1}\| \leq 3\kappa(E)\sqrt{km}$ . As a result,  $\|C_{m,k}^{-1}|0..0\rangle|\phi\rangle\| \leq \|C_{m,k}^{-1}\| \leq 3\kappa(E)\sqrt{km}$ . So the normalization constant is smaller than  $3\kappa(E)\sqrt{km}$ . Thus the amplitude of  $|0\rangle$  in the state (30), which is also the amplitude of  $|0\rangle$  in the state (31), is at least

$$\frac{1}{3\kappa(E)\sqrt{km}} \sqrt{\sum_{p=0}^m \left\| \sum_{j=1}^n \beta_j e^{2\pi i \lambda_j p \Delta t} |E_j\rangle \right\|_2^2}.$$

Note that if  $p=0$ , then  $\|\sum_{j=1}^n \beta_j |E_j\rangle\|_2^2 = \|\phi\|_2^2 = 1$ . Therefore, the amplitude of  $|0\rangle$  of the state (31) is larger than  $1/3\kappa(E)\sqrt{km}$ . By amplitude amplification and the choices of the parameters in the algorithm, the complexity to obtain the state (27) is (28) as claimed.  $\square$

**Remark 10.** There are several methods to find the upper bound of the eigenvalues. A simple one is based on the Gershgorin circle theorem [17], which states that every eigenvalue of  $M$  lies within at least one of the Gershgorin discs  $\{z \in \mathbb{C} : |z - m_{ii}| \leq \sum_{j \neq i} |m_{ij}|\}$ , where  $i = 1, \dots, n$ . As a result,  $\|M\|_1, \|M\|_\infty$  are upper bounds of the eigenvalues. The spectral norm  $\|M\|$  also provides a upper bound of the eigenvalues. Since we can estimate the singular values efficiently in a quantum computer, we can estimate the spectral norm efficiently as well. For instance, see [23].

**Remark 11.** For eigenvalue problems of diagonalizable matrices, Bauer and Fike in [5] shown that the condition number  $\kappa(E)$  describes the stability and conditioning of calculating the eigenvalues. If  $\kappa(E)$  is large, then small perturbations on the matrix  $M$  will give rise to large perturbations on the eigenvalues. This makes the calculation of the eigenvalues inaccurate. Thus the complexity of Algorithm 1 depends on  $\kappa(E)$  seems realistic. The dependence on  $\kappa(E)$  might be improved by using the variable time amplitude amplification technique [2].

## 2.4 Sparse matrices

In the following, we consider sparse matrices in which the complexity of inverting  $C_{m,k}$  can be determined explicitly. The following lemma about the sparsity of  $C_{m,k}$  is easy to prove.

**Lemma 12.** *If  $M$  is  $s$ -sparse, then the sparsity of  $C_{m,k}$  is  $\Theta(s + k)$ .*

*Proof.* By equation (12), for any  $p \in \{0, \dots, m\}$ ,  $q \in \{0, \dots, k\}$  and  $r \in \{1, \dots, n\}$

$$\begin{aligned} \langle p(k+1) + q | \otimes \langle r | C_{m,k} &= \langle p(k+1) + q | \otimes \langle r | - \langle p(k+1) + q - 1 | \otimes \langle r | \frac{2\pi i M \Delta t}{q} \\ &\quad - \delta_q^p \sum_{q'=0}^k \langle p(k+1) + q' | \otimes \langle r |. \end{aligned}$$

The nonzero element of this row vector is bounded by  $1 + s + k + 1 = \Theta(s + k)$ . Similar analysis also holds for the columns of  $C_{m,k}$ .  $\square$

By the quantum linear solver [12, Theorem 5], if  $M$  is  $s$  sparse, then combining Lemma 12,

$$\begin{aligned} &T(\kappa(C_{m,k}), \epsilon, m(k+1)n) \\ &= O((s + \log(1/\epsilon))\kappa(C_{m,k})(\log n \epsilon^{-1} \log(1/\epsilon))\text{polylog}((s + \log(1/\epsilon))\kappa(C_{m,k})/\epsilon)) \\ &= \tilde{O}(s\kappa(C_{m,k})). \end{aligned}$$

By [10, Theorem 5],  $\kappa(C_{m,k}) = O(\kappa(E)km) = O(\kappa(E)\epsilon^{-1}(\log 1/\epsilon))$ , Thus, equation (28) can be simplified into  $\tilde{O}(s\rho^2\kappa(E)^2/\epsilon^2)$ .

The quantum linear solver [12] depends on an oracle  $\mathcal{O}_C$  to query  $C_{m,k}$ . Assume that we have the oracle  $\mathcal{O}_M$  to query  $M$ . It is defined as

$$\mathcal{O}_M|i, j, z\rangle = |i, j, z \oplus m_{ij}\rangle, \quad \mathcal{O}_M|i, l\rangle = |i, \nu(i, l)\rangle, \quad (32)$$

where  $\nu(i, l)$  is the index of the  $l$ -th nonzero element in the  $i$ -th row/column. For any  $0 \leq p_1, p_2 \leq m, 0 \leq q_1, q_2 \leq k$  and  $1 \leq r_1, r_2 \leq n$ , it is easy to check that

$$\langle p_1(k+1) + q_1, r_1 | C_{m,k} | p_2(k+1) + q_2, r_2 \rangle \quad (33)$$

$$= \delta_{r_2}^{r_1} \delta_{p_2}^{p_1} \delta_{q_2}^{q_1} - [p_2 \leq m-1][q_2 \leq k-1] \delta_{p_2}^{p_1} \delta_{q_2+1}^{q_1} \langle r_1 | \frac{2\pi i M \Delta t}{q_2+1} | r_2 \rangle \quad (34)$$

$$- [p_2 \leq m-1] \delta_{r_2}^{r_1} \delta_{p_2+1}^{p_1} \delta_0^{q_1}, \quad (35)$$

where the notation  $[a \leq b]$  means that it equals 1 if  $a \leq b$  and 0 otherwise. The three terms in equations (34), (35) cannot coexist, so it is easy to build the oracle  $\mathcal{O}_C$  to query  $C_{m,k}$  when we have  $\mathcal{O}_M$ . The cost to build this oracle  $\mathcal{O}_C$  is the same as that to build  $\mathcal{O}_M$ .

**Theorem 13.** *With the same assumptions and notation as Theorem 9. Suppose there is an oracle defined by (32) to query  $M$ . If  $M$  is  $s$  sparse, then Algorithm 1 returns the state (27) in time  $\tilde{O}(s\rho^2\kappa(E)^2/\epsilon^2)$ .*

To obtain all the eigenvalues with classical output, we can perform measurements on the state (27). The following lemma shows how many measurements we should perform.

**Lemma 14.** *Let  $\mathcal{P} = \{p_1, \dots, p_n\}$  be a probability distribution. Set  $p_{\max} = \max\{p_1, \dots, p_n\}$ . To see every events under the distribution  $\mathcal{P}$  it suffices to make  $O(p_{\max}^{-1} \log(n/\delta))$  measurements. The success probability is at least  $1 - \delta$ .*

We defer the proof of this lemma to Appendix C. To apply Lemma 14, we need to analyze the probability to obtain each eigenvalue. Assume that  $M$  has  $d$  distinct eigenvalues  $\lambda_1, \dots, \lambda_d$ , we can rewrite the initial state as  $\sum_{j=1}^d \gamma_j |V_j\rangle$ , where  $|V_j\rangle$  is a normalized vector generated by the eigenvectors corresponding to  $\lambda_j$ . Then the right hand side of equation (27) can be written as  $\frac{1}{Z} \sum_{j=1}^d \gamma_j |\tilde{\lambda}_j\rangle |V_j\rangle$ . The probability to obtain  $\tilde{\lambda}_j$  equals  $p_j = |\gamma_j|^2 / Z^2$ . Note that  $Z^2 = \sum_{j=1}^d |\gamma_j|^2$ , so  $p_{\max} = \max_j |\gamma_j|^2 / Z^2 \geq 1/d$ . Thus, it suffices to make  $O(d \log d) = O(n \log n)$  measurements by Lemma 14. The sparse access oracle of  $M$  can be built in time  $O(sn)$ . Thus we obtain the following result.

**Corollary 15.** *With the same assumptions and notation as Theorem 13, then there is a quantum algorithm that returns all the eigenvalues of  $M$  up to precision  $\epsilon$  in time  $\tilde{O}(sn\rho^2\kappa(E)^2/\epsilon^2)$ .*

## 2.5 What if the matrices have complex eigenvalues

Algorithm 1 also works for diagonalizable matrices that only have purely imaginary eigenvalues. It suffices to change  $2\pi iM$  into  $2\pi M$  in the ODE (3). In the following, we consider the problem that what would happen if we apply Algorithm 1 directly to any diagonalizable matrix. We will show that Algorithm 1 has many difficulties in estimating the complex eigenvalues, even the real parts.

To do the analysis, we just focus on the special case that the initial state is  $|E_j\rangle$ . Denote the corresponding eigenvalue as  $\lambda_{j0} + i\lambda_{j1}$ , where  $\lambda_{j0}, \lambda_{j1} \in \mathbb{R}$ . Then similar to the analysis of obtaining (24), we will obtain an approximation of

$$|\mathbf{x}\rangle = \frac{1}{Z} \sum_{l=0}^m |l\rangle |\mathbf{x}(t_l)\rangle = \frac{1}{Z} \sum_{l=0}^m e^{2\pi i \lambda_j l \Delta t} |l\rangle |E_j\rangle, \quad (36)$$

where  $Z$  is the normalization constant. Since  $\lambda_j \in \mathbb{C}$ , usually  $Z \neq \sqrt{m+1}$ . If we set  $\lambda_{j1} \Delta t = -b$  for simplicity, then

$$Z^2 = \sum_{l=0}^m e^{4\pi b l} = \frac{1 - e^{4\pi b(m+1)}}{1 - e^{4\pi b}}.$$

To make sure the quantum differential equation solver works, one assumption made in [10] is that the real parts of the eigenvalues are non-positive. This assumption relates to the stability of the differential equation. Here we should make the same assumption, that is  $\lambda_{j1} > 0$  as we use  $2\pi iM$  in the differential equation (3). Thus  $b < 0$ . When concerning about computing eigenvalues, this assumption is easy to be satisfied. We just need to consider  $M - i\rho I$ . Also notice that  $\lambda_{j1} \Delta t = -b$ , so  $-1 \leq b < 0$ .

If we apply quantum Fourier inverse transform to the first register of  $|\mathbf{x}\rangle$ , then we obtain

$$\frac{1}{Z\sqrt{m+1}} \sum_{k=0}^m \sum_{l=0}^m e^{2\pi i l(\lambda_{j0}\Delta t - \frac{k}{m+1})} e^{2\pi i l b} |k\rangle |E_j\rangle. \quad (37)$$

Assume that  $q$  is the integer such that  $\lambda_{j0}\Delta t - \frac{q}{m+1} > 0$  is minimal. For convenience, we set  $a = \lambda_{j0}\Delta t - \frac{q}{m+1}$ , then  $a \leq 1/(m+1)$ . The probability of  $k = q + s \pmod{m+1}$  is

$$P_s = \frac{1}{Z^2(m+1)} \left| \sum_{l=0}^m e^{2\pi i l(a - \frac{s}{m+1})} e^{2\pi i l b} \right|^2 \quad (38)$$

$$= \frac{(1 - e^{4\pi b})}{(1 - e^{4\pi b(m+1)})(m+1)} \times \frac{(e^{2\pi b(m+1)} - 1)^2 + 4e^{2\pi b(m+1)} \sin^2(\pi(m+1)(a - \frac{s}{m+1}))}{(e^{2\pi b} - 1)^2 + 4e^{2\pi b} \sin^2(\pi(a - \frac{s}{m+1}))} \quad (39)$$

$$\leq \frac{(1 - e^{4\pi b})(e^{2\pi b(m+1)} + 1)^2}{4e^{2\pi b}(1 - e^{4\pi b(m+1)})(m+1) \sin^2(\pi(a - \frac{s}{m+1}))} \quad (40)$$

$$\leq \frac{e^{2\pi}}{16} \times \frac{(1 - e^{4\pi b})(m+1)}{(1 - e^{4\pi b(m+1)})} \times \frac{1}{(a(m+1) - s)^2}. \quad (41)$$

Next, we aim to bound the probability of obtaining an integer  $k$  such that  $|k - q| > r$ , where  $r$  is a positive integer characterizing the desired tolerance to error. For simplicity, we assume that  $m+1 = 2^t$ . This probability is

$$\Pr(|k - q| > r) = \left( \sum_{s=-2^{t-1}+1}^{-(s+1)} + \sum_{r+1}^{2^{t-1}} \right) P_s \quad (42)$$

$$\leq \frac{e^{2\pi}}{16} \times \frac{(1 - e^{4\pi b})(m+1)}{(1 - e^{4\pi b(m+1)})} \times \left( \sum_{s=-2^{t-1}+1}^{-(s+1)} + \sum_{s=r+1}^{2^{t-1}} \right) \frac{1}{(a(m+1) - s)^2} \quad (43)$$

$$\leq \frac{e^{2\pi}}{16} \times \frac{(1 - e^{4\pi b})(m+1)}{(1 - e^{4\pi b(m+1)})} \times \left( \sum_{s=-2^{t-1}+1}^{-(s+1)} \frac{1}{s^2} + \sum_{s=r+1}^{2^{t-1}} \frac{1}{(s-1)^2} \right) \quad (44)$$

$$\leq \frac{e^{2\pi}}{8} \times \frac{(1 - e^{4\pi b})(m+1)}{(1 - e^{4\pi b(m+1)})} \times \sum_{s=r}^{2^{t-1}-1} \frac{1}{s^2} \quad (45)$$

$$\leq \frac{e^{2\pi}}{8} \times \frac{(1 - e^{4\pi b})(m+1)}{(1 - e^{4\pi b(m+1)})} \times \int_{r-1}^{2^{t-1}-1} \frac{1}{s^2} ds \quad (46)$$

$$\leq \frac{e^{2\pi}}{8(r-1)} \times \frac{(1 - e^{4\pi b})(m+1)}{(1 - e^{4\pi b(m+1)})}. \quad (47)$$

Assume that  $b = -C/(m+1)$  for some  $C \in \{1, 2, \dots, m+1\}$ , then

$$\Pr(|k - q| > r) \leq \frac{e^{2\pi}}{8(r-1)} \times \frac{4\pi C}{1 - e^{-4\pi}} = \Theta(C/r). \quad (48)$$

Suppose we wish to approximate  $\lambda_{j0}\Delta t$  to an accuracy  $2^{-x}$ , that is, we choose  $r = 2^{t-x} - 1$ . By making  $t = x + y$ , the probability of obtaining an approximation correct to this accuracy is at least  $1 - C/2^y$ .

Since  $b = -\lambda_{j1}\Delta t$ , we have  $\Delta t = C/(m+1)\lambda_{j1}$ . Now let  $k$  be the integer such that  $k/(m+1)$  is an  $2^{-x}$ -approximation of  $\lambda_{j0}\Delta t$ . Then from  $m+1 = 2^{x+y}$  and

$$\left| \lambda_{j0}\Delta t - \frac{k}{m+1} \right| = \left| \lambda_{j0} \frac{C}{(m+1)\lambda_{j1}} - \frac{k}{m+1} \right| \leq \frac{1}{2^x},$$

we obtain

$$\left| \lambda_{j0} - \frac{k\lambda_{j1}}{C} \right| \leq \frac{2^y\lambda_{j1}}{C}. \quad (49)$$

This leads to a contradiction to the choices of  $C$ . We cannot find a  $C$  such that the success probability is high, meanwhile, the error is small. The above analysis shows that when the eigenvalues are complex, Algorithm 1 may not return a good approximation of the real parts of the eigenvalues.

**Remark 16.** To compute all the complex eigenvalues, it suffices to have a quantum algorithm to compute all the real parts. More precisely, let  $M$  be a diagonalizable matrix with complex eigenvalues  $\lambda_j + i\mu_j$ , where  $j = 1, \dots, n$ . The corresponding unit eigenvectors are  $|E_1\rangle, \dots, |E_n\rangle$ . Suppose that we have a quantum algorithm that can output  $\sum_{j=1}^n \beta_j |\lambda_j\rangle |E_j\rangle$  (up to a normalization) when the input is  $\sum_{j=1}^n \beta_j |E_j\rangle$ . Then we can apply this algorithm further to obtain  $\sum_{j=1}^n \beta_j |\lambda_j\rangle |\mu_j\rangle |E_j\rangle$ . This is obtained by considering  $iM$  and viewing  $\sum_{j=1}^n \beta_j |\lambda_j\rangle |E_j\rangle$  as the new initial state.

### 3 A quantum algorithm to estimate complex eigenvalues

Based on Remark 16, it suffices to propose a quantum algorithm that can estimate the real parts of the eigenvalues. The following is a simple idea but with an extra assumption to generalize Algorithm 1 to achieve this goal.

Suppose the complex eigenvalues of  $M$  are  $\lambda_1 + i\mu_1, \dots, \lambda_n + i\mu_n$ . The corresponding eigenvectors are  $|E_1\rangle, \dots, |E_n\rangle$ . Denote  $\overline{M}$  as the complex conjugate of  $M$ . Then  $\{(\lambda_j - i\mu_j, |\overline{E}_j\rangle) : j = 1, 2, \dots, n\}$  are the eigenpairs of  $\overline{M}$ . Here  $|\overline{E}_j\rangle$  is the complex conjugate of  $|E_j\rangle$ .

Consider the following differential equation:

$$\begin{cases} \frac{d\mathbf{x}}{dt} = \pi i(M \otimes I + I \otimes \overline{M})\mathbf{x}, \\ \mathbf{x}(0) = |E_j\rangle \otimes |\overline{E}_j\rangle. \end{cases} \quad (50)$$

It's obvious that the solution is

$$|\mathbf{x}(t)\rangle = e^{\pi i t(M \otimes I + I \otimes \overline{M})} |E_j\rangle \otimes |\overline{E}_j\rangle = e^{\pi i t M} |E_j\rangle \otimes e^{\pi i t \overline{M}} |\overline{E}_j\rangle = e^{2\pi i t \lambda_j} |E_j\rangle \otimes |\overline{E}_j\rangle. \quad (51)$$

Similar to the differential equation (3), if we use quantum algorithm to solve (50), then we obtain a superposition of the solutions (see equation (24)):

$$\frac{1}{\sqrt{m+1}} \sum_{l=0}^m |l\rangle |\mathbf{x}(t_l)\rangle = \frac{1}{\sqrt{m+1}} \sum_{l=0}^m e^{2\pi i l \lambda_j \Delta t} |l\rangle |E_j\rangle \otimes |\overline{E}_j\rangle. \quad (52)$$

If we apply quantum Fourier inverse transform to the first register of the superposition, then we obtain

$$\frac{1}{m+1} \sum_{k=0}^m \left( \sum_{l=0}^{m-1} e^{2\pi i l (\lambda_j \Delta t - \frac{k}{m+1})} \right) |k\rangle |E_j\rangle \otimes |\overline{E}_j\rangle \approx |\tilde{\lambda}_j \Delta t\rangle |E_j\rangle \otimes |\overline{E}_j\rangle. \quad (53)$$

In the general case, we can choose the initial vector of the differential equation (50) as

$$\mathbf{x}(0) = \sum_{j=1}^n \beta_j |E_j\rangle \otimes |\bar{E}_j\rangle. \quad (54)$$

Then the superposition of the solutions is proportional to

$$\sum_{l=0}^{m-1} \sum_{j=1}^n \beta_j e^{2\pi i l \lambda_j \Delta t} |l\rangle |E_j\rangle \otimes |\bar{E}_j\rangle. \quad (55)$$

Similarly, we can apply quantum Fourier inverse transform to the first register to estimate the real parts of the eigenvalues

$$\sum_{k=0}^{m-1} \sum_{j=1}^n \beta_j \left( \sum_{l=0}^{m-1} e^{2\pi i l (\lambda_j \Delta t - \frac{k}{m})} \right) |k\rangle |E_j\rangle \otimes |\bar{E}_j\rangle \approx \sum_{j=1}^n \beta_j |\tilde{\lambda}_j \Delta t\rangle |E_j\rangle \otimes |\bar{E}_j\rangle. \quad (56)$$

If we further view (56) as the initial state and implement the above procedure by changing  $\pi i(M \otimes I + I \otimes \bar{M})$  into  $\pi(M \otimes I - I \otimes \bar{M})$  in the differential equation (50). Then we can further obtain the state

$$\sum_{j=1}^n \beta_j |\tilde{\lambda}_j \Delta t\rangle |\tilde{\mu}_j \Delta t\rangle |E_j\rangle \otimes |\bar{E}_j\rangle \quad (57)$$

up to a normalization. With the above idea, the quantum algorithm to estimate complex eigenvalues can be stated as follows.

---

**Algorithm 2** Quantum algorithm for computing the eigenvalues of diagonalizable matrices

---

**Input:** (1). An  $n \times n$  diagonalizable matrix  $M$ . Suppose that the eigenvalues are  $\{\lambda_1 + i\mu_1, \dots, \lambda_n + i\mu_n\}$  and the unit eigenvectors are  $\{|E_1\rangle, \dots, |E_n\rangle\}$ .  
(2). A upper bound  $\rho \geq 1$  of the eigenvalues.  
(3). Quantum access to copies of the state  $|\phi\rangle$  of the form  $|\phi\rangle = \sum_{j=1}^n \beta_j |E_j\rangle |\bar{E}_j\rangle$ .  
(4). The precision  $\epsilon \in (0, 1)$ ,  $\Delta t = 1/\rho$ ,  $m = \lceil \rho/\epsilon \rceil$ ,  $k = 2\lceil \log(\rho/\epsilon) \rceil$ .

**Output:** The quantum state

$$\sum_{j=1}^n \beta_j |\tilde{\lambda}_j\rangle |\tilde{\mu}_j\rangle |E_j\rangle |\bar{E}_j\rangle \quad (58)$$

up to a normalization, where  $|\tilde{\lambda}_j - \lambda_j| \leq \epsilon$  and  $|\tilde{\mu}_j - \mu_j| \leq \epsilon$  for all  $j$ .

- 1: Construct matrices  $C_1 := C_{m,k}(\pi i \Delta t (M \otimes I + I \otimes \bar{M}))$  and  $C_2 := C_{m,k}(\pi \Delta t (M \otimes I - I \otimes \bar{M}))$  based on equation (12).
  - 2: Use quantum linear algebraic technique to construct  $|\phi_1\rangle = C_1^{-1} |0..0\rangle |\phi\rangle$ .
  - 3: Apply quantum Fourier inverse transform to the first register of  $|\phi_1\rangle$ . Then the result is proportional to  $\sum_j \beta_j |\tilde{\lambda}_j\rangle |E_j\rangle |\bar{E}_j\rangle |0\rangle + |0\rangle^\perp$ . Define  $|\phi_2\rangle = \sum_j \beta_j |\tilde{\lambda}_j\rangle |0..0\rangle |E_j\rangle |\bar{E}_j\rangle |0\rangle + |0\rangle^\perp$ .
  - 4: Use quantum linear algebraic technique to construct  $|\phi_3\rangle = I \otimes C_2^{-1} |\phi_2\rangle$ .
  - 5: Apply quantum Fourier inverse transform to the second register of  $|\phi_3\rangle$ .
  - 6: Measure the last register of  $|\phi_3\rangle$  and return the post-selected state if the output is  $|0\rangle$ .
- 

**Lemma 17.** Let  $P$  be an nonsingular matrix, then the condition number  $\kappa(P \otimes \bar{P}) = \kappa(P)^2$ .

*Proof.* Assume that the SVD of  $P$  is  $UDV$ , then the SVD of  $\bar{P}$  is  $\bar{U}D\bar{V}$ . Thus  $P, \bar{P}$  have the same singular values. If  $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_n > 0$  are the singular values of  $P$ , then the singular values of  $P \otimes \bar{P}$  are  $\sigma_i \sigma_j$ . Therefore

$$\kappa(P \otimes \bar{P}) = \frac{\max_{i,j} \sigma_i \sigma_j}{\min_{i,j} \sigma_i \sigma_j} = \frac{\sigma_1^2}{\sigma_n^2} = \kappa(P)^2$$

as claimed.  $\square$

Note that if  $M = PDP^{-1}$ , then  $M \otimes I \pm I \otimes \bar{M} = (P \otimes \bar{P})(D \times I \pm I \otimes \bar{D})(P \otimes \bar{P})^{-1}$ . So the matrix of the eigenvectors of  $M \otimes I \pm I \otimes \bar{M}$  is  $P \otimes \bar{P}$ . The cost of Algorithm 2 is mainly determined by the quantum linear algebraic technique to implement  $C_1^{-1}, C_2^{-1}$ . Similar to the proof of Theorem 9, we have

**Theorem 18.** *Let  $M$  be an  $n \times n$  diagonalizable matrix. Assume that its eigenvalues are  $\lambda_1 + i\mu_1, \dots, \lambda_n + i\mu_n$ , and the corresponding normalized eigenvectors are  $|E_1\rangle, \dots, |E_n\rangle$ . Let  $\rho \geq 1$  be an upper bound of the eigenvalues. Given access to copies of the state  $\sum_{j=1}^n \beta_j |E_j\rangle |\bar{E}_j\rangle$ , then Algorithm 2 returns*

$$\sum_{j=1}^n \beta_j |\tilde{\lambda}_j\rangle |\tilde{\mu}_j\rangle |E_j\rangle |\bar{E}_j\rangle \quad (59)$$

up to a normalization in time

$$O\left(T_0 \times T\left(\frac{\rho \kappa(E)^2 \log(\rho/\epsilon)}{\epsilon}, \frac{\epsilon}{\rho}, \frac{n\rho \log(\rho/\epsilon)}{\epsilon}\right) \times \frac{\rho^2 \kappa(E)^4}{\epsilon^2} \log \frac{\rho}{\epsilon}\right), \quad (60)$$

where  $T_0$  is the complexity to generate the initial state,  $\kappa(E)$  is the condition number of the matrix generated by the eigenvectors,  $|\lambda_j - \tilde{\lambda}_j| \leq \epsilon$  and  $|\mu_j - \tilde{\mu}_j| \leq \epsilon$  for all  $j$ . Especially, if  $M$  is  $s$  sparse, then the complexity is  $\tilde{O}(T_0 s \rho^3 \kappa(E)^6 (\log n) / \epsilon^3)$ .

*Proof.* The proof of this theorem is similar to that of Theorem 9. By equation (14), up to a normalization

$$\begin{aligned} C_1^{-1} |0..0\rangle |\mathbf{x}(0)\rangle &= \sum_{j=1}^n \beta_j C_1^{-1} |0..0\rangle |E_j\rangle |\bar{E}_j\rangle \\ &= \sum_{j=1}^n \beta_j \left( \sum_{p=0}^m |p(k+1)\rangle |\mathbf{x}_{p,0}\rangle + \sum_{p=0}^{m-1} \sum_{q=1}^k |p(k+1)+q\rangle |\mathbf{x}_{p,q}\rangle \right). \end{aligned}$$

Since  $k+1$  is invertible modulo  $m(k+1)+1$ , we can find  $(k+1)^{-1}$  and multiple it on the first register. As a result, we obtain

$$\sum_{j=1}^n \beta_j \left( \sum_{p=0}^m |p\rangle |\mathbf{x}_{p,0}\rangle |0\rangle + |0\rangle^\perp \right) \quad (61)$$

by adding a new ancilla qubit  $|0\rangle$  to separate the two summation terms.

By Proposition 6 and Lemma 7, the state (61) is close to the state

$$\sum_{j=1}^n \sum_{p=0}^m \beta_j e^{2\pi i \lambda_j p \Delta t} |p\rangle |E_j\rangle |\bar{E}_j\rangle |0\rangle + |0\rangle^\perp. \quad (62)$$

If we apply quantum Fourier inverse transform to  $|p\rangle$ , then we obtain

$$\sum_{j=1}^n \sum_{q=0}^m \sum_{p=0}^m \beta_j e^{2\pi i p(\lambda_j \Delta t - \frac{q}{m+1})} |q\rangle |E_j\rangle |\bar{E}_j\rangle |0\rangle + |0\rangle^\perp \approx \sum_{j=1}^n \beta_j |\tilde{\lambda}_j \Delta t\rangle |E_j\rangle |\bar{E}_j\rangle |0\rangle + |0\rangle^\perp \quad (63)$$

up to a normalization, where  $|\tilde{\lambda}_j - \lambda_j| \leq \epsilon$ .

To estimate the imaginary parts of the eigenvalues, we can consider the differential equation

$$\frac{d\mathbf{x}(t)}{dt} = \pi(M \otimes I - I \otimes \bar{M})\mathbf{x}(t) \quad (64)$$

with the initial state (63) in that  $e^{\pi t(M \otimes I - I \otimes \bar{M})} |E_j\rangle |\bar{E}_j\rangle = e^{2\pi i t \mu_j} |E_j\rangle |\bar{E}_j\rangle$ . To obtain the superposition of this differential equation, we apply the inverse of  $C_2 = C_{m,k}(\pi t(M \otimes I - I \otimes \bar{M}))$  to the state (63) to obtain

$$\sum_{j=1}^n \beta_j |\tilde{\lambda}_j \Delta t\rangle C_2^{-1} |0..0\rangle |E_j\rangle |\bar{E}_j\rangle |0\rangle + |0\rangle^\perp. \quad (65)$$

Similar to the analysis of the state (62), equation (65) is close to

$$\sum_{j=1}^n \sum_{p=0}^m \beta_j e^{2\pi i \mu_j p \Delta t} |\tilde{\lambda}_j \Delta t\rangle |p\rangle |E_j\rangle |\bar{E}_j\rangle |0\rangle + |0\rangle^\perp. \quad (66)$$

Apply quantum Fourier inverse transform to the second register, then we obtain

$$\sum_{j=1}^n \beta_j |\tilde{\lambda}_j \Delta t\rangle |\tilde{\mu}_j \Delta t\rangle |E_j\rangle |\bar{E}_j\rangle |0\rangle + |0\rangle^\perp, \quad (67)$$

where  $|\tilde{\mu}_j - \mu_j| \leq \epsilon$ .

Next, we estimate the success probability. So we need to compute the amplitude of  $|0\rangle$  in the state (67). By Lemma 3 of [10] and Lemma 17,  $\|C_1^{-1}\| \leq 3\kappa(E)^2 \sqrt{km}$ ,  $\|C_2^{-1}\| \leq 3\kappa^2 \sqrt{km}$ . As a result,  $\|C_1^{-1} |0..0\rangle |x(0)\rangle\| \leq \|C_1^{-1}\| \leq 3\kappa(E)^2 \sqrt{km}$ . Before normalization, the amplitude of  $|0\rangle$  in the state (63) equals

$$\sqrt{\sum_{p=0}^m \left\| \sum_{j=1}^n \beta_j e^{2\pi i \lambda_j p \Delta t} |E_j\rangle \right\|_2^2} \geq 1$$

in that when  $p = 0$ , we have  $\|\sum_{j=1}^n \beta_j |E_j\rangle\|_2^2 = \|\phi\|_2^2 = 1$ . Therefore, the amplitude of  $|0\rangle$  of the state (63) is larger than  $1/3\kappa(E)^2 \sqrt{km}$ . Similar analysis shows that the amplitude of  $|0\rangle$  of the state (67) is larger than  $1/9\kappa(E)^4 km^2$ .

If  $M$  is  $s$  sparse, then  $M \otimes I \pm I \otimes \bar{M}$  is at most  $2s$  sparse. By Lemma 12,  $C_1, C_2$  is  $O(s + \log \frac{1}{\epsilon})$  sparse. By [12, Theorem 5], the cost to solve an  $s$  sparse linear system with condition number  $\kappa$  in a quantum computer is  $\tilde{O}(s\kappa)$ . Thus, the claimed result comes from the cost of amplitude amplification and the choices of the parameters in the algorithm.  $\square$

## 4 Normal matrices

A square matrix is called normal if it commutes with its conjugate transpose. The condition of normality may be strong, but it includes the unitary, Hermitian, skew-Hermitian matrices and their

real counterparts as special cases. These matrices are of great interests to physicists [28]. In [18], Grone et al. listed 70 different equivalent conditions of normal matrices. 19 more were added later in [16]. One interesting result we will use in this paper is the fact that normal matrices can be diagonalized by unitary matrices. The list [16, 18] reflects the fact that normality arises in many ways.

In this section, we solve Problem 1 for normal matrices. A quantum algorithm based on quantum singular value decomposition and quantum phase estimation will be given.

#### 4.1 Main result

Assume that  $M$  is an  $n \times n$  normal matrix, then there is a diagonal matrix  $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_n)$  and a unitary matrix  $U$  such that  $M = U\Lambda U^\dagger$ . Thus  $\{\sigma_j := |\lambda_j| : j = 1, \dots, n\}$  are the singular values of  $M$ . Denote  $\lambda_j = \sigma_j e^{2\pi i \theta_j}$ , the problem we want to solve in this section is to estimate  $\sigma_j, \theta_j$  for all  $j$  up to certain precision in a quantum computer. To be more precise, assume that the  $j$ -th column of  $U$  is  $|u_j\rangle$ . Let  $|b\rangle$  be any given state. Since  $U$  is unitary, there exist  $\beta_1, \dots, \beta_n$  such that  $|b\rangle = \sum_{j=1}^n \beta_j |u_j\rangle$ . The main objective we want to obtain is to find a quantum algorithm to return

$$\sum_{j=1}^n \beta_j |u_j\rangle |\tilde{\sigma}_j\rangle |\tilde{\theta}_j\rangle, \quad (68)$$

where  $\tilde{\sigma}_j$  and  $\tilde{\theta}_j$  are respectively the approximations of  $\sigma_j$  and  $\theta_j$ .

To state our main result, we need the technique of quantum singular value estimation. Assume that the singular value decomposition (SVD) of  $M = \sum_{j=1}^n \sigma_j |u_j\rangle \langle v_j|$ . Denote

$$\widetilde{M} = \begin{pmatrix} 0 & M \\ M^\dagger & 0 \end{pmatrix}, \quad (69)$$

which is Hermitian. The eigenvalues of  $\widetilde{M}$  are  $\{\pm \sigma_j : j = 1, \dots, n\}$ . The corresponding eigenvectors are

$$|w_j^\pm\rangle := \frac{1}{\sqrt{2}}(|0\rangle |u_j\rangle \pm |1\rangle |v_j\rangle), \quad j = 1, \dots, n. \quad (70)$$

Based on quantum phase estimation, we can implement the following transformation

$$\sum_{j=1}^n \beta_j^+ |w_j^+\rangle + \beta_j^- |w_j^-\rangle \mapsto \sum_{j=1}^n \beta_j^+ |w_j^+\rangle |\tilde{\sigma}_j\rangle + \beta_j^- |w_j^-\rangle |-\tilde{\sigma}_j\rangle \quad (71)$$

in a quantum computer, where  $|\sigma_j - \tilde{\sigma}_j| \leq \epsilon$ . More details can be found in Appendix A. Usually, the complexity is poly-log at  $n$  and linear at  $1/\epsilon$ . In the following, we shall use  $O(T/\epsilon)$  to denote the complexity of implementing the transformation (71).

With the above preliminaries, our main result is stated as follows. We will prove it in the next subsection.

**Theorem 19.** *Let  $M$  be an  $n$ -by- $n$  normal matrix. Assume that its eigenvalue decomposition is  $\sum_{j=1}^n \sigma_j e^{2\pi i \theta_j} |u_j\rangle \langle u_j|$ . Suppose the complexity to implement (71) for  $M$  to precision  $\epsilon_1$  is  $O(T/\epsilon_1)$ , then there is a quantum algorithm that returns the state (68) in time  $O(T/\epsilon_1 \epsilon_2)$ , where  $|\sigma_j - \tilde{\sigma}_j| \leq \epsilon_1$ ,  $|\theta_j - \tilde{\theta}_j| \leq \epsilon_2$  for all  $j$ .*

Let  $M = (m_{ij})_{n \times n}$  be a matrix, we use  $\|M\|_{\max}$  to denote the quantity  $\max_{i,j} |m_{ij}|$ . As a direct application of Theorem 19 and Proposition 24 in Appendix A, we have the following result.

**Theorem 20.** Let  $M$  be an  $s$  sparse  $n \times n$  normal matrix, let  $\rho$  be an upper bound of its eigenvalues. Then there is a quantum algorithm that prepares the state (68) in time  $\tilde{O}(s\rho\|M\|_{\max}/\epsilon_1\epsilon_2)$ , where  $|\sigma_j - \tilde{\sigma}_j| \leq \epsilon_1$ ,  $|\theta_j - \tilde{\theta}_j| \leq \epsilon_2$  for all  $j$ .

If we perform measurements on the last two registers of (68), then we can obtain all the eigenvalues of  $M$ . For sparse matrices, we have the following result.

**Corollary 21.** Let  $M$  be an  $s$  sparse  $n \times n$  normal matrix with eigenvalues  $\sigma_j e^{i\theta_j}$ ,  $j = 1, \dots, n$ . Let  $\epsilon_1, \epsilon_2$  be the precisions to approximate  $\sigma_j, \theta_j$  respectively. Assume that  $\sigma_j \leq \rho$  for all  $j$ . Then there is a quantum algorithm that returns all the eigenvalues in time  $\tilde{O}(sn\rho\|M\|_{\max}/\epsilon_1\epsilon_2)$ .

*Proof.* We choose the initial state as maximally mixed state  $|\phi\rangle = \frac{1}{\sqrt{n}} \sum_{j=1}^n |j, j\rangle$ . Assume that the eigenvalue decomposition of  $M$  is  $\sum_{j=1}^n \sigma_j e^{2\pi i \theta_j} |u_j\rangle\langle u_j|$ . Then we have  $|\phi\rangle = \frac{1}{\sqrt{n}} \sum_{j=1}^n |u_j, \bar{u}_j\rangle$ . By Corollary 20, there is a quantum algorithm that returns  $\frac{1}{\sqrt{n}} \sum_{j=1}^n |u_j, \bar{u}_j\rangle |\tilde{\sigma}_j\rangle |\tilde{\theta}_j\rangle$  in time  $\tilde{O}(s\rho\|M\|_{\max}/\epsilon_1\epsilon_2)$ , where  $|\sigma_j - \tilde{\sigma}_j| \leq \epsilon_1$ ,  $|\theta_j - \tilde{\theta}_j| \leq \epsilon_2$ . By Lemma 14, to obtain all the eigenvalues, it suffices to make  $O(n \log n)$  measurements.  $\square$

## 4.2 Proof of Theorem 19

For any  $j$ , denote  $|v_j\rangle = e^{-2\pi i \theta_j} |u_j\rangle$ , then the SVD of  $M$  is  $\sum_{j=1}^n \sigma_j |u_j\rangle\langle v_j|$ . We can rewrite the initial state  $|0\rangle|b\rangle$  as  $|0\rangle|b\rangle = \sum_{j=1}^n \frac{\beta_j}{\sqrt{2}} (|w_j^+\rangle + |w_j^-\rangle)$ . The main technique is described in the following lemma.

**Claim 22.** With the same notation as Theorem 19, then there is a unitary operator  $W$  that performs

$$W : \sum_{j=1}^n \beta_j |0\rangle |u_j\rangle \mapsto \sum_{j=1}^n \beta_j e^{-2\pi i \theta_j} |0\rangle |u_j\rangle. \quad (72)$$

The operator  $W$  is implemented in time  $O(T/\epsilon_1)$ .

*Proof.* By viewing  $|0, b\rangle$  as the initial state, if we perform the transformation (71) to it, then we obtain  $\sum_{j=1}^n \frac{\beta_j}{\sqrt{2}} (|w_j^+\rangle |\tilde{\sigma}_j\rangle + |w_j^-\rangle |-\tilde{\sigma}_j\rangle)$ . Since  $-\tilde{\sigma}_j \leq 0$ , we can add a negative sign to the second term to change it into  $\sum_{j=1}^n \frac{\beta_j}{\sqrt{2}} (|w_j^+\rangle |\tilde{\sigma}_j\rangle - |w_j^-\rangle |-\tilde{\sigma}_j\rangle)$ . Based on analysis of QPE in Appendix A about the signs of eigenvalues, the operation here is feasible. Now we perform the inverse procedure of the transformation (71), then we obtain  $\sum_{j=1}^n \frac{\beta_j}{\sqrt{2}} (|w_j^+\rangle - |w_j^-\rangle) = \sum_{j=1}^n \beta_j |1\rangle |v_j\rangle$ . Finally, apply Pauli- $X$  to the first register to generate  $\sum_{j=1}^n \beta_j |0\rangle |v_j\rangle = \sum_{j=1}^n \beta_j e^{-2\pi i \theta_j} |0\rangle |u_j\rangle$ . The complexity is determined by the implementation of the transformation (71), which equals  $O(T/\epsilon_1)$ .  $\square$

The unitary  $W$  constructed above has eigenvectors  $|u_j\rangle$  and eigenvalues  $e^{-2\pi i \theta_j}$ , so by quantum phase estimation, we can approximate  $\theta_j$ . As for  $\sigma_j$ , we can apply quantum singular value estimation (71) to estimate them. Now we can state our quantum algorithm to prepare the state (68).

---

### Algorithm 3 Quantum eigenvalue estimation of normal matrices

---

- Input:** (1). An  $n \times n$  normal matrix  $M$  with (unknown) eigenvalues  $\{\sigma_1 e^{2\pi i \theta_1}, \dots, \sigma_n e^{2\pi i \theta_n}\}$  and (unknown) eigenvectors  $\{|u_1\rangle, \dots, |u_n\rangle\}$ .  
(2). A quantum state  $|b\rangle$  which formally equals  $\sum_{j=1}^n \beta_j |u_j\rangle$ .  
(3). The precisions  $\epsilon_1, \epsilon_2 \in (0, 1)$ .

**Output:** The quantum state

$$\sum_{j=1}^n \beta_j |u_j\rangle |\tilde{\sigma}_j\rangle |\tilde{\theta}_j\rangle, \quad (73)$$

where  $|\tilde{\sigma}_j - \sigma_j| \leq \epsilon_1$  and  $|\tilde{\theta}_j - \theta_j| \leq \epsilon_2$  for all  $j$ .

- 1: Apply Claim 22 to construct  $W$  defined by equation (72).
- 2: Apply QPE (see Algorithm 4 in Appendix A) to  $W$  with initial state  $|0\rangle|b\rangle$ .
- 3: Apply quantum SVD (see equation (71)) to estimate the singular values of  $M$ .

In the following, we show more analysis about the steps 2 and 3 of Algorithm 3.

**Claim 23.** *The state obtained in step 2 of Algorithm 3 is an approximation of*

$$\sum_{j=1}^n \beta_j |0\rangle |u_j\rangle |\tilde{\theta}_j\rangle. \quad (74)$$

*The complexity to obtain this state is  $O(T/\epsilon_1\epsilon_2)$ .*

*Proof.* This is a direct application of QPE. More precisely, to apply QPE, we first generate the state  $|0\rangle|b\rangle \otimes \frac{1}{\sqrt{m}} \sum_{k=0}^{m-1} |k\rangle = \frac{1}{\sqrt{m}} \sum_{j=1}^n \sum_{k=0}^{m-1} \beta_j |0\rangle |u_j\rangle |k\rangle$  by Hadamard transform, where  $m$  is determined by the precision  $\epsilon_2$ . Usually, it equals  $O(1/\epsilon_2)$ . Then view  $|k\rangle$  as a control qubit to apply  $W^k$  to  $|0\rangle|b\rangle$ , we obtain  $\frac{1}{\sqrt{m}} \sum_{j=1}^n \sum_{k=0}^{m-1} \beta_j e^{-2\pi i \theta_j k} |0\rangle |u_j\rangle |k\rangle$ . Finally, apply quantum Fourier transform to  $|k\rangle$  to generate  $\frac{1}{m} \sum_{j=1}^n \sum_{l=0}^{m-1} \beta_j (\sum_{k=0}^{m-1} e^{2\pi i k(\frac{l}{m} - \theta_j)}) |0\rangle |u_j\rangle |l\rangle$ . Similar to the analysis of QPE, the final state is an approximation of (74). The complexity comes from QPE, which equals  $O(T/\epsilon_1\epsilon_2)$ .  $\square$

In the state (74), we already obtain approximations of the phases. As for the singular values, we can apply the quantum singular value estimation technique, which is a simple application of the transformation (71). More precisely, apply (71) to the state (74), then we have  $\sum_{j=1}^n \frac{\beta_j}{\sqrt{2}} (|w_j^+\rangle |\tilde{\sigma}_j\rangle + |w_j^-\rangle |-\tilde{\sigma}_j\rangle) |\tilde{\theta}_j\rangle$ . Apply the oracle  $|x\rangle|0\rangle \mapsto |x\rangle||x\rangle$  to the second register to obtain  $\sum_{j=1}^n \frac{\beta_j}{\sqrt{2}} (|w_j^+\rangle |\tilde{\sigma}_j\rangle + |w_j^-\rangle |-\tilde{\sigma}_j\rangle) |\tilde{\sigma}_j\rangle |\tilde{\theta}_j\rangle$ . The implementation of this oracle is discussed in detail in Appendix A (see equation (84)). Finally, apply the inverse of (71) to yield the claimed state (73). The complexity is  $O(T/\epsilon_1)$ . Therefore, the total cost of Algorithm 3 is  $O(T/\epsilon_1\epsilon_2)$  as claimed.

## 5 Conclusions

For the problem of estimating eigenvalues, we proposed a quantum algorithm based on quantum phase estimation and quantum differential equation solver for diagonalizable matrices whose eigenvalues are real, and a quantum algorithm based on quantum phase estimation and quantum singular value estimation for normal matrices. The output is a state with the first register storing the eigenvalues, the second register storing the corresponding eigenvectors. We also generalized the first quantum algorithm to estimate all the complex eigenvalues of any diagonalizable matrix. The complexities of the quantum algorithms are dominated by certain quantum linear algebraic operations, which are usually exponentially faster than the corresponding classical operations.

This work provides a new attempt to solve the eigenvalue problem in the quantum computer. However, there are still many problems that need to be solved. For instance, the complexities of

our quantum algorithms on the condition number  $\kappa(E)$  and the precision  $\epsilon$  are not optimal. There should be a way to improve the dependence into linear. Our quantum algorithm for computing complex eigenvalues is far from optimal. Besides the complexity, it needs the initial state has the form (54). Currently, we do not know how to prepare this kind of initial state.

## A Quantum phase estimation: brief overview

Quantum phase estimation (QPE) [25] is a useful technique to design quantum algorithms. Many quantum algorithms are related to it, such as Shor's algorithm [32] and the HHL algorithm to solve linear systems [19]. QPE is an algorithm to estimate the eigenvalues of unitary matrices. As a simple generalization, it can be used to estimate the eigenvalues of Hermitian matrices [1] or the singular values of general matrices [19, 24]. In this paper, QPE is also an important technique we will apply to estimate the eigenvalues of more general matrices. Thus in the following, we briefly review the QPE to estimate the eigenvalues of Hermitian matrices, the error and complexity analyses can be found in [30, Section 5.2]. One aspect we want to emphasize is how to determine the signs of the eigenvalues.

### A.1 Apply QPE to estimate the eigenvalues of Hermitian matrices

Let  $H$  be an  $n \times n$  Hermitian matrices with eigenvalues  $\lambda_1, \dots, \lambda_n$  and eigenvectors  $|u_1\rangle, \dots, |u_n\rangle$ . Let  $|b\rangle$  be any given quantum state, which can formally be written as a linear combinations of the eigenvectors  $|b\rangle = \sum_{k=1}^n \beta_k |u_k\rangle$ . Suppose we know an upper bound of the eigenvalues, then choose an upper bound  $C > 0$  such that  $|\lambda_j/C| < 1/2$ . Let  $\epsilon$  be the precision to approximate the eigenvalues and  $\delta$  be the failure probability of the quantum algorithm, denote  $q = \lceil \log 1/\epsilon \rceil + \lceil \log(2 + 1/2\delta) \rceil$  and  $Q = 2^q = O(1/\epsilon\delta)$ , then QPE can be stated as follows:

---

#### Algorithm 4 Quantum phase estimation (QPE)

---

**Input:** (1). An  $n \times n$  Hermitian matrix  $H$  with (unknown) eigenvalues  $\{\lambda_1, \dots, \lambda_n\}$  and (unknown) eigenvectors  $\{|u_1\rangle, \dots, |u_n\rangle\}$ .  
(2). A quantum state  $|b\rangle$  which formally equals  $\sum_{k=1}^n \beta_k |u_k\rangle$ .  
(3). The precision  $\epsilon$  and failure probability  $\delta$ .

**Output:** The quantum state

$$\sum_{k=1}^n \beta_k |\tilde{\lambda}_k\rangle |u_k\rangle, \quad (75)$$

where  $|\tilde{\lambda}_k - \lambda_k| \leq \epsilon$  for all  $k$ .

1: Set the initial state as

$$|\psi_0\rangle = \frac{1}{\sqrt{Q}} \sum_{j=0}^{Q-1} |j\rangle |b\rangle. \quad (76)$$

2: Apply control operator  $\sum_{j=0}^{Q-1} |j\rangle\langle j| \otimes e^{2\pi i j H/C}$  to  $|\psi_0\rangle$  to prepare

$$|\psi_1\rangle = \frac{1}{\sqrt{Q}} \sum_{j=0}^{Q-1} \sum_{k=1}^n \beta_k e^{2\pi i j \lambda_k / C} |j\rangle |u_k\rangle. \quad (77)$$

3: Apply quantum inverse Fourier transform to the first register of  $|\psi_1\rangle$

$$|\psi_2\rangle = \frac{1}{Q} \sum_{l=0}^{Q-1} \sum_{k=1}^n \beta_k \sum_{j=0}^{Q-1} e^{2\pi i j (\frac{\lambda_k}{C} - \frac{l}{Q})} |l\rangle |u_k\rangle. \quad (78)$$

Denote

$$\Lambda_k = \begin{cases} \{l \in \{0, 1, \dots, Q-1\} : |\frac{\lambda_k}{C} - \frac{l}{Q}| \leq \epsilon\}, & \text{if } \lambda_k \geq 0, \\ \{l \in \{0, 1, \dots, Q-1\} : |1 + \frac{\lambda_k}{C} - \frac{l}{Q}| \leq \epsilon\}, & \text{if } \lambda_k < 0. \end{cases} \quad (79)$$

$$|\Lambda_k\rangle = \frac{1}{Q} \sum_{l \in \Lambda_k} \sum_{j=0}^{Q-1} e^{2\pi i j (\frac{\lambda_k}{C} - \frac{l}{Q})} |l\rangle. \quad (80)$$

In theory, we do not know  $\Lambda_k$ . The notation introduced here is to simplify the expression of  $|\psi_2\rangle$ . Then we can rewrite  $|\psi_2\rangle$  as

$$|\psi_2\rangle = \sum_{k=1}^n \beta_k |\Lambda_k\rangle |u_k\rangle + \text{others}. \quad (81)$$

It is shown that the amplitude of the first term is larger than  $\sqrt{1-\delta}$ . Thus, if we choose  $\delta$  small enough (e.g. 0.01 or  $1/\text{poly log } n$ ), then we can approximately write  $|\psi_2\rangle$  as

$$|\psi_2\rangle \approx \sum_{k=1}^n \beta_k |\Lambda_k\rangle |u_k\rangle. \quad (82)$$

Any integer  $l$  in  $\Lambda_k$  provides an  $\epsilon$ -approximation  $l/Q$  of  $\lambda_k/C$  or  $1 + \lambda_k/C$ .

One problem we need pay attention to the above procedure is the signs of the eigenvalues. In  $|\psi_1\rangle$ , if  $\lambda_k \geq 0$ , then the coefficient of  $|j\rangle |u_k\rangle$  is  $\beta_k e^{2\pi i j \lambda_k / C}$ . However, if  $\lambda_k < 0$ , then the coefficient becomes  $\beta_k e^{2\pi i j (1 + \lambda_k / C)}$  as we need to make sure the phase lies between 0 and  $2\pi$ . As a result, in QPE we actually obtain approximations of  $\lambda_k/C$  if  $\lambda_k \geq 0$  and of  $1 + \lambda_k/C$  if  $\lambda_k < 0$ . Note that  $C$  is chosen such that  $|\lambda_k/C| < 1/2$ , thus in the former case, if  $l/Q$  is an approximation of  $\lambda_k/C$ , then  $l \leq Q/2$ . In the latter case, if  $l/Q$  is an approximation of  $1 + \lambda_k/C$ , then  $(Q-l)/Q$  is an approximation of  $-\lambda_k/C$ . Hence  $l > Q/2$ . In conclusion, if integers in  $\Lambda_k$  are smaller than or equal to  $Q/2$ , then we know  $\lambda_k \geq 0$ , otherwise  $\lambda_k < 0$ . Therefore, based on the integers in  $\Lambda_k$ , we can determine the signs of the eigenvalues.

The complexity of QPE is dominated by the second step. If the complexity to implement the unitary  $e^{iHt'}$  to precision  $\epsilon'$  in the quantum circuit is  $T(t', \epsilon', n)$ , then the complexity of QPE to compute  $\epsilon$ -approximations of eigenvalues of Hermitian matrices is  $T(C/\epsilon\delta, \epsilon', n)$ . For example, for an  $s$  sparse  $n \times n$  Hermitian matrix  $H = (h_{ij})$ , it is shown in [26] that  $T(t', \epsilon', n) = O((st' \|H\|_{\max} + \frac{\log 1/\epsilon'}{\log \log 1/\epsilon'}) \log n)$ , which is optimal at the parameters  $t'$  and  $\epsilon'$ . Here  $\|H\|_{\max} = \max_{i,j} |h_{ij}|$ . In this case, the complexity of QPE is  $O(sC \|H\|_{\max} (\log n) / \epsilon\delta)$  if we set  $\epsilon' = \epsilon$ .

In the following of this paper, we will simply write equation (82) as

$$\sum_{k=1}^n \beta_k |\tilde{\lambda}_k\rangle |u_k\rangle. \quad (83)$$

Although this state is not rigorous especially when  $\lambda_k < 0$ , it clearly describes the result of QPE. It can be viewed as the quantum eigenvalue decomposition of Hermitian matrices. Moreover, for simplicity we will ignore  $\delta$  in the complexity analysis by setting it as a small constant.

At the end of this part, we give a method to implement the following transformation

$$\sum_{k=1}^n \beta_k |\tilde{\lambda}_k\rangle |u_k\rangle |0\rangle \mapsto \sum_{k=1}^n \beta_k |\tilde{\lambda}_k\rangle |u_k\rangle |\tilde{\lambda}_k\rangle, \quad (84)$$

which will be useful in Section 4. Define the function  $f : \mathbb{Z}_Q \rightarrow \mathbb{Z}_Q$  by

$$f(l) = \begin{cases} l & \text{if } l \leq Q/2, \\ Q - l & \text{if } l > Q/2. \end{cases} \quad (85)$$

It defines an oracle  $U_f : |x, y\rangle \mapsto |x, y \oplus f(x)\rangle$ . Based on this oracle, we can implement (84) via

$$\sum_{k=1}^n \beta_k \sum_{l \in \Lambda_k} \Lambda_{kl} |l\rangle |u_k\rangle |0\rangle \mapsto \sum_{k=1}^n \beta_k \sum_{l \in \Lambda_k} \Lambda_{kl} |l\rangle |u_k\rangle |f(l)\rangle. \quad (86)$$

The equivalence comes naturally from the above analysis about the signs of eigenvalues. If  $\lambda_k \geq 0$ , then  $|\lambda_k| = \lambda_k$  and  $l \leq Q/2$  for all  $l \in \Lambda_k$ . Thus  $f(l) = l$ . If  $\lambda_k < 0$ , then  $|\lambda_k| = -\lambda_k$  and  $l > Q/2$  for all  $l \in \Lambda_k$ . Moreover,  $(Q - l)/Q$  are approximations of  $\lambda_k/C$  for all  $l \in \Lambda_k$ , thus  $f(l) = Q - l$ .

## A.2 Apply QPE to estimate the singular values of matrices

For any matrix  $M = (m_{ij})_{m \times n}$ , in a quantum computer we can compute its singular value decomposition (SVD). More precisely, assume that its SVD is  $M = \sum_{j=1}^d \sigma_j |u_j\rangle \langle v_j|$ , where  $d = \min\{m, n\}$ . Denote

$$\widetilde{M} = \begin{pmatrix} 0 & M \\ M^\dagger & 0 \end{pmatrix}, \quad (87)$$

which is Hermitian. The eigenvalues of  $\widetilde{M}$  are  $\{\pm \sigma_j : j = 1, \dots, d\}$ . The corresponding eigenvectors are

$$|w_j^\pm\rangle := \frac{1}{\sqrt{2}}(|0\rangle |u_j\rangle \pm |1\rangle |v_j\rangle), \quad j = 1, \dots, d. \quad (88)$$

Based on QPE, we can implement the following transformation (see equation (83))

$$\sum_{j=1}^d \beta_j^+ |w_j^+\rangle + \beta_j^- |w_j^-\rangle \mapsto \sum_{j=1}^d \beta_j^+ |w_j^+\rangle |\tilde{\sigma}_j\rangle + \beta_j^- |w_j^-\rangle |-\tilde{\sigma}_j\rangle \quad (89)$$

in a quantum computer [11], where  $|\sigma_j - \tilde{\sigma}_j| \leq \epsilon$ . Based on the analysis about QPE, the minus sign in equation (89) is reasonable.

If  $M$  is  $s$  sparse, then we can implement (89) in cost  $O(sC\|M\|_{\max}(\log(m+n))/\epsilon)$ . Finally, we conclude the above analysis into the following proposition.

**Proposition 24.** *Let  $M$  be an  $m \times n$  matrix. Let  $C$  be an upper bound of its singular values. If  $M$  is  $s$  sparse, then we can implement (89) in time  $O(\epsilon^{-1}sC\|M\|_{\max} \log(m+n))$ .*

## B Verification of equations (15)-(18)

Recall from (12), (14) that

$$\begin{aligned}
C_{m,k}(2\pi i M \Delta t) &= \sum_{p=0}^{m(k+1)} |p\rangle\langle p| \otimes I - \sum_{p=0}^{m-1} \sum_{q=1}^k |p(k+1)+q\rangle\langle p(k+1)+q-1| \otimes \frac{2\pi i M \Delta t}{q} \\
&\quad - \sum_{p=0}^{m-1} \sum_{q=0}^k |(p+1)(k+1)\rangle\langle p(k+1)+q| \otimes I, \\
\tilde{\mathbf{x}} &= \sum_{p=0}^{m-1} \sum_{q=0}^k |p(k+1)+q\rangle |\mathbf{x}_{p,q}\rangle + |m(k+1)\rangle |\mathbf{x}_{m,0}\rangle.
\end{aligned}$$

Then

$$C_{m,k}(2\pi i M \Delta t) |m(k+1)\rangle |\mathbf{x}_{m,0}\rangle = |m(k+1)\rangle |\mathbf{x}_{m,0}\rangle.$$

Moreover,

$$\begin{aligned}
&C_{m,k}(2\pi i M \Delta t) \sum_{p=0}^{m-1} \sum_{q=0}^k |p(k+1)+q\rangle |\mathbf{x}_{p,q}\rangle \\
&= \sum_{p=0}^{m-1} \sum_{q=0}^k |p(k+1)+q\rangle |\mathbf{x}_{p,q}\rangle - \sum_{p=0}^{m-1} \sum_{q=1}^k |p(k+1)+q\rangle \otimes \frac{2\pi i M \Delta t}{q} |\mathbf{x}_{p,q-1}\rangle \\
&\quad - \sum_{p=0}^{m-1} |(p+1)(k+1)\rangle \sum_{q=0}^k |\mathbf{x}_{p,q}\rangle \\
&= |0\rangle |\mathbf{x}_{0,0}\rangle - |m(k+1)\rangle \sum_{q=0}^k |\mathbf{x}_{p,q}\rangle + \sum_{p=1}^{m-1} |p(k+1)\rangle \left( |\mathbf{x}_{p,0}\rangle - \sum_{q=0}^k |\mathbf{x}_{p-1,q}\rangle \right) \\
&\quad + \sum_{p=0}^{m-1} \sum_{q=1}^k |p(k+1)+q\rangle \left( |\mathbf{x}_{p,q}\rangle - \frac{2\pi i M \Delta t}{q} |\mathbf{x}_{p,q-1}\rangle \right).
\end{aligned}$$

Consequently,  $|\mathbf{x}_{0,0}\rangle = |E_j\rangle$ . If  $0 \leq p \leq m-1$  and  $1 \leq q \leq k$ , then

$$|\mathbf{x}_{p,q}\rangle = \frac{2\pi i M \Delta t}{q} |\mathbf{x}_{p,q-1}\rangle = \frac{(2\pi i M \Delta t)^q}{q!} |\mathbf{x}_{p,0}\rangle.$$

If  $0 \leq p \leq m$  and  $q = 0$ , then

$$|\mathbf{x}_{p,0}\rangle = \sum_{q=0}^k |\mathbf{x}_{p-1,q}\rangle = \sum_{q=0}^k \frac{(2\pi i M \Delta t)^q}{q!} |\mathbf{x}_{p-1,0}\rangle = T_k(2\pi i M \Delta t) |\mathbf{x}_{p-1,0}\rangle.$$

## C Proof of Lemma 14

First we consider the special case of uniform distribution. Denote  $|\phi\rangle = \frac{1}{\sqrt{n}} \sum_{j=1}^n |j\rangle$ . This corresponds to a uniform distribution, and  $|j\rangle$  can be viewed as the  $j$ -th event. Consider  $|\phi\rangle^{\otimes m}$ . Perform

measurements on the basis states, then the probability to obtain all the basis states  $|j_1, \dots, j_m\rangle$  such that  $\{j_1, \dots, j_m\} = \{1, \dots, n\}$  is

$$P := \frac{1}{n^m} \sum_{\substack{i_1 + \dots + i_n = m \\ i_1, \dots, i_n \geq 1}} \binom{m}{i_1, \dots, i_n},$$

where

$$\binom{m}{i_1, \dots, i_n} := \frac{m!}{i_1! \dots i_n!}$$

is multinomial coefficient.

Let  $x_1, \dots, x_n$  be  $n$  variables, then

$$(x_1 + \dots + x_n)^m = \sum_{i_1 + \dots + i_n = m} \binom{m}{i_1, \dots, i_n} x_1^{i_1} \dots x_n^{i_n}.$$

Especially when  $x_1 = \dots = x_n = 1$ , we have

$$n^m = \sum_{i_1 + \dots + i_n = m} \binom{m}{i_1, \dots, i_n}.$$

Note that  $Pn^m$  refers to the number of monomials in  $(x_1 + \dots + x_n)^m$  such that all  $x_i$  appear. Thus,

$$\sum_{\substack{i_1 + \dots + i_n = m \\ i_1, \dots, i_n \geq 1}} \binom{m}{i_1, \dots, i_n} \geq n^m - n(n-1)^m.$$

The right hand side of the above inequality means that we set  $x_i = 0$  and the remaining variables as 1 in  $(x_1 + \dots + x_n)^m$ . There are  $n$  possibilities. However, it may happen that different cases have common terms. Thus

$$P \geq \frac{n^m - n(n-1)^m}{n^m} = 1 - n(1 - \frac{1}{n})^m \approx 1 - ne^{-m/n}.$$

Choose  $m$  such that  $ne^{-m/n} = \delta$  is small (say 0.01), that is  $m = n \log(n/\delta)$ , then  $P \geq 1 - \delta$ . The above analyses show that in a uniform distribution, to make sure every event happen, it suffices to make  $m = O(n \log n)$  experiments.

In the general case, assume that  $|\phi\rangle = \sum_{j=1}^n \sqrt{p_j} |j\rangle$ , where  $p_1 + \dots + p_n = 1$ . Also consider  $|\phi\rangle^{\otimes m}$ , then

$$P = \sum_{\substack{i_1 + \dots + i_n = m \\ i_1, \dots, i_n \geq 1}} \binom{m}{i_1, \dots, i_n} p_1^{i_1} \dots p_n^{i_n}.$$

Denote  $p_{\max} = \max\{p_1, \dots, p_n\}$ . We assume that  $p_{\max} \neq 1$ , otherwise the distribution is trivial. Then similar analysis shows that

$$P \geq 1 - \sum_{j=1}^n (1 - p_j)^m \geq 1 - n(1 - p_{\max})^m \approx 1 - ne^{-mp_{\max}}.$$

Thus it suffices to choose  $m = p_{\max}^{-1} \log(n/\delta)$ . Since  $\sum_j p_j = 1$ , we have  $p_{\max} \geq 1/n$ . Consequently,  $m \leq n \log(n/\delta)$ .
