Deep Transfer Learning Based Downlink Channel Prediction for FDD Massive MIMO Systems

Yuwen Yang, Feifei Gao, Zhimeng Zhong, Bo Ai and Ahmed Alkhateeb

Abstract—Artificial intelligence (AI) based downlink channel state information (CSI) prediction for frequency division duplexing (FDD) massive multiple-input multiple-output (MIMO) systems has attracted growing attention recently. However, existing works focus on the downlink CSI prediction for the users under a given environment and is hard to adapt to users in new environment especially when labeled data is limited. To address this issue, we formulate the downlink channel prediction as a deep transfer learning (DTL) problem, where each learning task aims to predict the downlink CSI from the uplink CSI for one single environment. Specifically, we develop the direct-transfer algorithm based on the fully-connected neural network architecture, where the network is trained on the data from all previous environments in the manner of classical deep learning and is then fine-tuned for new environments. To further improve the transfer efficiency, we propose the meta-learning algorithm that trains the network by alternating inner-task and across-task updates and then adapts to a new environment with a small number of labeled data. Simulation results show that the direct-transfer algorithm achieves better performance than the deep learning algorithm, which implies that the transfer learning benefits the downlink channel prediction in new environments. Moreover, the meta-learning algorithm significantly outperforms the direct-transfer algorithm in terms of both prediction accuracy and stability, which validates its effectiveness and superiority.

Index Terms—Deep transfer learning (DTL), meta-learning, few-sample learning, downlink CSI prediction, FDD, massive MIMO

I. INTRODUCTION

The acquisition of downlink channel state information (CSI) is a very challenging task for frequency division duplexing (FDD) massive multiple-input multiple-output (MIMO) systems due to the prohibitively high overheads associated with downlink training and uplink feedback [1]–[3]. By exploiting the angular and delay reciprocities between the uplink and the downlink [4]–[6], conventional methods proposed to reduce the downlink training overhead by extracting frequency-independent information from the uplink CSI, or to reduce the uplink feedback overhead by using compressive sensing based algorithms [7]–[10]. Nevertheless, the conventional methods either assume that the propagation paths are distinguishable and limited or highly rely on the sparsity of channels.

Recently, artificial intelligence (AI, including machine learning and deep learning, etc.) has been recognized as a potential solution to deal with the high complexity and overheads of wireless communication system [11]–[28]. Great success has been achieved in various applications such as channel estimation [13], [14], data detection [15], [16], CSI feedback [17]–[19], beamforming [20]–[22], and hybrid precoding [23], etc. Furthermore, AI based downlink CSI prediction for FDD systems has also been studied in many works [24]–[28]. In [25], a convolutional neural network is proposed to predict the downlink CSI from the uplink CSI for single-antenna FDD systems. Based on the CSI correlations between different base station (BS) antennas, linear and supper vector based regression methods have been proposed to use the downlink CSI of partial BS antennas to predict the whole downlink CSI, which can reduce the overheads of both downlink pilots and uplink feedback [26]. In fact, [27] develops the channel mapping in space and frequent concept which proves that deep neural networks (DNNs) can learn not only the correlation between closely-located BS antennas but also between the base station arrays that are positioned at different locations or different frequency bands in the same environment. By exploiting the mapping relation between the uplink and downlink CSI in FDD massive MIMO systems, an efficient complex-valued based DNN is trained to predict the downlink CSI only from the uplink CSI, i.e., no downlink pilot is needed at all [28].

Compared with conventional methods (e.g. [7], [8]), AI aided downlink CSI prediction benefits from the excellent learning capability of DNNs and does not require accurate channel models or high computational operations. However, existing AI aided downlink CSI prediction methods [25]–[28] all focus on training models for users in a certain environment. Since users may experience different wireless transmission environments, data collection and training the models from scratch are required for the users in new environments [25]–[28]. Typically thousands of samples and training epochs are required for training one DNN, and thus training a new DNN for each user would face unacceptable time and data cost. Therefore, it is highly desirable to design a method that can adapt to new environments with a small amount of data.

Inspired by human’s capability to transfer knowledge from previous experience, transfer learning, which aims to improve the performance of target tasks by exploiting the knowledge from source tasks, becomes a promising technology in machine learning area to solve similar tasks with limited labeled data. Studies on transfer learning date back from 1995 in
different names, such as incremental/cumulative learning, lifelong learning, multi-task learning, and learning to learn, etc \cite{29}. Generally, transfer learning algorithms acquire knowledge from source tasks by pre-training a model on a large-scale source dataset and then fine-tune the pre-trained model on a small-scale target dataset.\footnote{In unsupervised learning, labeled data in target tasks are not required. Unsupervised learning algorithms require strong assumptions of data distributions and are hard to be generalized to different problems, and therefore will not be discussed here.} With the rapid development of deep learning, the concept of deep transfer learning (DTL) is proposed by combining transfer learning with deep learning \cite{31}. The methodology in transfer learning can be easily generalized to DTL, including instance-transfer, feature-representation-transfer, and parameter-transfer, etc \cite{29}. In particular, the model-agnostic meta-learning algorithm proposed in \cite{32}, a typical parameter-transfer learning algorithm, is known for its universal applicability and the state-of-the-art performance. Unlike prior meta-learning algorithms \cite{33–35} that learn an update function and impose restrictions on the model architecture, the model-agnostic meta-learning algorithm learns a model initialization that can effectively adapt to a new task with a small amount of labeled data.

In this paper, we formulate the downlink channel prediction for FDD massive MIMO systems as a DTL problem, where each learning task aims to predict the downlink CSI from the uplink CSI for users in a certain environment. Based on the fully-connected neural network (FNN) architecture, we develop the direct-transfer algorithm, where the network is trained on the data from all previous environments in the manner of classical deep learning and is then fine-tuned with limited data from a new environment. To achieve more effective transfer, we further proposed the meta-learning algorithm that learns a model initialization by an alternating training procedure, consisting of the inner-task and the across-task updates. In the inner-task updates, the meta-learning algorithm learns task-specific parameters by performing gradient descents on task-specific loss functions. In the across-task updates, the meta-learning algorithm update the network parameters by optimizing the loss function associated with multiple tasks. The proposed meta-learning algorithm can adapt to any new environment with a few number of labeled data. We also propose the no-transfer algorithm as a baseline algorithm, where the network is trained in the manner of classical deep learning and is directly tested on the data from a new environment without parameter adaption. Simulation results show that the direct-transfer algorithm outperforms the no-transfer algorithm, which validates that transfer learning can effectively improve the performance of downlink channel prediction in new environments. Moreover, the meta-learning algorithm significantly outperforms the direct-transfer algorithm, which demonstrates its superiority over the direct-transfer algorithm.

The remainder of this paper is organized as follows. The system model for FDD massive MIMO systems is introduced in Section \textbf{II}. The DTL problem is formulated in Section \textbf{III}. The no-transfer and direct-transfer algorithms are presented in Section \textbf{IV}. The meta-learning algorithm is developed in Section \textbf{V}. Numerical results are given in Section \textbf{VI}. Our main conclusions are given in Section \textbf{VII}.

\textbf{Notations:} The bold and lowercase letters denote vectors while the bold and capital letters denote matrices. The notations $[\pi]_p$ and $\len(z)$ denote the $p$-th entry and the length of the vector $\pi$, respectively. The notations $\Re[\cdot]$ and $\Im[\cdot]$, respectively, denote the real and imaginary parts of matrices, vectors or scales. The notation $||\pi||_1$ denotes the $L_1$ norm of $\pi$. The notation $(\cdot)^T$ denotes the transpose of a matrix or a vector. The notation $\mathbb{R}^{2M}$ represents the $2M$-dimensional real vector space. The notation $\circ$ represents the composite mapping operation. The notation $\mathcal{N}_C(\mathbf{0}, J)$ represents the standard complex Gaussian distribution. The notation $\mathcal{E}[\cdot]$ represents the expectation with respect to all random variables within the brackets. The notation $\leftarrow$ represents the assignment operation while the notation $\rightarrow$ represents the direction of the trajectory.

\section{System Model}

We consider an FDD massive MIMO system, where BS is equipped with $M \gg 1$ antennas in the form of uniform linear array (ULA)\footnote{We adopt the ULA model here for simpler illustration, nevertheless, the proposed approach does not restrict to the specific array shape, and therefore is applicable for array with arbitrary geometry.} and serves multiple single-antenna users, as shown in Fig. 1. The users are randomly distributed in $K$ regions and users in the same region share the same propagation environment. Denote $\mathbb{B}_k$ as the set of users in the $k$-th region. Then, the channel between the $u$-th ($u \in \mathbb{B}_k$) user and BS can be expressed as \cite{8}:

$$
\mathbf{h}_u(f) = \int_{\theta \in \mathcal{A}_k} \alpha_u(\theta) \mathbf{a}(\theta) \, d\theta
= \int_{\theta_k^+}^{\theta_k^-} |\alpha_u(\theta)| e^{-j2\pi f \tau_u(\theta) + j\phi_u(\theta)} \, d\theta,
$$

where $f$ is the carrier frequency of the $u$-th user, while $|\alpha_u(\theta)|$, $\phi_u(\theta)$ and $\tau_u(\theta)$ are the attenuation amplitude, the phase shift and the delay of the incident signal ray coming from direction of arrival (DOA) $\theta$, respectively.
Although the mapping function described by known mathematical tools, it can be approximated downlink frequencies of the $u$th region with $\bar{\theta}_k$ being the corresponding lower and upper bounds of AS. The incident AS is assumed to be limited in a narrow region due to the limited local scattering effects at the BS side \[49\text{--}604\]. Moreover, $a(\theta)$ is the the array manifold vector defined as
\[
a(\theta) = \left[1, e^{-j\pi \sin \theta}, \ldots, e^{-j\pi(M-1)\sin \theta}\right]^T,
\]
where $\bar{\omega} = 2\pi df/c$, $d$ is the antenna spacing, and $c$ represents the speed of light.

III. FORMULATION OF DTL PROBLEM

In this section, we first prove the feasibility of applying deep learning to predict the downlink CSI from uplink CSI for a single user. Then, we formulate the downlink channel prediction as a DTL problem and analyze the related transfer learning algorithms.

A. Deep Learning for Uplink-to-Downlink Mapping

Since the downlink and the uplink of a certain user share common physical paths and similar spatial propagation characteristics, there exists a deterministic mapping between the downlink and the uplink channels when the position-to-channel mapping is bijective (see more details referring to \[49\text{--}604\]). Denote $f_{u,u}$ and $f_{d,u}$ as the uplink and the downlink frequencies of the $u$th user, respectively. Then, the uplink-to-downlink mapping function can be written as
\[
\Psi_{f_{u,u} \rightarrow f_{d,u}} : \{h_u(f_{u,u})\} \rightarrow \{h_u(f_{d,u})\}.
\]
Although the mapping function $\Psi_{f_{u,u} \rightarrow f_{d,u}}$ cannot be described by known mathematical tools, it can be approximated by deep neural networks as shown in the following.

Let us consider the simplest three-layers FNN with only one input layer, one hidden layer with $N$ neurons, and one output layer. Denote $x$ and $\Omega$ as the input data and the network parameter of FNN, respectively. Then the corresponding output can be expressed as $\text{NET}_N(x, \Omega)$. Since deep learning algorithms work in real domain, we introduce the isomorphism between the complex and real domains as
\[
\xi : z \rightarrow (\Re(z)^T, \Im(z)^T)^T.
\]
Denote the inverse mapping of $\xi$ as $\xi^{-1}$ that can be given as
\[
\xi^{-1} : (\Re(z)^T, \Im(z)^T)^T \rightarrow z.
\]
Based on the universal approximation theorem \[37\], we obtain the following theorem:

**Theorem 1:** For any given error $\varepsilon > 0$, there exists a positive constant $N$ large enough such that
\[
\sup_{x \in \mathbb{H}} |\text{NET}_N(x, \Omega) - \Psi_{\xi, u, U \rightarrow D}(x)| \leq \varepsilon,
\]
with $\Psi_{\xi, u, U \rightarrow D}(x) = \xi \circ \Psi_{f_{u,u} \rightarrow f_{d,u}} \circ \xi^{-1}(x)$.

**Proof.** (i) Since $\forall x \in \mathbb{H}$, $|x| = |h_u(f_{u,u})| \leq \sqrt{M} \bar{\theta}_u |\alpha_u(\theta)|$, we know $x$ is bounded. Therefore, $\mathbb{H}$ is a compact set; (ii) Since $\Psi_{f_{u,u} \rightarrow f_{d,u}}$ and $\xi$ are continuous mapping and composition of continuous mappings is still a continuous mapping, we know $\Psi_{\xi, u, U \rightarrow D}(x)$ is a continuous function for $\forall x \in \mathbb{H}$. Therefore, the $i$-th element of $\Psi_{\xi, u, U \rightarrow D}(x)$, denoted by $[\Psi_{\xi, u, U \rightarrow D}(x)]_i$, is also a continuous function of $x$. Based on (i), (ii) and universal approximation theorem \[37\], we know for any $\varepsilon_i > 0$, there exists a positive constant $N_i$ such that
\[
\sup_{x \in \mathbb{H}} |\text{NET}_{N_i}(x, \Omega_i) - [\Psi_{\xi, u, U \rightarrow D}(x)]_i| \leq \varepsilon_i,
\]
where $\text{NET}_{N_i}(x, \Omega_i)$ is the output of the network with only one neuron in the output layer, and $\Omega_i$ denotes the corresponding network parameters. By stacking $2M$ of the above networks together, we can construct a larger network $\text{NET}_N(x, \Omega)$ with $N = \sum_{i=1}^{2M} N_i$, where $\Omega$ denotes the corresponding network parameters. By choosing $\varepsilon_i = \varepsilon / \sqrt{2M}$, Eq. \((6)\) can be proved.

**Theorem 1** reveals that the uplink-to-downlink mapping function can be approximated arbitrarily well by an FNN with a single hidden layer. It should be mentioned that although the network proposed in this work cannot obtain arbitrarily high prediction accuracy due to inadequate learning or insufficient number of hidden units \[37\], **Theorem 1** still provides theoretical foundation for the application of deep neural networks.

B. Definitions of DTL

For the users in the $k$th environment (region), let $\mathcal{X}_k$ and $\mathcal{Y}_k$ denote the space of the uplink and the downlink channels, respectively. Then, the definitions of the “domain” and the “task” are given in the following two definitions:

**Definition 1:** The “domain” $D(k)$ is composed of the feature space $\mathcal{X}_k$ and the marginal probability distribution $P(h_u(f_{u,u}))_{u \in \mathcal{B}_k}$, i.e., $D(k) = \{\mathcal{X}_k, P(h_u(f_{u,u}))_{u \in \mathcal{B}_k}\}$.

**Definition 2:** Define the “task” $T(k)$ as the prediction of the downlink channels from the uplink channels for the users in the $k$-th environment. Given the specific domain $D(k)$, the “task” $T(k)$ is composed of the label space $\mathcal{Y}_k$ and the prediction function $F_k$, i.e., $T(k) = \{\mathcal{Y}_k, F_k\}$.

**Remark 1:** The prediction function $F_k$ can be learned from the training data of the $k$-th environment and then be used to predict the downlink channels for the users in the $k$-th environment. Based on the analysis in Section III-A, the prediction function $F_k$ can be interpreted as the fitting function for all the uplink-to-downlink mapping functions defined in the $k$-th environment, i.e., $\{\Psi_{f_{u,u} \rightarrow f_{d,u}}\}_{u \in \mathcal{B}_k}$. The prediction function $F_k$ can also be interpreted as the conditional probability distribution $P(h_u(f_{d,u})|h_u(f_{u,u}))_{u \in \mathcal{B}_k}$ from probabilistic view.

Classical transfer learning consists of two aspects, namely, the source domain transfer and the target domain adaption. Based on \[29\], the definition of transfer learning can be given as following:

\[3\] The space of the uplink channels is $\mathcal{X}$ means that any possible uplink channel vector belongs to $\mathcal{X}$, i.e. $h_u(f_{u,u}) \in \mathcal{X}$ holds for any possible $u$ or $f_{u,u}$.
**Definition 3:** Given the source task $T_S$, the source domain $D_S$, the target task $T_T$, and the target domain $D_T$, the aim of transfer learning is to improve the performance of the target task $T_T$ by using the knowledge from $T_S$ and $D_T$, where $D_T \neq D_S$ or $T_T \neq T_S$.

Here we extend the single-source domain transfer to the multi-source domain transfer. Then, a more generalized definition of transfer learning can be provided as follows:

**Definition 4:** Given the number of source tasks $K_s$, the source tasks $\{T_S(k)\}_{k=1}^{K_s}$, the source domains $\{D_S(k)\}_{k=1}^{K_s}$, and the target domain $D_T$, the aim of transfer learning is to improve the performance of the target task $T_T$ by using the knowledge from $\{T_S(k)\}_{k=1}^{K_s}$ and $D_S(k)$, where $T_T \neq D_S(k)$ or $T_T \neq T_S(k)$ holds for $k = 1, \ldots, K_s$.

In Definition 4, the condition $D_T \neq D_S(k)$ means that either the corresponding feature space $X_T \neq X_S(k)$ holds or the corresponding marginal probability distribution $P_T(h_u(f_U,u)) \nexists_{B_S} \neq P_S(k)(h_u(f_U,u)) |u \in B_S$ holds, where $B_T$ is the set of users in the target environment. The condition $T_T \neq T_S(k)$ means that either the corresponding label space $Y_T \neq Y_S(k)$ holds or the corresponding conditional probability distribution $P_T(h_u(f_D,u)|h_u(f_U,u)) |u \in B_T \neq P_S(k)(h_u(f_D,u)|h_u(f_U,u)) |u \in B_S$ holds. Since the conditional probability distributions for different prediction tasks are different, the condition $T_T \neq T_S(k)$ is satisfied. Therefore, the downlink channel prediction for massive MIMO systems can be formulated as a transfer learning problem.

DTL is to transfer knowledge by deep neural networks, which is defined as follows [31]:

**Definition 5:** Given a transfer learning task characterized by $\{\{T_S(k)\}_{n=1}^{N_s}\}$, $\{D_S(k)\}_{k=1}^{K_s}$, $T_T$, $D_T$, it is a DTL task when the prediction function $F_T$ of $T_T$ is a non-linear function that is approximated by a deep neural network.

Based on Definition 4 and Definition 5, the downlink channel prediction for massive MIMO systems can be formulated as a typical DTL problem, where the $k$-th learning task is to predict the downlink channel $h_u(f_D,u)$ from the uplink channel $h_u(f_U,u)$ for the users in the $k$-th environment.

**C. Motivation of Meta-learning**

Before resorting to DTL methods, we should first consider the question “whether to transfer”. In fact, if the source and target tasks are highly related, a deep neural network would perform well, without the need for fine-tuning the neural network based on the target environment, thanks to its remarkable generalization capability.

The second question is “how to transfer”. One natural solution is to directly use all the labeled data in the source tasks to train the network, and then fine-tune the network with the labeled data in the target task. However, the direct transfer method tends to overfit when the number of labeled data in the target task is small, as will be verified by simulations in Section VI. To overcome this challenge, and motivated by the state-of-the-art performance of the model-agnostic meta-learning algorithm in few-sample learning [32], we will propose the meta-learning algorithm based downlink channel prediction in Section VII.

**IV. NO-TRANSFER AND DIRECT-TRANSFER ALGORITHMS**

Based on the analysis in Section III-C, we propose the no-transfer algorithm based on classical deep learning algorithms to investigate the necessity of transfer learning. Then, the direct-transfer algorithm is proposed and used as the benchmark of the meta-learning algorithm. Both the no-transfer and the direct-transfer algorithms adopt the FNN architecture as described in the following subsection.

**A. Network Architecture**

The FNN architecture has $L$ layers, including one input layer, $L - 2$ hidden layers, and one output layer, as shown in Fig. 2. The input of FNN is $\mathbf{x} = \mathbf{g} \circ h_u(f_U,u)$. The output of the network is a cascade of nonlinear transformation of $\mathbf{x}$, i.e.,

$$\hat{\mathbf{y}} = \text{Net}(\mathbf{x}, \mathbf{\Omega}) = f^{(L-1)} \circ f^{(L-2)} \circ \cdots \circ f^{(1)}(\mathbf{x}),$$  

where $\mathbf{\Omega} \triangleq \{\mathbf{W}^{(l)}, \mathbf{b}^{(l)}\}_{l=1}^{L}$ is the network parameters to be trained. Moreover, $f^{(l)}$ is the nonlinear transformation function of the $l$-th layer and can be written as,

$$f^{(l)}(\mathbf{x}) = \mathbf{r}^{(l)} \left( \mathbf{W}^{(l)} \mathbf{x} + \mathbf{b}^{(l)} \right), \quad 1 \leq l \leq L - 1,$$

where $\mathbf{W}^{(l)}$ is the weight matrix associated with the $(l - 1)$-th and the $l$-th layers, while $\mathbf{b}^{(l)}$ and $\mathbf{r}^{(l)}$ are the bias vector and the activation function of the $l$-th layer, respectively. The activation function for the hidden layers is selected as the rectified linear unit (ReLU) function $|r_{\text{Re}}(z)|_{p} = \max\{0,|z|_{p}\}$ with $p = 1, 2, \cdots, \text{len}(z)$. The activation function for the output layer is the linear function, i.e., $r_{\text{Li}}(z) = z$. The loss function can be written as follow:

$$\text{Loss}_{\text{DS}}(\mathbf{\Omega}) = \frac{1}{V} \sum_{v=0}^{V-1} \left\| \mathbf{y}^{(v)} - \mathbf{y}^{(v)} \right\|_{2}^{2},$$

where $\mathbf{y} = \mathbf{g} \circ h_u(f_D,u)$ is the supervise label, $V$ is the batch size, the superscript $(v)$ denotes the index of the $v$-th training sample, $\mathbb{D} = \{(\mathbf{x}^{(v)}, \mathbf{y}^{(v)})\}_{v=1}^{V}$ is the training dataset, and $\|\|_{2}$ denotes the $L_2$ norm.

$^4$Batch size is the number of samples in one training batch.
B. Definitions and Generation of Datasets

As mentioned in Definition 2, each task represents the prediction of downlink channel from the uplink channel for the users in a certain environment. In the $k$-th environment, $U$ different users are involved in the generation of datasets. Denote $\Delta f$ as the frequency difference between the uplink and the downlink. Then, each uplink frequency corresponds to a certain downlink frequency, i.e., $f_{D,u} = f_{U,u} + \Delta f$. Denote the training dataset of the $k$-th source task as $D_{STr}(k)$. We can collect $N_{T_{tr}}$ sample pairs $\{(\xi \circ h_{u}(f_{U,u}), \xi \circ h_{u}(f_{D,u}))\}$ as the dataset $D_{Tr}(k)$ by randomly selecting $N_{T_{tr}}/U$ uplink frequencies for each user in the $k$-th environment.

Denote the adaption and testing datasets of the $k$-th target task as $D_{Ad}(k)$ and $D_{Te}(k)$, respectively. Similarly, the datasets $D_{Ad}(k)$ and $D_{Te}(k)$ can be obtained by separately collecting $N_{T_{ad}}$ and $N_{T_{te}}$ sample pairs for the $k$-th target task. Note that $D_{Ad}(k) \cap D_{Ad}(k) = \emptyset$ should be satisfied to ensure the testing dataset not known to the networks.

C. No-Transfer Algorithm

The no-transfer algorithm regards the DTL problem as one classical deep learning problem, including the training and the testing stages.

In the training stage, the datasets $\{D_{Tr}(k)\}_{k=1}^{K_{S}}$ for $K_{S}$ source tasks are collected as a complete training dataset $D_{STr}$. In each time step, $V$ training samples are randomly selected from $D_{STr}$ as the training batch $D_{STr}$. Then, we employ the adaptive momentum estimation (ADAM) algorithm [38] to minimize the loss function on $D_{STr}$, i.e., $\text{Loss}_{\text{STr}}(\Omega)$. Instead of using the gradient of the current step to guide the updates, ADAM adopts moments of the gradient to determine the direction of the optimization, which can accelerate the training, especially in the case of high curvature or noisy gradients [39, chapter 8]. The $q$-th moment of a random variable is defined as the expected value of the $q$-th power of the variable. To estimate the 1st and the 2nd moment vectors of the gradient, i.e., $\nabla_{\Omega} \text{Loss}_{\text{STr}}(\Omega)$, ADAM computes the exponentially decaying moving averages of past gradients and elementwise squared gradients, i.e.,

$$
\begin{align*}
\mu_{1} & \leftarrow \rho_{1}\mu_{1} + (1 - \rho_{1})\nabla_{\Omega} \text{Loss}_{\text{STr}}(\Omega), \\
\nu_{1} & \leftarrow \rho_{2}\nu_{1} + (1 - \rho_{2})(\nabla_{\Omega} \text{Loss}_{\text{STr}}(\Omega))^{2},
\end{align*}
$$

where $(\nabla_{\Omega} \text{Loss}_{\text{STr}}(\Omega))^{2}$ represents the elementwise square of the gradient, and the hyper-parameters $\rho_{1}, \rho_{2} \in [0,1]$ are the exponential decay rates of the moving averages. The vectors $\mu_{1}$ and $\nu_{1}$ are initialized with zeros and updated with moving averages, which results in biased moment estimates of the gradient. Following [38], unbiased 1st and 2nd moment vectors can be obtained by

$$
\begin{align*}
\bar{\mu}_{1} & \leftarrow \frac{\mu_{1}}{1 - \rho_{1}^{t}}, \\
\bar{\nu}_{1} & \leftarrow \frac{\nu_{1}}{1 - \rho_{2}^{t}},
\end{align*}
$$

where $t$ represents the time step. Then, the unbiased 1st and 2nd moment vectors, i.e., $\bar{\mu}_{1}$ and $\bar{\nu}_{1}$, are used to scale the learning rate individually for all elements in $\Omega$, which can be expressed as

$$
\Omega \leftarrow \Omega - \eta \bar{\mu}_{1}/(\sqrt{\bar{\nu}_{1}} + \varepsilon),
$$

where $\eta$ is the learning rate, $\varepsilon$ is the disturbance factor, and the notation ‘/’ is the elementwise division operation.

By iteratively executing the ADAM algorithm on the dataset $D_{STr}$ until $\text{Loss}_{\text{STr}}(\Omega)$ converges, we can obtain the trained network parameter $\Omega_{N_t}$.

In the testing stage, the network parameter $\Omega_{N_t}$ is fixed. The testing datasets $\{D_{Te}(k)\}_{k=1}^{K_{T}}$ of $K_{T}$ target tasks are generated and are used to test the performance of the no-transfer algorithm. Denote $\hat{h}_{D} = \xi^{-1} \circ \hat{y}$ and $h_{D} = \xi^{-1} \circ y$ as the estimated and the true downlink channel, respectively. Normalized mean-squared-error (NMSE) is used to measure the prediction accuracy, which is defined as

$$
\text{NMSE} = E \left[ \frac{\|h_{D} - \hat{h}_{D}\|_{2}^{2}}{\|h_{D}\|_{2}^{2}} \right].
$$

Denote the prediction NMSE of the no-transfer algorithm as $\text{NMSE}_{N_{t}}$ that can be calculated by averaging the NMSEs of the no-transfer algorithm evaluated on $K_{T}$ target environments. i.e., $\text{NMSE}_{N_{t}} = \sum_{k=1}^{K_{T}} \text{NMSE}_{N_{t}}(k)/K_{T}$, where $\text{NMSE}_{N_{t}}(k)$ is the NMSE evaluated on the $k$-th target environment. The concrete steps of the no-transfer algorithm are given in the Algorithm 1.

D. Direct Transfer Algorithm

In the training stage, the direct-transfer algorithm trains the network via the ADAM algorithm on the training dataset $D_{STr}$ until $\text{Loss}_{\text{STr}}(\Omega)$ converges. During the training, the network tries to learn a generalized parameter to predict the downlink CSI for users in different environments. After the training finished, the network has learned the parameter $\Omega_{N_{t}}$ from the $K_{S}$ source tasks. Then, the datasets $\{D_{Ad}(k)\}_{k=1}^{K_{T}}$ and $\{D_{Te}(k)\}_{k=1}^{K_{T}}$ of $K_{T}$ target tasks are generated following Section IV-B. For the $k$-th target task, the direct-transfer algorithm initializes the target-task-specific parameter $\Omega_{T_{k}}$ of the trained network parameter $\Omega_{N_{t}}$, then fine-tunes $\Omega_{T_{k}}$ on the adaption dataset $D_{Ad}(k)$ via $G_{Ad}$ steps of ADAM updates, and then tests the network on the testing dataset $D_{Te}(k)$. Specifically, ADAM aims to minimize $\text{Loss}_{\text{Ad}}(\Omega_{T_{k}})$ by updating the parameter $\Omega_{T_{k}}$, and unbiased moment vectors of the gradient $\nabla_{\Omega_{T_{k}}} \text{Loss}_{\text{Ad}}(\Omega_{T_{k}})$ are used to determine the direction of the update. Based on the derivations in Section IV-C, biased 1st and 2nd moment vectors are initialized with zeros and are then updated in each step following

$$
\begin{align*}
\mu_{2} & \leftarrow \rho_{1}\mu_{2} + (1 - \rho_{1})\nabla_{\Omega_{T_{k}}} \text{Loss}_{\text{Ad}}(\Omega_{T_{k}}), \\
\nu_{2} & \leftarrow \rho_{2}\nu_{2} + (1 - \rho_{2})(\nabla_{\Omega_{T_{k}}} \text{Loss}_{\text{Ad}}(\Omega_{T_{k}}))^{2},
\end{align*}
$$

Next, we obtain the unbiased 1st and 2nd moment vectors by

$$
\begin{align*}
\bar{\mu}_{2} & \leftarrow \frac{\mu_{2}}{1 - \rho_{1}^{g}}, \\
\bar{\nu}_{2} & \leftarrow \frac{\nu_{2}}{1 - \rho_{2}^{g}},
\end{align*}
$$

where $g$ represents the step index. The update of $\Omega_{T_{k}}$ can be written as

$$
\Omega_{T_{k}} \leftarrow \Omega_{T_{k}} - \eta \bar{\mu}_{2}/(\sqrt{\bar{\nu}_{2}} + \varepsilon).
$$

After the fine-tuning finished, the target-task-specific parameter $\Omega_{T_{k}}$ will be fixed. Let $\text{NMSE}_{E_{N_{t}}}(k)$ represent the NMSE of the direct-transfer algorithm evaluated on the $k$-th target
Algorithm 1: No-transfer algorithm for downlink CSI prediction

Input: Source tasks: \( \{ T_S(k) \}_{k=1}^{K_s} \), Target tasks: \( \{ T_T(k) \}_{k=1}^{K_t} \), learning rate: \( \eta \), exponential decay rates: \( \{ \rho_1, \rho_2 \} \), disturbance factor: \( \varepsilon \), batch size: \( V \)

Output: Trained network parameter: \( \Omega_{Ni} \), predicted downlink CSI based on \( \{ D_T(k) \}_{k=1}^{K_t} \), NMSE of the no-transfer algorithm: \( \text{NMSE}_{Ni} \)

1. **Training stage**
   2. Randomly initialize the network parameters \( \Omega \)
   3. Initialize the time step: \( t \leftarrow 0 \)
   4. Initialize the 1st and 2nd moment vectors: \( \mu_1, \nu_1 \leftarrow 0 \)
   5. Generate the training dataset \( \mathbb{D}_{ST}^{\Delta} = \{ D_T(k) \}_{k=1}^{K_S} \) for \( K_S \) source tasks
   6. for \( t = 1, \cdots \) do
      7. Randomly select \( V \) training samples from \( \mathbb{D}_{ST}^{\Delta} \) as the training batch \( \mathbb{D}_{STB} \)
      8. \( t \leftarrow t + 1 \)
      9. Update biased 1st and 2nd moment vectors using Eq. (11)
     10. Compute unbiased 1st and 2nd moment vectors using Eq. (12)
     11. Update the parameter \( \Omega \) using unbiased 1st and 2nd moment vectors: \( \Omega \leftarrow \Omega - \eta \mu_1 / (\sqrt{\nu_1} + \varepsilon) \)
   end

12. **Testing stage**
   13. Initialize NMSE: \( \text{NMSE}_{Ni} \leftarrow 0 \)
   14. for \( k = 1, \cdots, K_T \) do
      15. Generate the testing dataset \( D_T(k) \) for \( T_T(k) \)
      16. Predict the downlink CSI base on \( D_T(k) \) and \( \Omega \) using Eq. (8)
      17. Calculate \( \text{NMSE}_{Ni}(k) \) using Eq. (14)
      18. \( \text{NMSE}_{Ni} \leftarrow \text{NMSE}_{Ni} + \text{NMSE}_{Ni}(k) / K_T \)
   end

Algorithm 2: Direct-transfer algorithm for downlink CSI prediction

Input: Source tasks: \( \{ T_S(k) \}_{k=1}^{K_s} \), Target tasks: \( \{ T_T(k) \}_{k=1}^{K_t} \), learning rate: \( \eta \), exponential decay rates: \( \{ \rho_1, \rho_2 \} \), disturbance factor: \( \varepsilon \), batch size: \( V \), number of gradsteps for adaption: \( G_{Ad} \)

Output: Trained network parameter: \( \Omega_{Ni} \), predicted downlink CSI based on \( \{ D_T(k) \}_{k=1}^{K_t} \), NMSE of the direct-transfer algorithm: \( \text{NMSE}_{Dt} \)

1. **Training stage**
   2. Implement the Algorithm 1 and obtain the trained network parameter \( \Omega_{Ni} \)
   3. Direct-adaptation and Testing for target tasks
   4. Initialize NMSE: \( \text{NMSE}_{Dt} \leftarrow 0 \)
   5. for \( k = 1, \cdots, K_T \) do
      6. Generate the datasets \( D_{Ad}(k) \) and \( D_T(k) \) for \( T_T(k) \)
      7. Direct-adaption stage
      8. Load the network parameter \( \Omega_{Tk} \leftarrow \Omega_{Ni} \)
      9. Initialize the 1st and 2nd moment vectors: \( \mu_2, \nu_2 \leftarrow 0 \)
     10. for \( g = 1, \cdots, G_{Ad} \) do
         11. Update biased 1st and 2nd moment vectors using Eq. (15)
         12. Compute unbiased 1st and 2nd moment vectors using Eq. (16)
         13. Update the parameter \( \Omega_{Tk} \) using unbiased moment vectors: \( \Omega_{Tk} \leftarrow \Omega_{Tk} - \eta \mu_2 / (\sqrt{\nu_2} + \varepsilon) \)
     end

14. **Testing stage**
   15. Predict the downlink CSI base on \( D_T(k) \) and \( \Omega_{Tk} \) using Eq. (8)
   16. Calculate \( \text{NMSE}_{Dt}(k) \) using Eq. (14)
   17. \( \text{NMSE}_{Dt} \leftarrow \text{NMSE}_{Dt} + \text{NMSE}_{Dt}(k) / K_T \)
   end

environment that can be obtained by testing the network on the dataset \( D_T(k) \) using Eqs. (8) and (14). Then, the prediction NMSE of the direct-transfer algorithm can be obtained by \( \text{NMSE}_{Dt} = \sum_{k=1}^{K_t} \text{NMSE}_{Dt}(k) / K_T \). The concrete steps of the direct-transfer algorithm are given in the Algorithm 2.

Notice that the direct-transfer algorithm utilizes the trained network parameter \( \Omega_{Ni} \) as the initialization of the direct-adaption stage for every target task. By contrast, another way is to utilize previous target-task-specific parameter \( \Omega_{Tk-1} \) as the initialization of the direct-adaption stage for the \( k \)-th target task since \( \Omega_{Tk-1} \) appears to contain the information in all the source environments and \( k-1 \) target environments, and therefore could enhance the performance of the algorithm. However, the real situation is that a good initialization in DTL is not to train the network parameter with as much data as possible, but to find such a parameter that can easily adapt to any target task. In a way, a good initial parameter can be interpreted as a parameter point in the parameter space that is near (or easy to get) to the optimal parameter point for most target tasks. Fig. 3 illustrates the trajectory of parameter updating during the training and direct-adaption stages of the direct-transfer algorithm. The black solid line represents the updating trajectory of the network parameter \( \Omega \) during the training stage. The blue dashed lines represent the updating trajectories of the target-task-specific parameters \( \{ \Omega_{Tk} \}_{k=1}^{K_t} \) during the direct-adaption stage following Algorithm 2. The red dash-dotted lines represent the parameter adaption process with previous target-task-specific parameter as the initial parameter. As shown in Fig. 3, the trajectory of red dash-dotted lines, i.e., \( \Omega_{Ni} \rightarrow \Omega_{Tk-1} \rightarrow \Omega_{Tk-2} \rightarrow \Omega_{Tk-3} \), is longer than the trajectory of blue dashed lines, i.e., \( \{ \Omega_{Ni} \rightarrow \Omega_{Tk} \}_{k=1}^{K_t} \), which indicates \( \Omega_{Ni} \) is a better initialization than \( \Omega_{Tk-1} \). The intrinsic reason is that \( \Omega_{Ni} \) is obtained by training the network on a large-scale and shuffled dataset, i.e., \( \mathbb{D}_{ST} \), which has more stronger representativeness of different tasks than the small-scale adaption dataset \( D_{Ad}(k) \). In fact, the fine-tuning on the adaption dataset \( D_{Ad}(k) \) renders the network parameter away from the generalized parameter \( \Omega_{Ni} \) and gets closed to the task-specific parameter \( \Omega_{Tk} \).

Remark 2: It should be emphasized that parameter initializa-
tion is one of the most crucial tasks in deep learning, especially in DTL. A high-quality initialization can effectively prevent the training from getting stuck in a low-performance local minimum and thus accelerates the convergence.\textsuperscript{40, 41}

V. META-LEARNING ALGORITHM

The proposed meta-learning algorithm also adopts the FNN architecture in Section 4 and has three stages, namely, the meta-training, the meta-adaptation and the testing stages.

A. Definitions and Generation of Datasets

For the $k$-th source task, two datasets should be obtained for the meta-training stage, i.e., the training support dataset $\mathcal{D}_{\text{TrSup}}(k)$ and the training query dataset $\mathcal{D}_{\text{TrQue}}(k)$. Following Section 4-B, we can collect $N_T$ sample pairs for each source task and then randomly divide the $N_T$ sample pairs, i.e., $\{ (\xi \circ h_u(f_{k,u}), \xi \circ h_u(f_{k,u}) ) \}$, into the training support dataset $\mathcal{D}_{\text{TrSup}}(k)$ and the training query dataset $\mathcal{D}_{\text{TrQue}}(k)$. Note that $\mathcal{D}_{\text{TrSup}}(k) \cap \mathcal{D}_{\text{TrQue}}(k) = \emptyset$ should be satisfied to improve the generalization capability of the network. For the $k$-th target task, the adaption dataset $\mathcal{D}_{\text{Ad}}(k)$ and the testing dataset $\mathcal{D}_{\text{Te}}(k)$ can be obtained following Section 4-B.

B. Meta-training Stage

In the meta-training stage, the meta-learning algorithm aims to learn a network initialization that can effectively adapt to a new task. The parameter of FNN, i.e., $\Omega$, is randomly initialized and is then updated by two iterative processes, i.e., the inner-task and the across-task updates.

1) Inner-task update: Denote the source-task-specific parameter as $\Omega_{S,k}$. The goal of the inner-task updates is to minimize the loss function on the training support dataset $\mathcal{D}_{\text{TrSup}}(k)$, i.e., $\text{Loss}_{\text{TrSup}}(k)(\Omega_{S,k})$, by iteratively updating the parameter $\Omega_{S,k}$. Specifically, $\Omega_{S,k}$ is initialized as the current network parameter $\Omega$, and is then updated with $G_{Te}$ steps of gradient descents. Since an overlarge gradient leads to the instability of gradient descents, we limit the values of the source-task-specific gradient $\nabla_{\Omega_{S,k}} \text{Loss}_{\text{TrSup}}(k)(\Omega_{S,k})$ into a certain range and obtain the truncated source-task-specific gradient $\nu_{S,k}$ as \textsuperscript{42}

$$[\nu_{S,k}]_p = \min \left\{ \Upsilon, \left[ \nabla_{\Omega_{S,k}} \text{Loss}_{\text{TrSup}}(k)(\Omega_{S,k}) \right]_p \right\},$$

$$p = 1, \cdots, \text{len}(\nu_{S,k}),$$

where $\Upsilon$ is the upper threshold of the gradient. Generally, an overlarge $\Upsilon$ may lead to large fluctuations of the loss function, while a too small $\Upsilon$ distorts the direction of the update, resulting in too early convergence. By trails and adjustments, a proper $\Upsilon$ is selected such that the inner-task updates converge stably and efficiently. Then, the parameter $\Omega_{S,k}$ is updated based on the truncated gradient $\nu_{S,k}$, i.e.,

$$\Omega_{S,k} \leftarrow \Omega_{S,k} - \beta \nu_{S,k},$$

where $\beta$ is the inner-task learning rate. It should be mentioned that in \textsuperscript{32}, the inner-task update only involves one step of gradient descent. Here we extend it to $G_{Te}$ steps for better performance.

2) Across-task update: In the $t$-th time step, we randomly select $K_B$ source tasks out of $K_S$ source tasks$^5$ and generate corresponding support datasets $\{ \mathcal{D}_{\text{TrSup}}(k) \}_{k=1}^{K_B}$ and query datasets $\{ \mathcal{D}_{\text{TrQue}}(k) \}_{k=1}^{K_B}$ following Section 4-A. The optimization objective of the $t$-th update is the loss function associated with the $K_B$ training query datasets $\{ \mathcal{D}_{\text{TrQue}}(k) \}_{k=1}^{K_B}$ and the meta-trained source-task-specific parameter $\Omega_{S,k}$, i.e.,

$$\sum_{k=1}^{K_B} \text{Loss}_{\text{TrQue}}(k)(\Omega_{S,k}).$$

The network parameter $\Omega$ is updated via the ADAM algorithm. Specifically, the biased $1^{st}$ and $2^{nd}$ moment vectors are initialized with zeros and are then updated in the $t$-th time step following

$$\mu_3 \leftarrow \rho_1 \mu_3 + (1 - \rho_1) \nabla_{\Omega} \sum_{k=1}^{K_B} \text{Loss}_{\text{TrQue}}(k)(\Omega_{S,k}),$$

$$\nu_3 \leftarrow \rho_2 \nu_3 + (1 - \rho_2) \left( \nabla_{\Omega} \sum_{k=1}^{K_B} \text{Loss}_{\text{TrQue}}(k)(\Omega_{S,k}) \right)^2.$$  \hspace{1cm} (20)

Next, the unbiased $1^{st}$ and $2^{nd}$ moment vectors can be obtained by

$$\bar{\mu}_3 \leftarrow \mu_3 / (1 - \rho_3^t),$$

$$\bar{\nu}_3 \leftarrow \nu_3 / (1 - \rho_2^t).$$  \hspace{1cm} (21)

The update of network parameter $\Omega$ can be written as follows:

$$\Omega \leftarrow \Omega - \gamma \bar{\mu}_3 / (\sqrt{\bar{\nu}_3} + \varepsilon).$$  \hspace{1cm} (22)

After the across-task updates finished, the meta-trained network parameter will be obtained by $\Omega_{Mt} \leftarrow \Omega$. By alternately implementing the inner-task and across-task updates until the loss converges, the network learns model initialization that can adapts to a new task using only a small number of samples.

There are two important differences between the inner-task and across-task updates. (i) Each inner-task update is performed on the support dataset of one source task while each across-task update is performed on the query datasets of $K_B$ source tasks; (ii) The aim of inner-task updates is to optimize the task-specific parameters $\{ \Omega_{T,k} \}_{k=1}^{K_B}$ while the aim of across-task updates is to optimize the overall network parameters $\Omega$.

It should be mentioned that in \textsuperscript{32}, the across-task update is performed by stochastic gradient descent (SGD) like the inner-task update. Here we adopt the ADAM algorithm instead.

$^5$Typically, there is $K_B \ll K_S$. 

of SGD since the ADAM learning algorithm benefits from the moment technique and the parameter-specific learning rates, and thus significantly outperforms SGD in many situations [43].

C. Meta-adaption and Testing Stages

Following Section V-A, we generate the adaption datasets \( \{ D_{Ad}(k) \}_{k=1}^{K_s} \) and the testing datasets \( \{ D_{Te}(k) \}_{k=1}^{K_T} \) for the meta-adaption and testing stages, respectively. In the meta-adaption stage, the meta-learning algorithm aims to fine-tune the network on the adaption dataset \( D_{Ad}(k) \) so that the network can predict the downlink CSI on \( D_{Te}(k) \) as accurately as possible. For the \( k \)-th target task, the direct-transfer algorithm initializes the target-task-specific parameter \( \Omega_{T,k} \) as the meta-trained network parameter \( \Omega_{Mt} \), and then fine-tunes \( \Omega_{T,k} \) on the adaption dataset \( D_{Ad}(k) \) via \( G_{Ad} \) steps of gradient descent. The optimization objective is the loss function on the \( D_{Ad}(k) \), i.e., \( \text{Loss}_{D_{Ad}}(k) (\Omega_{T,k}) \). Then, the truncated target-task-specific gradient \( v_{T,k} \) can be obtained by

\[
[v_{T,k}]_p = \min \left\{ \nabla_{\Omega_{T,k}} \text{Loss}_{D_{Ad}}(k) (\Omega_{T,k}) \right\}, \quad p = 1, \ldots, \text{len}(v_{T,k}). \tag{23}
\]

Then, the parameter \( \Omega_{T,k} \) is updated based on the truncated gradient \( v_{T,k} \), i.e.,

\[
\Omega_{T,k} \leftarrow \Omega_{T,k} - \beta v_{T,k}. \tag{24}
\]

After the fine-tuning finished, the target-task-specific parameter \( \Omega_{T,k} \) will be fixed. Let \( \text{NMSE}_{Mt}(k) \) represent the NMSE of the meta-learning algorithm evaluated on the \( k \)-th target environment that can be obtained by testing the network on the dataset \( D_{Te}(k) \) using Eqs. (8) and (14). Then, the prediction \( \text{NMSE}_{Mt} \) of the meta-learning algorithm can be obtained by \( \text{NMSE}_{Mt} = \sum_{k=1}^{K_T} \text{NMSE}_{Mt}(k)/K_T \). The concrete steps of the meta-learning algorithm are given in Algorithm 3.

Fig. 4 illustrates the trajectory of the parameter updating during the meta-training and meta-adaption stages of the meta-learning algorithm. The black solid line represents the updating trajectory of the network parameter \( \Omega \) during the meta-training stage. The blue dashed lines represent the updating trajectories of the target-task-specific parameters \( \{ \Omega_{T,k} \}_{k=1}^{K_T} \) during the meta-adaption stage. The green dotted lines represent the trajectories of the source-task-specific parameters \( \{ \Omega_{S,k} \}_{k=1}^{K_s} \) during the inner-task updates. As shown in Fig. 4, \( K_B \) red dash-dotted lines point to the next position of parameter \( \Omega \), which implies that \( K_B \) trained source-task-specific parameters

**Algorithm 3: Meta-learning algorithm for downlink CSI prediction**

**Input:** Source tasks: \( \{ T_S(k) \}_{k=1}^{K_s} \), Target tasks: \( \{ T_T(k) \}_{k=1}^{K_T} \), inner-task learning rate: \( \beta \), across-task learning rate: \( \gamma \), exponential decay rates for across-task learning: \( \{ \rho_1, \rho_2 \} \), disturbance factor: \( \varepsilon \), number of graddsteps for inner-task training: \( T_T \), number of tasks in each time index: \( K_B \).

**Output:** Meta-trained network parameter: \( \Omega_{Mt} \). Predicted downlink CSI based on \( \{ D_{Te}(k) \}_{k=1}^{K_T} \), NMSE of the meta-learning algorithm: \( \text{NMSE}_{Mt} \).

1. **Meta-training stage**
   2. Randomly initialize the network parameters \( \Omega \).
   3. Initialize the time step: \( t \leftarrow 0 \).
   4. Initialize the 1st and 2nd moment vectors: \( \mu, \nu \leftarrow 0 \).
   5. for \( t = 1, \ldots \) do
      6. Randomly select \( K_B \) tasks from \( \{ T_S(k) \}_{k=1}^{K_s} \).
      7. Generate corresponding support dataset \( \{ D_{Sup}(k) \}_{k=1}^{K_B} \) and query dataset \( \{ D_{Query}(k) \}_{k=1}^{K_B} \).
      8. for \( k = 1, \ldots, K_B \) do
         9. Initialize the parameter \( \Omega_k \leftarrow \Omega \).
         10. for \( g = 1, \ldots, G_{Ad} \) do
              11. Obtain truncated gradient \( \nu_{S,k} \) using Eq. (18).
              12. Update the parameter \( \Omega_{S,k} \) with gradient descent: \( \Omega_{S,k} \leftarrow \Omega_{S,k} - \beta \nu_{S,k} \).
         end
      end
      13. Update biased 1st and 2nd moment vectors using Eq. (20).
      15. Update the parameter \( \Omega \) unbiased 1st and 2nd moment vectors: \( \Omega \leftarrow \Omega - \gamma \mu_\beta / (\sqrt{\nu_\beta} + \varepsilon) \).
      16. end
   17. Meta-trained network parameter: \( \Omega_{Mt} \leftarrow \Omega \).
   18. Meta-adaption and Testing
   19. Initialize NMSE: \( \text{NMSE}_{Mt} \leftarrow 0 \).
   20. for \( k = 1, \ldots, K_T \) do
      21. Generate the datasets \( D_{Ad}(k) \) and \( D_{Te}(k) \) for \( T_T(k) \).
      22. Load the parameter network \( \Omega_{T,k} \leftarrow \Omega_{Mt} \).
      23. for \( g = 1, \ldots, G_{Ad} \) do
         24. Obtain truncated gradient \( \nu_{T,k} \) using Eq. (23).
         25. Update the parameter \( \Omega_{T,k} \) with gradient descent: \( \Omega_{T,k} \leftarrow \Omega_{T,k} - \beta \nu_{T,k} \).
      end
   26. Testing stage
   27. Predict the downlink CSI base on \( \Omega_{T,k} \) using Eq. (8).
   28. Calculate \( \text{NMSE}_{Mt}(k) \) using Eq. (14).
   29. \( \text{NMSE}_{Mt} \leftarrow \text{NMSE}_{Mt} + \text{NMSE}_{Mt}(k)/K_T \).
   30. end

Fig. 4. Illustration of the meta-learning algorithm, where \( K_B = K_T = 3 \).
are involved in the across-task update to determine the updating direction of $\Omega$. As depicted in Fig. 3 and Fig. 4, the meta-learning algorithm takes the unique features of different tasks into account and exploits the joint guidance of multiple source tasks while the direct-transfer algorithm simply regards all the source tasks as one source task and ignores the structure information in different tasks.

VI. SIMULATION RESULTS

In this section, we will first present the simulation scenario and default algorithm parameters. Then, the performance of the no-transfer, the direct-transfer, and the meta-learning algorithms will be evaluated and analyzed.

A. Simulation Setup

In the simulations, we consider the outdoor massive MIMO scenario that is constructed based on the accurate 3D ray-tracing simulator Wireless InSite [44]. The scenario comprises 4 BSs and massive randomly distributed user antennas and each BS is equipped with 64 antennas. The scenario covers an area of $1500 \times 1500$ square metres. A partial view of the ray-tracing scenario is illustrated in Fig. 5. There are total 1300 environments randomly distributed in the outdoor massive MIMO scenario, where each environment contains multiple possible user locations as shown in the partial enlarged picture.

To generate the training dataset, the uplink frequency is randomly selected in $[1, 3]$ GHz. The frequency difference between the uplink and the downlink is 120 MHz. For each environment, the 3D ray-tracing simulator first generates the channels between the user antennas and the corresponding BS antenna. Then, the uplink and downlink channels of $U$ selected users are collected as the sample pairs for the corresponding environment. After obtained the sample pairs for all the environments, we randomly select 1500 environments out as the source environments and the rest of them are used as the target environments. For each source task, $N_{Tr}$ sample pairs of one source environment are randomly selected out as the training dataset. For each target task, $N_{Ad}$ and $N_{Te}$ sample pairs of one target environment are separately selected out as the adaption and the testing datasets. The datasets of this paper are available at [46].

The meta-learning, the no-transfer and the direct-transfer algorithms are all implemented on one computer with one Nvidia GeForce GTX 1080 Ti GPU. TensorFlow 1.4.0 is employed as the deep learning framework. Unless otherwise specified, the parameters of the no-transfer, the direct-transfer, and the meta-learning algorithms are given in Tab. I. The specifical values of these parameters are basically selected by trails and errors such that these algorithms perform well. The numbers of neurons in the input and the output layers are consistent with the lengths of input and output data vectors, respectively. The trainable parameters of FNN are randomly initialized as truncated normal variables with normalized variance. To be fair, the number of training samples in $D_{Str}$ are equal to the number of training samples used in the meta-learning algorithm, i.e., $K_S \times N_{Tr}$. We use the average NMSE as the metric to evaluate the performance of algorithms, i.e., calculating the average NMSE of the prediction accuracy by repetitively (fine-tuning and then) testing 800 different target environments.

For more details about how to generate channels using Wireless InSite, please refer to [45].

The truncated normal distribution is a normal distribution bounded by two standard deviations from the mean.

The weights of neurons in the $l$-th layer are initialized as truncated normal variables with variance $1/n_l$. 

---

Fig. 5. A partial view of the ray-tracing scenario. The green little box represents the BS antennas. The red little box represents the user antennas. The red square array represents the user antennas in the same environments, where the distance between adjacent red little boxes is 2 m. This ray-tracing scenario is constructed using the Remcom Wireless InSite [44].

B. Performance Evaluation

Fig. 6 depicts the NMSE performance of the no-transfer, the direct-transfer, and the meta-learning algorithms (i.e., NMSE\text{N}, NMSE\text{D} and NMSE\text{M}) versus the number of gradsteps $G_{Ad}$. Since the network parameters of the no-transfer algorithm do not fine-tune based on the target environment, the accuracy curve of the no-transfer algorithm is a horizontal line. As shown in Fig. 6, both the meta-learning and the direct-transfer algorithms are significantly better than the no-transfer algorithm, which indicates that additional samples for the target task and appropriate fine-tuning can improve the prediction accuracy, i.e., transfer learning is more suitable than classical deep learning in downlink channel prediction. It also can be noticed that the performance of the meta-learning algorithm without meta-adaptation stage is significantly better than the no-transfer learning algorithm, which demonstrates that the meta-learning algorithm can find a better initialization for fast adaption than the direct-transfer learning algorithm. Furthermore, as shown in the left partial enlarged picture, the prediction accuracy of the direct-transfer algorithm oscillates dramatically when the number of gradsteps $G_{Ad}$ is smaller than 30, while the prediction accuracy of the meta-learning algorithm improves smoothly as $G_{Ad}$ increases and becomes saturated when $G_{Ad}$ is larger than 1500. This implies the meta-adaptation exhibits a better convergence property than the direct-adaptation. Besides, as shown in the right partial enlarged picture, the prediction accuracy of the direct-transfer algorithm exhibits obvious oscillations even when the direct-adaptation has converged, while the prediction accuracy of the meta-learning algorithm can achieve a stable converged prediction accuracy. As shown in Fig. 6, the meta-learning algorithm outperforms the no-transfer and the direct-transfer algorithms in all aspects, i.e., prediction accuracy, adaption stability and convergence property, which demonstrates the superiority of the meta-learning algorithm.

Fig. 7 depicts the NMSE performance of the no-transfer, the direct-transfer, and the meta-learning algorithms versus the number of samples in $D_{AdSup}$. Since the network parameters of the no-transfer algorithm do not use the dataset $D_{AdSup}$, the accuracy curve of the no-transfer algorithm is a horizontal line. As shown in Fig. 7 the meta-learning algorithm consistently outperforms the direct-transfer algorithm as the sample size increases, which validates its superiority in transfer learning. Moreover, the prediction accuracies of both the direct-transfer and the meta-learning algorithms improve as the sample size increases while the improvement rates of both algorithms decrease as the sample size increases. When the sample size is larger than 130, the performance of the direct-transfer and the meta-learning algorithms both become saturated, which indicates that a maximum of 130 channel samples in a new environment are required for the network to fully adapt to task training. As shown in Fig. 7 the NMSE performance of all algorithms improves as the number of time index $t$ increases and becomes saturated when $t$ is larger than 1e4, which implies that adequate training enhances the performance of the algorithms and the knowledge of source tasks has been fully exploited by the algorithms when $t$ is larger than 1e4. Furthermore, the meta-learning algorithm without meta-adaption consistently outperforms the direct-transfer algorithm without direct-adaption (i.e., the no-transfer algorithm) as the number of time index $t$ increases, which validates that the meta-learning algorithm acquires more knowledge from the source tasks compared with the direct-transfer algorithm, thus leading to a better initialization for subsequent adaption. It also can be noticed that when $t$ is within the range of $[3000, 7000]$, the gap between the direct-transfer and the meta-learning algorithms is significantly larger than that when $t$ reaches 1e4, which indicates that the meta-adaption achieves more improvements than the direct-adaption when the source task training is relatively insufficient. It should be mentioned that in all the simulations presented in Section VI-B, we choose $t$ to be 1e4 to make sure the source task training sufficient.

Fig. 8 depicts the NMSE performance of the no-transfer, the direct-transfer, and the meta-learning algorithms versus the number of samples in $D_{AdSup}$. Since the network parameters of the no-transfer algorithm do not use the dataset $D_{AdSup}$, the accuracy curve of the no-transfer algorithm is a horizontal line. As shown in Fig. 8 the meta-learning algorithm consistently outperforms the direct-transfer algorithm as the sample size increases, which validates its superiority in transfer learning. Moreover, the prediction accuracies of both the direct-transfer and the meta-learning algorithms improve as the sample size increases while the improvement rates of both algorithms decrease as the sample size increases. When the sample size is larger than 130, the performance of the direct-transfer and the meta-learning algorithms both become saturated, which indicates that a maximum of 130 channel samples in a new environment are required for the network to fully adapt to
the new environment, i.e., to predict the downlink channels for any users in the new environment. Besides, it can be noticed that the prediction accuracy of the direct-transfer algorithm oscillates slightly. Empirically, when the NMSE of the prediction accuracy is smaller than $5 \times 10^{-4}$, it is hard for the direct-transfer algorithm to obtain a smooth NMSE curve by testing more target environments. Therefore, we still present the average accuracy of channel prediction from 800 target tasks in Fig. 8 to keep consistent with other simulations.

Fig. 9 shows the NMSE performance of the no-transfer, the direct-transfer, and the meta-learning algorithms versus the frequency difference $\Delta f$. The prediction accuracies of the three algorithms all degrade as the frequency difference increases, even the accuracy degradation of the no-transfer algorithm is not obvious in Fig. 9. This is because the channel correlation between the uplink and the downlink tends to weaken as the frequency difference increases, and the degradation resulted from the frequency difference is not destructive for the uplink based downlink channel prediction. It can be observed that the prediction accuracies of both the meta-learning and the direct-transfer algorithms are higher than $10^{-2}$ even when the frequency difference reaches 1 GHz. The remarkable robustness of DNNs over frequency difference validates the feasibility of channel or beam predictions across wide bandwidths [22].

Fig. 10 shows NMSE performance of the no-transfer, the direct-transfer, and the meta-learning algorithms versus the number of BS antennas $M$. As shown in Fig. 10, the prediction accuracies of the three algorithms all degrade as the number of BS antennas increases. This is because the number of parameters that required to be optimized increases as the number of BS antennas increases while the number of training samples and training time remain unchanged. In fact, there is no theorem or evidence that reveals a deterministic relation between the number of network parameters, the training cost and network performance. Moreover, the gap between the direct-transfer and the meta-learning algorithms decreases as the number of BS antennas increases, which implies that the meta-learning algorithm gains more advantages over the direct-transfer algorithm when the number of BS antennas is small.

VII. CONCLUSION

In this paper, we formulated the downlink channel prediction for FDD massive MIMO systems as a deep transfer learning problem, where each learning task represents the downlink CSI prediction from the uplink CSI for a certain environment. Then, we proposed the no-transfer, direct-transfer and meta-learning algorithms based on the fully-connected neural network architecture. The no-transfer algorithm trains the network in the classical deep learning manner. The direct-transfer algorithm fine-tunes the network based on the initialization of the no-transfer algorithm. The meta-learning algorithm learns a model initialization that can effectively adapt to a new environment with a small amount of labeled

data. Simulation results have shown that the proposed meta-learning algorithm significantly outperforms the direct-transfer and the no-transfer algorithms in terms of both accuracy and stability, which demonstrates its effectiveness and superiority.
