The thermodynamics of modularity identifies how locally-implemented computation entails costs beyond those required by Landauer’s bound on thermal computing. We prove a general theorem for efficient local computation, giving the necessary and sufficient conditions for a local operation to have zero modularity cost. Applied to thermodynamically-generating stochastic processes it confirms a conjecture that classical generators are efficient if and only if they satisfy retrodiction, which places minimal memory requirements on the generator. We extend this to quantum computation: any quantum generator that employs quantum memory compression cannot be thermodynamically efficient.

Keywords: stochastic process, ε-machine, predictor, generator, causal states, modularity, Landauer principle.

I. INTRODUCTION

Recently, Google AI announced a breakthrough in quantum supremacy, using a 54-qubit processor ("Sycamore") to complete a target computation in 200 seconds, claiming the world’s fastest supercomputer would take more than 10,000 years to perform a similar computation [1]. Shortly afterward, IBM announced that they had proven the Sycamore circuit could be successfully simulated on the Summit supercomputer, leveraging its 250 PB storage and 200 petaFLOPS speed to complete the target computation in a matter of days [2]. This episode highlights two important aspects of quantum computing: first, the importance of memory and, second, the subtle relationship between computation and simulation.

Feynman [3] broached the notion that quantum computers would be singularly useful for the simulation of quantum processes, without supposing that this would also make them advantageous at simulating classical processes. Here, we explore issues raised by the recent developments in quantum computing, focusing on the problem of simulating classical stochastic processes via stochastic and quantum computers. We show that using quantum computers to simulate classical processes typically requires nonzero thermodynamic cost, while stochastic computers can theoretically achieve zero cost in simulating classical processes. This supports the viewpoint originally put forth by Feynman—that certain types of computers would each be advantageous at simulating certain physical processes—which challenges the current claims of quantum supremacy. Furthermore, we show that in both classical and quantum simulations, thermodynamic efficiency places a lower bound on the required memory of the simulator.

To demonstrate both, we must prove a new theorem on the thermodynamic efficiency of local operations. Correlation is a resource: it has been investigated as such, in the formalism of resource theories [4] such as that of local operations with classical communication [5], with public communication [6], and many others, as well as the theory of local operations alone, under the umbrella term of common information [7–9]. Correlations have long been recognized as a thermal resource [10–13], enabling efficient computation to be performed when taken properly into account. Local operations that act only on part of a larger system are known to never increase the correlation between the part and the whole; most often, they are destructive to correlations and therefore resource-expensive.

Thermodynamic dissipation induced by a local operation—say on system A of a bipartite system AB to make a new joint system CB—is classically proportional to the difference in mutual informations [14]:

\[ \Delta S_{\text{loc}} = k_B T (I(A : B) - I(C : B)) . \]

This can be asymptotically achieved for quantum systems [15]. By the data processing inequality [16, 17], it is always nonnegative: \( \Delta S_{\text{loc}} \geq 0 \). Optimal thermodynamic efficiency is achieved when \( \Delta S_{\text{loc}} = 0 \).

To identify the conditions, in both classical and quantum computation, when this is so, we draw from prior results on saturated information-theoretic inequalities [18–24]. Specifically, using a generalized notion of quantum sufficient statistic [24–27], we show that a local operation on part of a system is efficient if and only if it unitarily preserves the minimal sufficient statistic of the part for
the whole. Our geometric interpretation of this also draws on recent progress on fixed points of quantum channels [28–31].

Paralleling previous results on $\Delta S_{\text{loc}}$ [14], our particular interest in locality arises from applying it to thermal transformations that generate and manipulate stochastic processes. This is the study of information engines [12, 13, 32, 33]. Rooted in computational mechanics [34–37], which investigates the inherent computational properties of natural processes and the resources they consume, information engines embed stochastic processes and Markovian generators in the physical world, where Landauer’s bound for the cost of erasure holds sway [10].

A key result for information engines is the information-processing Second Law (IPSL): the cost of transforming one stochastic process into another by any computation is at least the difference in their Kolmogorov-Sinai entropy rates [33]. However, actual physical generators and transducers of processes, with their own internal memory dynamics, often exceed the cost required by the IPSL [14]. This arises from the temporal locality of a physical generator—only operating from timestep-to-timestep, rather than acting on the entire process at once. The additional dissipation $\Delta S_{\text{loc}}$ induced by this temporal locality gives the true thermodynamic cost of operating an information engine.

Previous work explored optimal conditions for a classical information engine to generate a process. Working from the hidden Markov model (HMM) [38] that determines an engine’s memory dynamics, it was conjectured that the HMM must be retrodictive to be optimal. For this to hold, the current memory state must be a sufficient statistic of the future data for predicting the past data [14].

Employing a general result on conditions for reversible local computation, the following confirms this conjecture, in the form of an equivalent condition on the HMM’s structure. We then extend this, showing that it holds for quantum generators of stochastic processes [15, 39–47]. Notably, quantum generators are known to provide potentially unbounded advantage in memory storage when compared to classical generators of the same process [40, 41, 43–46]. Surprisingly, the advantage is contingent: optimally-efficient generators—those with $\Delta S_{\text{loc}} = 0$—must not benefit from any memory compression.

While important on its own, this also provides a complementary view to our previous result on quantum generators which showed that a quantum-compressed generator is never less thermodynamically-efficient than the classical generator it compresses [15]. Combined with our current result, one concludes that a quantum-compressed generator is efficient with respect to the generator it compresses but, to the extent that it is compressed, it cannot be optimally efficient. In short, only classical retrodictive generators achieve the lower bound dictated by the IPSL.

II. STATE, MEASUREMENT, AND CHANNELS

The next two sections establish the setting in which we work.

Quantum systems are denoted by letters $A$, $B$, and $C$ and represented by Hilbert spaces $\mathcal{H}_A$, $\mathcal{H}_B$, $\mathcal{H}_C$, respectively. A system (say $A$) has state $\rho_A$ that is a positive bounded operator on $\mathcal{H}_A$. The set of bounded operators on $\mathcal{H}_A$ is denoted by $\mathcal{B}(\mathcal{H}_A)$ and the set of positive bounded operators by $\mathcal{B}_+(\mathcal{H}_A)$.

Measurements $W$, $X$, $Y$, and $Z$ take values in the countable sets $W, X, Y, Z$, respectively. A measurement $X$ on system $A$ is defined by a set of Kraus operators $\{K^{(x)} : x \in X\}$ over $\mathcal{H}_A$ that satisfy the completeness relation: $\sum_x K^{(x)*} K^{(x)} = I_A$—the identity on $\mathcal{H}_A$. Given state $\rho_A$ and measurement $X$, the probability of outcome $x \in X$ is:

$$\Pr(x \in X; \rho_A) := \text{Tr} \left( K^{(x)*} \rho_A K^{(x)} \right)$$

and the state is transformed into:

$$\rho_A|_{X=x} := \frac{K^{(x)*} \rho_A K^{(x)} \downarrow}{\Pr(x \in X; \rho_A)}.$$

If the Kraus operators $\{K^{(x)} : x \in X\}$ are orthogonal to one another and projective, then $X$ is called a projective measurement. Otherwise, $X$ is called a positive-operator valued measure (POVM).

Given a set of projectors $\{\Pi^{(x)}\}$ on a Hilbert space $\mathcal{H}_A$, such that $\sum_x \Pi^{(x)} = I_A$ is the identity, we may decompose $\mathcal{H}_A = \bigoplus_x \mathcal{H}_A^{(x)}$ into a direct sum of subspaces $\mathcal{H}_A^{(x)}$, each one corresponding to the support of projector $\Pi^{(x)}$. We will use the direct sum symbol $\bigoplus$ to indicate sums of orthogonal objects. For instance, if $\rho_A^{(x)}$ is a state on $\mathcal{H}_A^{(x)}$ for each $x$, then $\bigoplus_x \rho_A^{(x)}$ represents a block-diagonal density matrix over $\mathcal{H}_A$. Similarly, if $K_A^{(y|x)}$ represents a linear operator from $\mathcal{H}_A^{(x)}$ to $\mathcal{H}_A^{(y)}$, then $\bigoplus_{x,y} K_A^{(y|x)}$ represents a linear operator from $\mathcal{H}_A$ to itself, defined by a block matrix with diagonal ($x = y$) and off-diagonal elements.

If $\mathcal{H}_A = \bigoplus_x \mathcal{H}_A^{(x)}$ and all the $\mathcal{H}_A^{(x)}$ are unitarily equivalent to one another, then we can equivalently write $\mathcal{H}_A = \mathcal{H}_{A_1} \otimes \mathcal{H}_{A_2}$ where $\mathcal{H}_{A_1}$ is equivalent to each of the $\mathcal{H}_A^{(x)}$ and $\mathcal{H}_{A_2}$ is equivalent to $\mathbb{C}^{|X|}$.

Let $\rho_A$ and $\sigma_A$ be states in $\mathcal{B}_+(\mathcal{H}_A)$. If, for every measurement $X$ and outcome $x \in X$, $\Pr(x \in X; \sigma_A) > 0$ implies
that $\Pr(x;\rho_A) > 0$, then we write $\rho_A \ll \sigma_A$, indicating that $\rho_A$ is absolutely continuous with respect to $\sigma_A$.

To discuss classical systems, we eschew states and instead focus directly on the measurements. In this context, measurements are called random variables. Here, a random variable $X$ is defined over a countable set $\mathcal{X}$, taking values $x \in \mathcal{X}$ with a specified probability distribution $\Pr(X = x)$. When the variable can be inferred from context, we will simply write the probabilities as $\Pr(x)$.

A random variable $X$ can generate a quantum state $\rho_A$ through an ensemble \( \{ (\Pr(X = x), \rho_A^{(x)}) \} \) of potentially nonorthogonal states such that:

\[
\rho_A = \sum_{x \in \mathcal{X}} \Pr(X = x) \rho_A^{(x)}.
\]

A quantum channel is a linear map $\mathcal{E} : \mathcal{B}(\mathcal{H}_A) \to \mathcal{B}(\mathcal{H}_C)$ that is trace-preserving and completely positive. These conditions are equivalent to requiring that there is a random variable $X$ and a set of Kraus operators \( \{ K^{(x)} : x \in \mathcal{X} \} \) such that:

\[
\mathcal{E}(\rho_A) = \sum_x K^{(x)} \rho_A K^{(x)*},
\]

for all $\rho_A$.\(^1\) To every channel $\mathcal{E}$ there is an adjoint $\mathcal{E}^\dagger$:

\[
\text{Tr}(\mathcal{E}(\rho_A) M) = \text{Tr}\left( \rho_A^{\dagger}(M) \right),
\]

for every state $\rho_A \in \mathcal{B}_+(\mathcal{H}_A)$ and operator $M \in \mathcal{B}(\mathcal{H}_A)$. The adjoint has the form:

\[
\mathcal{E}^\dagger(M) = \sum_x K^{(x)*} M K^{(x)}.
\]

Given a subspace $\mathcal{H}_B \subseteq \mathcal{H}_A$, we denote the restriction of $\mathcal{E}$ to $\mathcal{H}_B$ as $\mathcal{E}|_{\mathcal{H}_B} : \mathcal{B}(\mathcal{H}_B) \to \mathcal{B}(\mathcal{H}_C)$. A map $\mathcal{E} : \mathcal{B}(\mathcal{H}_A) \to \mathcal{B}(\mathcal{H}_A)$ is ergodic on a space $\mathcal{H}_A$ if there is no proper subspace $\mathcal{H}_B \subseteq \mathcal{H}_A$ such that the range of $\mathcal{E}|_{\mathcal{H}_B}$ is limited to $\mathcal{B}(\mathcal{H}_B)$. $\mathcal{E}$ is ergodic if and only if it has a unique stationary state $\mathcal{E}(\pi_A) = \pi_A$ [20, and references therein].

The classical equivalent of a quantum channel is, of course, the classical channel that maps a set $\mathcal{X}$ to $\mathcal{Y}$ according to the conditional probabilities $\Pr(Y = y | X = x)$. This may be alternately represented by the stochastic matrix $\mathbf{T} := (T_{yx})$ such that $T_{yx} = \Pr(Y = y | X = x)$. Stochastic matrices are also defined by the conditions that $T_{yx} > 0$ for all $x \in \mathcal{X}$ and $y \in \mathcal{Y}$ and $\sum_y T_{yx} = 1$ for all $x \in \mathcal{X}$. A channel from $\mathcal{X}$ to itself is ergodic if there is no proper subset $\mathcal{Y} \subset \mathcal{X}$ such that, for $x \in \mathcal{Y}$, $\Pr(X' = x' | X = x) > 0$ only when $x' \in \mathcal{Y}$ as well. This is equivalent to requiring that $T_{x'x} := \Pr(X' = x' | X = x)$ is an irreducible matrix.

A classical channel $\Pr(Y = y | X = x)$ can be induced from a joint distribution $\Pr(x, y)$ by the Bayes’ rule $\Pr(y|x) := \Pr(x, y)/\sum_y \Pr(x, y)$, so that the joint distribution may be written as $\Pr(x, y) = \Pr(x) \Pr(y|x) \Pr(y)$. Given three random variables $X, Y, Z$, we write $X - Y - Z$ to denote that $X, Y$, and $Z$ form a Markov chain: $\Pr(x, y, z) = \Pr(x) \Pr(y|x) \Pr(z|y)$. The definition is symmetric in that it also implies $\Pr(x, y, z) = \Pr(z) \Pr(y|z) \Pr(x|y)$.

### III. ENTROPY, INFORMATION, AND DIVERGENCE

The uncertainty of a random variable or measurement is considered to be a proxy for its information content. Often, uncertainty is measured by the Shannon entropy:

\[
H(X) := -\sum_{x \in \mathcal{X}} \Pr(x) \log_2 \Pr(x),
\]

when it does not diverge. Given a system $A$ with state $\rho_A$, the quantum uncertainty is the von Neumann entropy:

\[
H(A) := -\text{Tr}(\rho_A \log_2 \rho_A).
\]

When the same system may have many states in the given context, this is written directly as $H(\rho_A)$. It is the smallest entropy that can be achieved by taking a projective measurement of system $A$. The minimum is attained by the measurement that diagonalizes $\rho_A$.

There are many ways of quantifying the information shared between two random variables $X$ and $Y$. The most familiar is the mutual information:

\[
I(X : Y) := H(X) + H(Y) - H(XY) = \sum_{x,y} \Pr(x, y) \log_2 \left( \frac{\Pr(x, y)}{\Pr(x) \Pr(y)} \right).
\]

Corresponding to the mutual information are the conditional entropies:

\[
H(X|Y) := H(X) - I(X : Y) \quad \text{and} \quad H(Y|X) := H(Y) - I(X : Y).
\]

We will also have occasion to use the conditional mutual information for three variables:

\[
I(X : Y|Z) := \sum_{x,y,z} \Pr(x, y, z) \log_2 \left( \frac{\Pr(x, y|z)}{\Pr(x|z) \Pr(y|z)} \right).
\]

---

\(^1\) It is sufficient for our purposes to consider the case where Kraus operators form a countable set. This holds, for instance, as long as we work with separable Hilbert spaces.
Note that an equivalent condition for $X - Y - Z$ is the vanishing of the conditional mutual information: $I(X : Z|Y) = 0$.

For a bipartite quantum state $\rho_{AB}$ the mutual information is usually taken to be the analogous quantity $I(A : B) = H(A) + H(B) - H(AB)$ and the conditional entropies as $H(A|B) = H(AB) - H(B)$ and so on.

We need a way to compare quantum systems and classical random variables. Consider an ensemble \( \{(\Pr(X = x), \rho_A(x))\} \) generating average state $\rho_A$ and define its Holevo quantity:

\[
I(A : X) := H(\rho_A) - \sum_x \Pr(x) H(\rho_A(x)) .
\]

Consider the ensemble-induced state $\rho_{AB}$ defined by:

\[
\rho_{AB} = \sum_{x \in X} \Pr(X = x) \rho_A(x) \otimes |x\rangle \langle x| ,
\]

where \( \{|x\rangle\} \) is an orthogonal basis on $\mathcal{H}_B$. Such a state is called quantum-classical or classical-quantum if the role of $A$ and $B$ are swapped. In the first case, $I(A : B) = I(A : X)$, where $I(A : B)$ is the mutual information of $\rho_{AB}$ and $I(A : X)$ is the Holevo quantity of the ensemble.

Consider random variables $X_1$ and $X_2$ over the same set $X$ with two possible distributions $\Pr(X_1 = x)$ and $\Pr(X_2 = x)$, respectively, and suppose that whenever $\Pr(X_2 = x) > 0$ we have $\Pr(X_1 = x) > 0$ as well. Then, we can quantify the difference between the two distributions with the relative entropy:

\[
D(\Pr(X_1)\|\Pr(X_2)) := \sum_{x \in X} \Pr(X_1 = x) \log_2 \frac{\Pr(X_1 = x)}{\Pr(X_2 = x)} .
\]

Similarly, two states $\rho_A$ and $\sigma_A$ with $\rho_A \ll \sigma_A$ may be compared via the quantum relative entropy:

\[
D(\rho_A\|\sigma_A) := \Tr(\rho_A \log_2 \rho_A - \rho_A \log_2 \sigma_A) .
\]

The relative entropy leads to allied information-theoretic quantities. For instance:

\[
I(X : Y) = D(\Pr(X,Y)\|\Pr(X) \Pr(Y)) ,
\]

and:

\[
I(A : B) = D(\rho_{AB}\|\rho_A \otimes \rho_B) .
\]

One of the most fundamental information-theoretic inequalities is the monotonicity of the relative entropy under transformations. This is the data processing inequality [16]. For a quantum channel $\mathcal{E}$ it says:

\[
D(\mathcal{E}(\rho_A)\|\mathcal{E}(\rho_A)) \leq D(\rho_A\|\sigma_A) \quad (1)
\]

The condition for equality requires constructing the Petz recovery channel:

\[
\mathcal{R}_\sigma(\cdot) = \sigma^{1/2} \mathcal{E}^\dagger \left(\mathcal{E}(\sigma_A)^{-1/2} \cdot \mathcal{E}(\sigma_A)^{-1/2}\right) \sigma^{1/2} .
\]

It is easy to check that $\mathcal{R}_\sigma \circ \mathcal{E}(\sigma_A) = \sigma_A$. A markedly useful result is that $D(\mathcal{E}(\rho_A)\|\mathcal{E}(\rho_A)) = D(\rho_A\|\sigma_A)$ if and only if $\mathcal{R}_\sigma \circ \mathcal{E}(\rho_A) = \rho_A$ as well [18, 19].

Two other forms of the data processing inequality are useful to note here. The first uses another quantity for measuring distance between states, called the fidelity. The fidelity is defined by

\[
F(\rho, \sigma) := \left(\Tr\left[\sqrt{\sqrt{\rho} \sqrt{\sigma}}\right]\right)^2
\]

which is another way of saying that the states become closer together under the application of a quantum channel $\mathcal{E}$.

The second form arises from applying Eq. (1) to the mutual information. Let $\mathcal{E}_A : \mathcal{B}(\mathcal{H}_A) \rightarrow \mathcal{B}(\mathcal{H}_C)$ be a quantum channel. The local operation $\mathcal{E}_A \otimes I_B$ maps a bipartite system $AB$ to $CB$. The data processing inequality Eq. (1) implies that we have $I(C : B) \leq I(A : B)$.

In these terms, our goal now is to determine conditions for equality using the Petz recovery channel and channel fixed points.

### IV. FIXED POINTS AND REVERSIBLE COMPUTATION

Our starting point is a key result on fixed points of quantum channels [28, 29] that leads to a natural decomposition, as illustrated in Fig. 1.

**Theorem 1** (Channel and Stationary State Decomposition). Suppose $\mathcal{E} : \mathcal{B}(\mathcal{H}_A) \rightarrow \mathcal{B}(\mathcal{H}_A)$ is a quantum channel, Hilbert space $\mathcal{H}_A$ has a transient subspace $\mathcal{H}_T$, and there is a projective measurement $X = \{\Pi(x)\}$ on $\mathcal{H}_T^+$ with countable outcomes $X$, such that $\mathcal{H}_A = \mathcal{H}_T \oplus \left(\bigoplus_x \mathcal{H}_A^{(x)}\right)$, where $\mathcal{H}_A^{(x)}$ is the support of $\Pi(x)$. Then:
The geometric structure implied by the theorem is displayed in Fig. 1. The ergodic subspace of quantum channel $\mathcal{E}$ has two complementary decompositions. First, there is an orthogonal decomposition $H_1^x = \bigoplus_z \mathcal{H}_A^{(x)}$ induced by a projective measurement $X$ whose values are conserved by $\mathcal{E}$’s action. This conservation is decoherent: only states compatible with $X$ are stationary under the action of $\mathcal{E}$. $X$ is called the conserved measurement of $\mathcal{E}$ [31]. Then, each $\mathcal{H}_A^{(x)}$ has a tensor decomposition $\mathcal{H}_A^{(x)} = \mathcal{H}_{AE}^{(x)} \otimes \mathcal{H}_{Adf}^{(x)}$ into an ergodic (E) and a decoherence-free (Df) part. The decoherence-free subspace $\mathcal{H}_{Adf}^{(x)}$ undergoes only a unitary transformation [30]. The ergodic part $\mathcal{H}_A^{(x)}$ is irreducibly mixed such that there is a single stationary state.

This result’s contribution here is to aid in identifying when the data-processing inequality saturates. That is, using Thm. 1 and the Petz recovery channel, we derive necessary and sufficient constraints on the structures of $\rho_A$, $\sigma_A$, and $\mathcal{E}_A$ for determining when $D(\mathcal{E}(\rho_A)||\mathcal{E}(\sigma_A)) = D(\rho_A||\sigma_A)$.

To achieve this, we recall a previously known result [22, 23], showing that it can be derived using only the Petz recovery map and Thm. 1. The immediate consequence is a novel proof; one adapted to our later needs.

**Theorem 2** (Reversible Information Processing). Suppose for two states $\rho_A$ and $\sigma_A$ on a Hilbert space $\mathcal{H}_A$ and a quantum channel $\mathcal{E} : \mathcal{B}(\mathcal{H}_A) \rightarrow \mathcal{B}(\mathcal{H}_A)$, we have:

$$D(\rho_A||\sigma_A) = D(\rho_C||\sigma_C),$$

where $\rho_C = \mathcal{E}_A(\rho_A)$ and $\sigma_C = \mathcal{E}_A(\sigma_A)$. Then there is a measurement $X$ on $A$ with countable outcomes $\mathcal{X}$ and orthogonal decompositions $\mathcal{H}_E = \bigoplus_z \mathcal{H}_A^{(x)}$ and $\mathcal{H}_C$ such that:

1. For all $\rho \in \mathcal{B}(\mathcal{H}_A^{(x)})$ and $\mathcal{E}(\rho) \in \mathcal{B}(\mathcal{H}_C^{(x)})$, the mapping $\mathcal{E}|_{\mathcal{H}_A^{(x)}}$ onto $\mathcal{B}(\mathcal{H}_C^{(x)})$ is surjective.

2. Subspaces $\mathcal{H}_A^{(x)}$ further decompose into:

$$\mathcal{H}_A^{(x)} = \mathcal{H}_{AE}^{(x)} \otimes \mathcal{H}_{Adf}^{(x)},$$

and the map $\mathcal{E}_A^{(x)}(\cdot) := \sum_z K_{AE}^{(a,x)} \cdot K_{AE}^{(a,x)}$ has a unique invariant state $\pi_{AE}$.

3. Any subspace of $\mathcal{H}$ satisfying the above two properties is, in fact, $\mathcal{H}_A^{(x)}$ for some $x \in \mathcal{X}$.

Furthermore, if $\rho_A$ is any invariant state—that is, $\rho_A = \mathcal{E}_A(\rho_A)$—then it decomposes as:

$$\rho_A = \bigoplus_{x \in \mathcal{X}} \Pr(x) \pi_{AE}^{(x)} \otimes \rho_{Adf}^{(x)},$$

for any distribution $\Pr(x)$ and state $\rho_{Adf}^{(x)}$ satisfying $L_{Adf}^{(a)} L_{Adf}^{(a)} = \rho_{Adf}$. The geometric structure implied by the theorem is displayed in Fig. 1.
for some $\pi_{A_E}^{(x)}$. And, their images are:

$$\rho_C = \sum_{x \in X} \Pr(x; \rho) \pi_{E}^{(x)} \otimes \rho_{C_{Di}}^{(x)}$$

$$\sigma_C = \sum_{x \in X} \Pr(x; \sigma) \pi_{E}^{(x)} \otimes \sigma_{C_{Di}}^{(x)},$$

where $\pi_x = E^{(x)}_{A_E} (\pi_{E}^{(x)})$ and $\rho_{C_{Di}}^{(x)} = U^{(x)}_{A_{Di}} (\rho_{A_{Di}}) U^{(x)}_{A_{Di}}$ and $\sigma_{C_{Di}}^{(x)} = U^{(x)}_{A_{Di}} (\sigma_{A_{Di}}) U^{(x)}_{A_{Di}}$.

We know that $\mathcal{N}_\sigma := \mathcal{R}_\sigma \circ \mathcal{E}$ must have both $\rho_A$ and $\sigma_A$ as stationary distributions. Let $X$ be the conserved measurement of $\mathcal{N}_\sigma$, which induces the decompositions $\mathcal{H}_A = \mathcal{H}_T \oplus (\bigoplus_x \mathcal{H}_A^{(x)})$ and $\mathcal{H}^{(x)}_A = \mathcal{H}_{A_E} \otimes \mathcal{H}^{(x)}_{A_{Di}}$, as well as the state decompositions Eq. (8).

From here we leverage the fact that $\mathcal{N}_\sigma |_{\mathcal{H}_A^0}$ has Kraus decomposition of the form Eq. (5). The net effect is summed up by two constraints:

1. For each $\alpha$, $K^{(x)}$ maps each $\mathcal{H}^{(x)}_A$ to itself.
2. Let $K^{(x)}$ be the block of $K^{(x)}$ restricted to $\mathcal{H}^{(x)}_A$. Let $M$ be a complete projective measurement on $\mathcal{H}^{(x)}_{A_{Di}}$ with basis $\{|m\}$ and define the transformed basis $\{|\tilde{m}\} = U^{(x)}(|m\rangle)$. Now, let $\mathcal{H}^{(x,m)}_A = \{|\psi\rangle \otimes |m\rangle : |\psi\rangle \in \mathcal{H}^{(x)}_A\}$ and similarly for $\mathcal{H}^{(x,m)}_{A_{Di}}$. Then, $K^{(x)}$ maps $\mathcal{H}^{(x,m)}_A$ to $\mathcal{H}^{(x,m)}_{A_{Di}}$. This is true for any measurement $M$.

These two constraints are what we need to prove Eq. (7). Each is a form of distinguishability criterion for the total channel $\mathcal{N}_\sigma |_{\mathcal{H}_A^0}$. Since $\mathcal{N}_\sigma$ can tell certain orthogonal outcomes apart, so too must $\mathcal{E}$. Or else, $\mathcal{R}_\sigma$ would “pull apart” nonorthogonal states. However, this is impossible for a quantum channel. By formally applying this notion to constraints 1 and 2 above, we will recover Eq. (7).

Let $L^{(x)}$ be the Kraus operators of $\mathcal{E} |_{\mathcal{H}_A^0}$. Then $K^{(x)} = \sigma^{1/2} L^{(x)} \sigma^{1/2} \mathcal{E} \sigma^{1/2} L^{(x)}$. Now, if $L^{(x)}$ did not map each $\mathcal{H}^{(x)}_A$ to some orthogonal subspace $\mathcal{H}^{(x)}_C$, then for some distinct $x$ and $x'$ there would be $|\psi\rangle \in \mathcal{H}^{(x)}_A$ and $|\phi\rangle \in \mathcal{H}^{(x')}_C$ such that $F(\mathcal{E}(|\psi\rangle \langle \psi|), \mathcal{E}(|\phi\rangle \langle \phi|)) > 0$ (recall fidelity is defined in Eq. (3)). However, we must also have $F(\mathcal{N}_\sigma(|\psi\rangle \langle \psi|), \mathcal{N}_\sigma(|\phi\rangle \langle \phi|)) = 0$, which is impossible as applying $\mathcal{R}_\sigma$ cannot reduce fidelity, by Eq. (4). So, it must be the case that $L^{(x)}$ maps each $\mathcal{H}^{(x)}_A$ to some orthogonal subspace $\mathcal{H}^{(x)}_C$. This proves Claim 1 in Thm. 2.

Let $L^{(x)}$ be the block of $L^{(x)}$ restricted to $\mathcal{H}^{(x)}_A$. Further, let $M$ be a complete measurement on $\mathcal{H}^{(x)}_{A_{Di}}$. Then $\mathcal{E} |_{\mathcal{H}^{(x,m)}_A}$ must map each $\mathcal{H}^{(x,m)}_C$ onto orthogonal subspaces $\mathcal{H}^{(x,m)}_C$ of $\mathcal{H}^{(x)}_C$, lest $\mathcal{N}_\sigma |_{\mathcal{H}^{(x)}_A}$ could not map each $\mathcal{H}^{(x,m)}_A$ to orthogonal spaces $\mathcal{H}^{(x,m)}_A$. This follows from fidelity, as in the previous paragraph.

Now, let $L^{(x,m)} : \mathcal{H}^{(x,m)}_A \rightarrow \mathcal{H}^{(x,m)}_C$, so that:

$$L^{(x)} = \bigoplus_m L^{(x,m)} \otimes |m\rangle.$$ 

Let $N$ be another complete measurement on $\mathcal{H}^{(x)}_{A_{Di}}$ such that $|n\rangle = \sum_m w_{m,n} |m\rangle$, with $w_{m,n}$ a unitary matrix. And, let $n, n' \in N$ be distinct. We have for any $|\psi\rangle$ that:

$$\mathcal{E}(|\psi\rangle \langle \psi| \otimes |n\rangle \langle n|) = \sum_{\alpha, \alpha, m, m'} \bigoplus_{w_{m,n}} w_{m,n} L^{(\alpha,x,m)} |\psi\rangle \langle \psi| L^{(\alpha,x,m')} |\psi\rangle \langle \psi| L^{(\alpha,x,m')}.$$ 

Now, it must be that $\mathcal{E}(|\psi\rangle \langle \psi| \otimes |n\rangle \langle n|)$ and $\mathcal{E}(|\psi\rangle \langle \psi| \otimes |n'\rangle \langle n'|)$ are orthogonal. However:

$$\text{Tr} \left[ \mathcal{E}^{(x)}(|\psi\rangle \langle \psi| \otimes |n\rangle \langle n|) \mathcal{E}^{(x)}(|\psi\rangle \langle \psi| \otimes |n'\rangle \langle n'|) \right] = \sum_{\alpha, \alpha' = m} \sum_{w_{m,n}} w_{m,n} L^{(\alpha,x,m)} \langle\psi| L^{(\alpha,x,m)} |\psi\rangle.$$ 

This vanishes for arbitrary $N$ and $|\psi\rangle$ only if $L^{(\alpha,x,m)} |\psi\rangle$ is independent of $m$ for each $\alpha$ and $\alpha'$. This implies that $L^{(\alpha,x,m)} = W^{(m)} L^{(\alpha,x)}$ for some unitary $W^{(m)}$.

All of which is to conclude that the $\mathcal{H}^{(x,m)}_C$ for each $m$ must be unitarily equivalent. And so, the decomposition $\mathcal{H}^{(x)}_C = \bigoplus_m \mathcal{H}^{(x,m)}_C$ instead becomes a tensor product decomposition $\mathcal{H}^{(x)}_C = \bigotimes \mathcal{H}^{(x,m)}_C$ and further that $L^{(x)} = L^{(x)} \bigotimes L^{(x,m)}$. Finally, the constraints Eq. (9) follow from the form of $\mathcal{E}$ and Eq. (8). □

Theorem 2’s main implication is that, when a channel $\mathcal{E}$ acts, information stored in the conserved measurement and in the decoherence-free subspaces is recoverable. Two states that differ in terms of the conserved measurement and the decoherence-free subspaces remain different and do not grow more similar under $\mathcal{E}$’s action. Conversely, information stored in measurements not compatible with the conserved measurement or stored in the ergodic subspaces is irreversibly garbled by $\mathcal{E}$.

The next section uses this decomposition to study how locally acting channels impact correlations between subsystems. This directly drives the thermodynamic efficiency of local operations. Namely, correlations must be stored specifically in the conserved measurement and
decoherence-free subspaces of the local channel for thermodynamic efficiency.

V. REVERSIBLE LOCAL COMPUTATION

Suppose we are given a bipartite system $AB$ with state $\rho_{AB}$. We wish to determine the conditions for a local channel $\mathcal{E}_A \otimes I_B$ that maps $A$ to $C$:

$$\rho'_{CB} = \mathcal{E}_A \otimes I_B (\rho_{AB})$$

to preserve the mutual information $I(A : B) = I(C : B)$. Potentially, this could be established by combining a former result—conditions for vanishing conditional mutual information $I(A : B|C)$ for a tripartite state [21]—with the channel-state duality. However, it is more straightforward and physically enlightening to derive the answer from Thm. 2.

Stating our result requires first defining the quantum notion of a sufficient statistic. Previously, quantum sufficient statistics of $A$ for $B$ were defined when $AB$ is a classical-quantum state [27]. That is, when $\rho_{AB}$ commutes with a local measurement on $A$. They were also introduced in the setting of sufficient statistics for a family of states [24, 25]. This corresponds to the case where $AB$ is quantum-classical—$\rho_{AB}$ commutes with a local measurement on $B$. Our definition generalizes these cases to fully-quantal correlations between $A$ and $B$.

We start, as an example, by giving the following definition of a minimum sufficient statistic of a classical joint random variable $XY \sim \text{Pr}(x, y)$ in terms of an equivalence relation. We define the predictive equivalence relation $\sim$ for which $x \sim x'$ if and only if $\text{Pr}(y|x) = \text{Pr}(y|x')$ for all $y$. The minimum sufficient statistic (MSS) $\{X\}_{Y}$ is given by the equivalence classes $\{x\}_{Y} := \{x' : x \sim x'\}$. Let us denote $\Sigma := \{X\}_{Y}$ and let $\text{Pr}(y|\sigma) := \text{Pr}(y|x)$ for any $x \in \sigma$.

This cannot be directly generalized to the quantum setting since correlations between $A$ and $B$ cannot always be described in the form of states conditioned on the outcome of a local measurement on $A$. If the latter were the case, the state would be classical-quantum, but general quantum correlations can be much more complicated than these. However, we can take the most informative local measurement that does not disturb $\rho_{AB}$ and then consider the “atomic” quantum correlations it leaves behind.

Let $\rho_{AB}$ be a bipartite quantum state. A maximal local commuting measurement (MLCM) of $A$ for $B$ is any local measurement $X$ on system $A$ such that:

$$\rho_{AB} = \bigoplus_x \text{Pr}(X = x)\rho_{AB}^{(x)} ,$$

where:

$$\text{Pr}(X = x) = \text{Tr}\left( (\Pi_X^{(x)} \otimes I_B)\rho_{AB} \right)$$

and:

$$\text{Pr}(X = x)\rho_{AB}^{(x)} = (\Pi_X^{(x)} \otimes I_B)\rho_{AB}(\Pi_X^{(x)} \otimes I_B) ,$$

and any further local measurement $Y$ on $\rho_{AB}^{(x)}$ disturbs the state:

$$\rho_{AB}^{(x)} \neq \sum_y (\Pi_Y^{(y)} \otimes I_B)\rho_{AB}^{(x)}(\Pi_Y^{(y)} \otimes I_B) .$$

We call the states $\{\rho_{AB}^{(x)}\}$ quantum correlation atoms.

We state several facts about an MLCM. First, it is unique.

**Proposition 1** (MLCM uniqueness). Given a state $\rho_{AB}$, there is a unique MLCM of $A$ for $B$.

Suppose there were two distinct MLCMs, $X$ and $Y$. Then:

$$\rho_{AB} = \sum_y \text{Pr}(X = x)(\Pi_Y^{(y)} \otimes I_B)\rho_{AB}(\Pi_Y^{(y)} \otimes I_B) .$$

This can be written as:

$$\rho_{AB} = \bigoplus_x \sum_y \text{Pr}(X = x)(\Pi_Y^{(y)} \otimes I_B)\rho_{AB}^{(x)}(\Pi_Y^{(y)} \otimes I_B) .$$

However, this means for each $x$:

$$(\Pi_Y^{(y)} \otimes I_B)\rho_{AB}^{(x)}(\Pi_Y^{(y)} \otimes I_B) = \rho_{AB}^{(x)} .$$

So, $X$ is not a MLCM, giving a contradiction. □

Second, the following proposition on MLCMs for classical-quantum states is useful in later applications.

**Proposition 2** (MLCM for a classical-quantum state). Given a classical-quantum state:

$$\rho_{AB} := \sum_x \text{Pr}(x) |x\rangle \langle x| \otimes \rho_B^{(x)} ,$$

the MLCM is the most refined measurement $\Theta$ such that:

$$\rho_{B}^{(x)} = \sum_\theta \Pi^{(\theta)}_B \rho_B^{(x)} \Pi^{(\theta)}$$

for all $x$.

Given that $\Theta$ is a commuting local measurement, the question is whether it is maximal. If it is not maximal, though, there is a refinement $Y$ that is also a commuting local measurement. By $\Theta$’s definition, there is an $x$ such that $\rho_{B}^{(x)} \neq \sum_y \Pi^{(y)}_B \rho_B^{(x)} \Pi^{(y)}$. This implies $\rho_{AB} \neq \sum_y (I \otimes$
Then, \( \Pi^{(y)}_B \rho_{AB} (I \otimes \Pi^{(y)}) \), contradicting the assumption that \( Y \) is commuting local. \( \square \)

Now, as in the classical setting, we define an equivalence class over the values of the MLCM via the equivalence between their quantum correlation atoms. Classically, these atoms are simply the conditional probability distributions \( \Pr (|x|) \); in the classical-quantum setting, they are the conditional quantum states \( \rho^{(x)}_B \). Note that each is defined as a distribution on the variable \( Y \) or system \( B \). In contrast, the general quantum correlation atoms \( \rho^{(x)}_{AB} \) depend on both systems \( A \) and \( B \).

The resulting challenge is resolved in the following way. Let \( \rho_{AB} \) be a bipartite quantum state and let \( X \) be the MLCM of \( A \) for \( B \). We define the correlation equivalence relation \( x \sim x' \) over values of \( X \) where \( x \sim x' \) if and only if \( \rho^{(x)}_{AB} = (U \otimes I_B) \rho^{(x')}_{AB} (U^\dagger \otimes I_B) \) for a local unitary \( U \).

Finally, we define the Minimal Local Sufficient Statistic (MLSS) \([X]_\sim\), as the equivalence class \([x]_\sim := \{x' : x' \sim x\}\) generated by the relation \( \sim \) over correlation atoms. Thus, our notion of sufficiency of \( A \) for \( B \) is to find the most informative local measurement and then coarse-grain its outcomes by unitary equivalence over their correlation atoms. The correlation atoms and the MLSS \([X]_\sim\) together describe the correlation structure of the system \( AB \).

The machinery is now in place to state our result.

**Theorem 3** (Reversible local operations). Let \( \rho_{AB} \) be a bipartite quantum state and let \( \mathcal{E}_A \otimes I_B \) be a local operation with \( \mathcal{E}_A : \mathcal{B}(\mathcal{H}_A) \rightarrow \mathcal{B}(\mathcal{H}_C) \). Suppose \( X \) is the MLCM of \( \rho_{AB} \) and \( Y \), that of \( \rho_{CB} = \mathcal{E}_A \otimes I_B (\rho_{AB}) \). The decomposition into correlation atoms is:

\[
\rho_{AB} = \bigoplus_x \Pr_A (x) \rho^{(x)}_{AB} \quad \text{and} \\
\rho_{CB} = \bigoplus_y \Pr_C (y) \rho^{(y)}_{CB} .
\]

Then, \( I (A : B) = I (C : B) \) if and only if \( \mathcal{E}_A \) can be expressed by Kraus operators of the form:

\[
K^{(x)} = \bigoplus_{x,y} e^{i\phi_{xy}} \sqrt{\Pr (y, \alpha|x)} U^{(y|x)} ,
\]

where \( \phi_{xy} \) is an arbitrary phase and \( \Pr (y, \alpha|x) \) is a stochastic channel that is nonzero only when \( \rho^{(x)}_{AB} \) and \( \rho^{(y)}_{CB} \) are equivalent up to a local unitary operation \( U^{(y|x)} \) that maps \( \mathcal{H}_A \) to \( \mathcal{H}_C \).

We can apply the Reversible Information Processing theorem (Thm. 2) from the previous section here. This demands that there be a measurement \( X \) and a decomposition of the Hilbert space \( \mathcal{H}_A = \mathcal{H}_{A_E} \otimes \mathcal{H}_{A_D} \) such that:

\[
\rho_{AB} = \sum_x \Pr_A (x) \rho^{(x)}_{AB} \otimes \rho^{(x)}_{AB} ; \\
\rho_A \otimes \rho_B = \sum_x \Pr_A (x) \rho^{(x)}_{AB} \otimes \left( \rho^{(x)}_{AB} \otimes \rho^{(x)}_{B_D} \right) ,
\]

such that \( \mathcal{E}_A \otimes I_B \) conserves measurement \( X \) and acts decoherently on \( (AB)_E \) and coherently on \( (AB)_D \). However, the local nature of \( \mathcal{E}_A \otimes I_B \) makes it clear we can simplify this decomposition to:

\[
\rho_{AB} = \sum_x \Pr_A (x) \rho^{(x)}_{AB} \otimes \left( \rho^{(x)}_{AB} \right) \\
\rho_A \otimes \rho_B = \sum_x \Pr_A (x) \rho^{(x)}_{AB} \otimes \left( \rho^{(x)}_{AB} \otimes \rho^{(x)}_{B_D} \right) ,
\]

where \( \mathcal{E}_A \) conserves the local measurement \( X \) on \( A \) and acts decoherently on \( A_E \) and acts as a local unitary \( U_{A_D} \otimes I_B \) on \( A_{D_B} \).

Suppose now, however, that given \( X \) the variable \( Y \) is the diagonalizing measurement of \( \rho^{(x)}_{AB} \) and \( Z_\Sigma \) is the MLCM of \( \rho^{(x)}_{AB} \). The joint measurement \( X Y X Z \)—where \( X \) is measured first and then the other two measurements are determined with knowledge of its outcome—is the MLCM of \( \rho_{AB} \). Note that for any \( x \) and \( z \), the outcomes \( (x, y, z) \) and \( (x', y, z) \) are correlation equivalent: measurement \( Y_X \) is completely decoupled from system \( B \). Then, the MLSS \( \Sigma := \{XYXZ\}_B \) is simply a function of \( X \) and \( Z_X \).

Since \( XZ_X \) is conserved by the action of \( \mathcal{E}_A \otimes I \)—where \( X \) is the conserved measurement, while \( Z_X \) is preserved through the unitary evolution—the MLSS \( \Sigma \) must be preserved and each correlation atom is transformed only by a local unitary. This results in the form Eq. (12).

This proves that \( I (A : B) = I (C : B) \) implies Eq. (12). The converse is straightforward to check. Let \( \Sigma = \{X\}_B \) and let \( I (A : B|\Sigma = \sigma) \) be the mutual information of \( \rho^{(x)}_{AB} \) for any \( x \in \sigma \). (This is the same for all such \( x \) by local unitary equivalence.) Then:

\[
I (A : B) = \sum_{\sigma} \Pr (\Sigma = \sigma) I (A : B|\Sigma = \sigma) .
\]

Similarly, let \( \Sigma' = \{Y\}_B \) and let \( I (C : B|\Sigma' = \sigma') \) be the mutual information of \( \rho^{(y)}_{CB} \) for any \( y \in \sigma' \); then:

\[
I (C : B) = \sum_{\sigma'} \Pr (\Sigma' = \sigma') I (C : B|\Sigma' = \sigma') .
\]

Since \( \mathcal{E} \) isomorphically maps each \( \sigma \) to a unique \( \sigma' \), such that \( I (A : B|\Sigma = \sigma) = I (C : B|\Sigma' = \sigma') \) by unitary equivalence, we must have \( I (A : B) = I (C : B) \). \( \square \)

The theorem’s classical form follows as a corollary.
Corollary 1 (Reversible local operations, classical). Let $XY$ be a joint random variable and let $\Pr(Z = z | X = x)$ be a channel from $X$ to some set $Z$, resulting in the joint random variable $ZY$. Then $I(X : Y) = I(Z : Y)$ if and only if $\Pr(Z = z | X = x) > 0$ only when $\Pr(Y = y | Z = z) = \Pr(Y = y | X = x)$ for all $y$. Equivalently, if we consider the joint random variable $ZXY \sim \Pr(Z = z | X = x, Y = y)$, then $I(X : Y) = I(Z : Y)$ if and only if $X - Z - Y$ (in addition to the Markov chain $Z - X - Y$, which holds by definition).

The first form in terms of the conditional distribution follows directly from Eq. (12) when classicality is enforced. The second form, in terms of Markov chains, follows from the fact that $I(X : Y) - I(Z : Y) = I(X : Y | Z)$ by the Markov chain $Z - X - Y$, but $I(X : Y | Z)$ only vanishes when $X - Z - Y$. □

VI. THERMODYNAMICS OF QUANTUM INFORMATION RESERVOIRS

The thermodynamic relevance of these theorems arises most immediately when applying Landauer’s Principle to a single subsystem of an information reservoir—a system all of whose states have the same energy level. Landauer’s Principle for quantum systems says that to change an information reservoir $A$ from state $\rho_A$ to state $\rho'_A$ requires a work cost satisfying the lower bound:

$$W \geq k_B T \ln 2 (\mathbb{H}[\rho_A] - \mathbb{H}[\rho'_A]) .$$

Note that the lower bound $W_{\text{min}} := k_B T \ln 2 (\mathbb{H}[\rho_A] - \mathbb{H}[\rho'_A])$ is simply the change in free energy for an information reservoir. Further, due to an information reservoir’s trivial Hamiltonian, all of the work $W$ becomes heat $Q$. Then the total entropy production—of system and environment—is:

$$\Delta S := Q + k_B T \ln 2 \Delta \mathbb{H}[A] = W - W_{\text{min}} .$$

Thus, not only does Landauer’s Principle provide the lower bound, but reveals that any work exceeding $W_{\text{min}}$ represents dissipation.

Reference [14] showed that Landauer’s bound may indeed be attained in the quasistatic limit for any channel acting on a classical information reservoir. This result generally does not extend to single-shot quantum channels [48]. However, when we consider asymptotically-many parallel applications of a quantum channel, we recover the tightness of Landauer’s bound [15].

Reference [14] introduced the following perspective. Consider a bipartite information reservoir $AB$, on which we wish to apply the local channel $\mathcal{E} \otimes I_B$, where $\mathcal{E} : \mathcal{B}(\mathcal{H}_A) \to \mathcal{B}(\mathcal{H}_C)$ maps system $A$ into system $C$, transforming joint state $\rho_{AB}$ to final state $\rho_{CB}$. The Landauer bound for $AB \to CB$ is given by $W_{\text{min}} = k_B T \ln 2 (\mathbb{H}[\rho_{AB}] - \mathbb{H}[\rho_{CB}])$. However, since we constrained ourselves to use local manipulations, the lowest achievable bound is $W_{\text{loc}} := k_B T \ln 2 (\mathbb{H}[\rho_A] - \mathbb{H}[\rho_C])$.

Thus, we must have dissipation of at least:

$$\Delta S \geq W_{\text{loc}} - W_{\text{min}} = k_B T \ln 2 (\mathbb{H}[\rho_A] - \mathbb{H}[\rho_{AB}] - \mathbb{H}[\rho_{CB}]) = k_B T \ln 2 (\mathbb{I}[A : B] - \mathbb{I}[C : B]) .$$

And so, we have a minimal locality dissipation:

$$\Delta S_{\text{loc}} := k_B T \ln 2 (\mathbb{I}[A : B] - \mathbb{I}[C : B]) ,$$

which arises because we did not use the correlations to facilitate our erasure. See Fig. 2 for a simple example of this phenomenon.

These considerations then lead to a simple thermodynamic interpretation of Thm. 3 and Cor. 1: local channels that circumvent dissipation due to their locality are precisely those channels that preserve the sufficiency structure of the joint state. They may create and destroy any information that is not stored in the sufficient statistic and the correlation atoms. However, the sufficient statistic itself must be conserved and the correlation atoms must be only unitarily transformed.

We now turn to apply this perspective to classical and quantum generators—systems that use thermodynamic mechanisms to produce stochastic processes. We compute the necessary and sufficient conditions for these generators to have zero locality dissipation: $\Delta S_{\text{loc}} = 0$. And so, determine precise criteria for when they are thermodynamically efficient.

VII. THERMODYNAMICS OF CLASSICAL GENERATORS

The core of a classical generator is a hidden Markov model (HMM) [38] $G = (S, \mathcal{X}, \{T_{s\to t}^{(x)}\})$, where (here) $S$ is countable, $\mathcal{X}$ is finite, and for each $x \in \mathcal{X}$, $T^{(x)}$ is a matrix with values given by a stochastic channel from $S$ to $S \times \mathcal{X}$, $T_{s\to t}^{(x)} := \Pr_{\mathcal{X}}(s', x | s)$. We define generators to use recurrent HMMs, which means the total transition matrix $T_{s\to t} := \sum_x T_{s\to t}^{(x)}$ is irreducible. In this case, there is a unique stationary distribution $\pi_{G}(s)$ over states $S$ satisfying $\pi_{G}(s) > 0$, $\sum_s \pi_{G}(s) = 1$, and $\sum_s T_{s\to t} \pi_{G}(s) = \pi_{G}(s')$.

During its operation, a generator’s function is to produce a stochastic process—for each $\ell$, a distribution
Typically, we view a generator as operating over discrete time, writing out a sequence of symbols from $x \in \mathcal{X}$ on a tape, while internally transforming its memory state; see Fig. 3. Starting with an initial state $S_0 \sim \pi(s)$ and empty tape at time $t = 0$, the entire system at time $t$ is described by the joint random variable $X_1 \ldots X_t S_t$, with distribution:

$$
\Pr_\Theta(x_1 \ldots x_t) := \sum_{s_0 \ldots s_{t-1} \in \mathcal{S}^t} T(x_{s_{t-1}}) \ldots T(x_{s_0}) \pi_\Theta(s_0).
$$

FIG. 2. Example of the thermodynamics of locality. Suppose we have two bits, $XY$, in a correlated state where $1/2$ probability is in $XY = 00$ and $1/2$ probability is in $XY = 11$. (a) A thermodynamically irreversible operation can be performed to erase only $X$ (that is, set $X = 0$ without changing $Y$) if we are not allowed to use knowledge about the state of $Y$. (b) A reversible operation can be performed to erase $X$ if we are allowed to use knowledge about $Y$. Both operations have the same outcome given our initial condition, but the nonlocal operation (a) is more thermodynamically costly because it is irreversible. According to Thm. 3, operation (a) is costly since it erases information in $X$ that is correlated with $Y$.

We have two bits, $X_1$, $X_2$, with

$$
\Pr(x_1 x_2) := \frac{1}{2} (\delta(x_1 0 \mid x_2) + \delta(x_1 1 \mid x_2)).
$$

We call this distribution $\pi_0$, and define the Markov chain $(S, \pi_0)$ by

$$
S_t = \begin{cases} 0 & \text{with probability } p, \\ 1 & \text{with probability } 1-p. 
\end{cases}
$$

Since $S_0 \sim \pi_0$, the process $(S, \pi_0)$ satisfies the assumptions of Thm. 3. The output of the controller is a sequence of symbols,

$$
\Phi(x_1 \ldots x_t) := \sum_{s_0 \ldots s_{t-1} \in \mathcal{S}^t} T(x_{s_{t-1}}) \ldots T(x_{s_0}) \pi_\Theta(s_0).
$$

Continuing this technique, one can compute the joint random variable $X_1 \ldots X_t S_t X_{t+1} X_{t+2} \ldots$ and see that $(X_1 \ldots X_t) - (S_t) - (X_{t+1} X_{t+2})$ is a Markov chain for all $t$.

This picture of a generator as operating on a tape while continually erasing and rewriting its internal memory allows us to define the possible thermodynamics, also shown in Fig. 3. Erasure generally requires work, drawn from the work reservoir, while the creation of noise often allows the extraction of work, which is represented in our sign convention by drawing negative work from the reservoir. Producing a process $X_1 \ldots X_t \sim \Pr(x_1 \ldots x_t)$ of length $t$ has an associated work cost $W \geq -k_B T \ln 2 \mathcal{H}(X_1 \ldots X_t)$. The negative sign, as discussed, indicates work $k_B T \ln 2 \mathcal{H}(X_1 \ldots X_t)$ may be transferred from the thermal reservoir to the work reservoir. For large $t$, this can be asymptotically expressed by the work rate $W/t \geq -k_B T \ln 2 \mu$, where:

$$
\mu := \lim_{t \to \infty} \frac{1}{t} \mathcal{H}[X_1 \ldots X_t]
$$

is the process’ Kolmogorov-Sinai entropy rate [33]. This
is a reasonable description of the average entropy rate of a process that is stationary—that is, \( \Pr(X_1 \ldots X_{t+1} = x_1 \ldots x_{t-1}) \) is independent of \( t \)—and ergodic. Said differently, for large \( t \) a typical realization \( x_1 \ldots x_t \) contains the word \( \tilde{x}_1 \ldots \tilde{x}_t \) approximately \( t \times \Pr(\tilde{x}_1 \ldots \tilde{x}_t) \) times. Recurrent generators produce exactly these sorts of processes.

Now, a given generator cannot necessarily be implemented as efficiently as the minimal work rate \( W_{\text{min}} := -k_B T \ln 2 \ h_\theta \) indicates. This is because a generator acts temporally locally, only being able to use its current memory state to generate the next memory state and symbol. The true cost at time \( t \) must be bounded below by \( W_{\text{loc}} := W_{\text{min}} + \Delta S_{\text{loc}} \), where in this case the locality dissipation is [14]:

\[
\Delta S_{\text{loc}} = k_B T \ln 2 \ (I(S_t : X_1 \ldots X_t) - I(S_{t+1} : X_1 \ldots X_t)).
\]

In this case, the dissipation does not represent work lost to heat but rather the increase in tape entropy that did not facilitate converting heat into work. To understand this in some detail, this section identifies the necessary and sufficient conditions for efficient generators—those with \( \Delta S_{\text{loc}} = 0 \).

To state our result for classical generators, we must introduce several, further notions regarding generators. Consider a partition of \( S \): \( P = \{P_\theta \}, P_\theta \cap P_\theta', \cup_\theta P_\theta = S \), labeled by index \( \theta \). Let:

\[
\Pr_\theta (\theta', x | \theta) := \sum_{s' \in P_{\theta'}} \Pr_\theta (s', x | s ) \pi(s | \theta),
\]

with \( \pi_\theta(s|\theta) = \pi_\theta(s)/\pi_\theta(\theta) \) and \( \pi_\theta(\theta) = \sum_{s \in P_\theta} \pi_\theta(s) \). We say a partition \( \{P_\theta \} \) is mergeable with respect to the generator \( \Phi = (S, \mathcal{X}, \{T_{\theta,s}^{(x)} \}) \) if the merged generator \( \Phi^P = (P, \mathcal{X}, \{T_{\theta,s}^{(x)} \}) \), with transitions \( T_{\theta,s}^{(x)} := \Pr(\theta', x | \theta) \), generates the same process as the original.

Pertinent to our goals here is the notion of retrodictive equivalence. Let \( \Pr_\theta (x_1 \ldots x_t | s_t) := \Pr_\theta (x_1 \ldots x_t, s_t) / \pi_\theta (s_t) \). Given two states \( s, s' \in S \) of a generator \( (S, \mathcal{X}, \{T_{s,s'}^{(x)} \}) \), we say that \( s \sim s' \) if \( \Pr_\theta (x_1 \ldots x_t | s) = \Pr_\theta (x_1 \ldots x_t | s') \) for all words \( x_1 \ldots x_t \). The equivalence class \( [S_t]_\sim \) is the sufficient statistic of \( S_t \) for predicting the past symbols \( X_1 \ldots X_t \). The set \( P_\sim := \{ [s]_\sim : s \in S \} \) of equivalence classes is a partition on \( S \) that we index by \( \sigma \). We then have another proposition.

**Proposition 3.** Given a generator \((S, \mathcal{X}, \{T_{s,s'}^{(x)} \})\), the partition \( P := P_\sim \) generated by retrodictive equivalence is mergeable.

To see this, we follow a proof by induction. We first suppose that the distribution \( \Pr_{\Phi^P} (x_1 \ldots x_t, \sigma_t) \) is equal to the distribution:

\[
\Pr_\Phi (x_1 \ldots x_t, \sigma_t) := \sum_{s_t \in P_{\sigma_t}} \Pr_\Phi (x_1 \ldots x_t, s_t),
\]

for some \( t \). Then, noting that:

\[
\Pr_\Phi (x_1 \ldots x_{t+1}, s_{t+1}) = \sum_{s_t \in P_{\sigma_t}} \Pr_\Phi (x_1 \ldots x_{t+1} | s_t) T_{s_{t+1} | s_t}^{(x_{t+1})},
\]

we have:

\[
\Pr_{\Phi^P} (x_1 \ldots x_{t+1}, \sigma_{t+1}) = \sum_{s_t \in P_{\sigma_t}, s_{t+1} \in P_{\sigma_{t+1}}} \Pr_{\Phi^P} (x_1 \ldots x_{t+1} | s_t, \sigma_{t+1}) T_{s_{t+1} | s_t}^{(x_{t+1})},
\]

Now, for \( t = 1 \), we have:

\[
\Pr_{\Phi^P} (x_1, \sigma_1) = \sum_{\sigma_0} \Pr_{\Phi^P} (\sigma_0) T_{\sigma_1 | \sigma_0}^{(x_1)},
\]

Then by induction, \( \Pr_{\Phi^P} (x_1 \ldots x_t, \sigma_t) = \Pr_\Phi (x_1 \ldots x_t, \sigma_t) \) for all \( t \). By summing over \( \sigma_t \), we have \( \Pr_{\Phi^P} (x_1 \ldots x_t) = \Pr_\Phi (x_1 \ldots x_t) \) for all \( t \) as well.

\( \square \)

We now state our theorem for efficient classical generators.

**Theorem 4.** A generator \( \Phi = (S, \mathcal{X}, \{T_{s,s'}^{(x)} \}) \) satisfies \( I(S_t : X_1 \ldots X_t) = I(S_{t+1} : X_1 \ldots X_t) \) for all \( t \) if and only if the retrodictively state-merged generator \( \Phi^P = (P_\sim, \mathcal{X}, \{T_{s,s'}^{(x)} \}) \) satisfies \( T_{s,s'}^{(x)} \propto \delta_{f(s', x)} \) for some function \( f : S \times \mathcal{X} \to S \).

To see this, recall from Cor. 1 that \( I(S_t : X_1 \ldots X_t) = I(S_{t+1} : X_1 \ldots X_t) \) only if \( \Pr_\Phi (s_{t+1}, x_t | s_t) > 0 \) implies:

\[
\Pr_\Phi (x_1 \ldots x_t | s_{t+1}, x_t) = \Pr_\Phi (x_1 \ldots x_t | s_t).
\]
Now, note that:
\[
\Pr_{\mathcal{G}} (x_1 \ldots x_{t+1} | s_{t+1}) = \Pr_{\mathcal{E}} (x_1 \ldots x_t | s_{t+1}, x_{t+1}) \Pr (x_{t+1} | s_{t+1}) \\
= \Pr_{\mathcal{E}} (x_1 \ldots x_t | s_t) \Pr (x_{t+1} | s_{t+1}).
\]
Rearranging and using the retrodictive equivalence partitions \( \sigma_t := [s_t]_\succcurlyeq \) and \( \sigma_{t+1} := [s_{t+1}]_\succcurlyeq \), we have:
\[
\Pr_{\mathcal{G}}^{\prec} (x_1 \ldots x_t | \sigma_t) = \frac{\Pr_{\mathcal{E}} (x_1 \ldots x_{t+1} | \sigma_{t+1})}{\Pr_{\mathcal{E}}^{\prec} (x_1 \ldots x_t | \sigma_{t+1})}. \tag{13}
\]
Define a function \( f : S \times X \rightarrow S \) as follows. For a given \( \sigma' \) and \( x \), let \( f(\sigma', x) \) be the equivalence class such that:
\[
\Pr_{\mathcal{G}}^{\prec} ( |f(\sigma', x)|) = \frac{\Pr_{\mathcal{G}}^{\prec} (x | \sigma')}{\Pr_{\mathcal{E}}^{\prec} (x | \sigma')}.
\]
Such an equivalence class \( f(\sigma', x) \) must exist by Eq. (13). It is unique since, by definition, equivalence classes \( \sigma \) have unique distributions \( \Pr (| \sigma |) \). Then \( \sigma = f(\sigma_{t+1}, x_{t+1}) \) is a requirement for \( \Pr_{\mathcal{G}}^{\prec} (\sigma_{t+1}, x_{t+1} | \sigma_t) > 0 \). If we then take the merged generator \( \mathcal{G}^{\prec} \), we must have \( T^{(e)}_{\sigma, \sigma'} > 0 \) only when \( \sigma = f(\sigma', x) \).

Conversely, suppose that the retrodictively state-merged generator \( \mathcal{G}^{\prec} = (P_{\succcurlyeq}, X, \{T^{(e)}_{s,s'}\}) \) satisfies \( T^{(e)}_{s,s'} \propto \delta_{s,f(s',x)} \) for some function \( f : S \times X \rightarrow S \). Then, for a given \( s_t \), its equivalence class \( [s_t]_\succcurlyeq \) is always a function of the next state and symbol: \( [s_t]_\succcurlyeq = f([s_{t+1}]_\succcurlyeq, x_{t+1}) \). This implies that \( [s_t]_\succcurlyeq - X_{t+1} S_{t+1} - X_0 \ldots X_t \). However, we also have \( X_{t+1} S_{t+1} - [s_t]_\succcurlyeq - X_0 \ldots X_t \) from the basic Markov property of the generator. Therefore, we must have:
\[
I (S_{t+1} X_{t+1} : X_1 \ldots X_t) = I ([s_t]_\succcurlyeq : X_1 \ldots X_t) = I (S_t : X_1 \ldots X_t).
\]

We say that a generator \( \mathcal{G} = (S, X, \{T^{(x)}_{s,s'}\}) \) satisfying \( T^{(e)}_{s,s'} \propto \delta_{s,f(s',x)} \) is called a \textit{retrodictor}. The reverse \( e \)-machine can then be considered the minimal retrodictor.

Reference [14] conjectured that the necessary and sufficient condition for \( \Delta S_{\text{loc}} = 0 \) is that the generator in question is a retrodictor. We confirm this by establishing that the conditions of Thm. 4 imply the generator is a retrodictor.

**Proposition 4.** A generator \( \mathcal{G} = (S, X, \{T^{(x)}_{s,s'}\}) \) whose retrodictively state-merged generator \( \mathcal{G}^{\prec} = (P_{\succcurlyeq}, X, \{T^{(e)}_{s,s'}\}) \) satisfies \( T^{(e)}_{s,s'} \propto \delta_{s,f(s',x)} \) for some function \( f : S \times X \rightarrow S \) is a retrodictor.

This follows since \( \mathcal{G}^{\prec} \), being co-unifilar and already retrodictively state-merged, must be the reverse \( e \)-machine with states \( \Sigma_t \). It is clear from the proof of Prop. 3 that for all \( t \), we have the Markov chain \( (X_1 \ldots X_t) - \Sigma_t - S_t \). Since \( \Sigma_t \) is also the minimum sufficient statistic of \( X_t \) for \( X_1 \ldots X_t \), we must have the Markov chain \( (X_1 \ldots X_t) - X_t - S_t \). Combined with the Markov chain \( (X_1 \ldots X_t) - S_t - X_t \), we conclude that \( S_t \) is a sufficient statistic of \( X_t \) for \( X_1 \ldots X_t \).

The reverse (forward) \( e \)-machine, being a state-merging of any co-unifilar (unifilar) generator, is minimal with respect to the co-unifilar (unifilar) generators via all quantifications of the memory, such as the number of memory states \( |S| \) and the entropy \( H[S] \) [46]. As a consequence, we now see we just showed that any \textit{thermodynamically efficient} generator can be state-merged into a co-unifilar generator. This means it can be further state-merged into the reverse \( e \)-machine of the process it generates. In short, thermodynamic efficiency comes with a memory constraint. And, when the memory falls below this constraint, dissipation must be present.

**VIII. THERMODYNAMICS OF QUANTUM GENERATORS**

A process’ forward \( e \)-machine, a key player in the previous section, may be concretely defined as the unique generator \( \mathcal{G} = (S, X, \{T^{(x)}_{s,s'}\}) \) satisfying [36]:

1. \textbf{Recurrence:} \( T_{s'}^{(x)} := \sum_x T_{s,s'}^{(x)} \) is an irreducible matrix;
2. \textbf{Unifilarity:} \( T_{s,s'}^{(x)} > 0 \) only when \( s' = f(s,x) \) for some function \( f : S \times X \rightarrow S \);
3. \textbf{Predictively Distinct States:} \( \Pr (x_1 x_{t+1} \ldots x_t | s_t) = \Pr (x_1 x_{t+1} \ldots x_t | s'_t) \) for all \( t \) and \( x_1 x_{t+1} \ldots x_t \) implies \( s_t = s'_t \).

\( e \)-Machines are a process’ minimal unifilar generators, in the sense that they are smallest with respect to the
number of memory states $|S|$, the entropy $H[S]$, and all other ways of measuring memory, such as the Rényi entropies $H_{\alpha}[S] := \frac{1}{1-\alpha} \log_2 \left( \sum_s \pi_\theta(s)^{\alpha} \right)$. In this, they are unique.

However, one can implement $\epsilon$-machines with even lower memory costs, by encoding them in a quantum system and generating symbols by means of a noisy measurement. In terms of qubits, as a unit of size, these implementations can generate the same process at a much lower memory cost that the $\epsilon$-machine’s bit-based memory cost. It has also been shown that these quantum implementations have a lower locality cost $W_{\text{loc}}$ than their corresponding $\epsilon$-machine, and so they are more thermodynamically efficient [15].

This section identifies the constraints for quantum generators to have zero dissipation; that is, $W_{\text{loc}} = 0$. We show that this results in a peculiar pair of constraints. First, the forward $\epsilon$-machine memory must not be smaller than the memory of the reverse $\epsilon$-machine. This mirrors the results of Thm. 4. Second, the quantum generator achieves no compression. That is, the memory of the quantum generator in qubits is precisely the memory of the forward $\epsilon$-machine in bits. Thus, compression of memory and perfect thermodynamic efficiency are exclusive outcomes.

Specifically, given a forward $\epsilon$-machine $\theta = (S, \mathcal{X}, \{T_{x,s}^{(s)}\})$, for any set of phases $\{\phi_{xs} : x \in \mathcal{X}, s \in S\}$ there is an encoding $\{|\psi_s\rangle : s \in S\}$ of the memory states $S$ into a Hilbert space $\mathcal{H}_S$ and a set of Kraus operators $\{K^{(x)} : x \in \mathcal{X}\}$ on said Hilbert space such that:

$$K^{(x)} |\psi_s\rangle = e^{i\phi_{xs}} \sqrt{T_{f(s,x)}^{(x)}} |\psi_{f(s,x)}\rangle.$$ 

This expression implicitly defines the Kraus operators given the encoding $\{|\psi_s\rangle\}$. The encoding, in turn, is determined up to a unitary transformation by the following constraint on their overlaps:

$$\langle \psi_r | \psi_s \rangle = \sum_{x \in \mathcal{X}} e^{i(\phi_{rx} - \phi_{sx})} \sqrt{T_{f(r,x)}^{(x)} T_{f(s,x)}^{(x)}} \langle \psi_r | \psi_s \rangle,$$

where $r' = f(r, x)$ and $s' = f(s, x)$. This equation has a unique solution for every choice of phases $\{\phi_{xs}\}$ [47].

We note that if $\pi_\theta(s)$ is the $\epsilon$-machine’s stationary distribution, then the stationary state of this quantum generator is given by the ensemble:

$$\rho_\pi = \sum_s \pi_\theta(s) |\psi_s\rangle \langle \psi_s|$$

and satisfies:

$$\rho_\pi = \sum_x K^{(x)} \rho_\pi K^{(x)\dagger}.$$ 

When we say that a quantum generator uses less memory than its classical counterpart, we mean that $\dim \mathcal{H}_S \leq |S|$, $H[\rho_\pi] \leq H[S]$, and further that $H_\alpha[\rho_\pi] \leq H_\alpha[S]$, where $H_\alpha[\rho_\pi] := \frac{1}{\alpha} \log_2 \text{Tr} [\rho_\pi^\alpha]$ are the Rényi-von Neumann entropies [40, 45, 46].

To see this quantum generator as a physical system, as in Fig. 3, requires us interpreting the tape being written on as a series of copies of a single Hilbert space $\mathcal{H}_A$ that represents one cell on the tape. On $\mathcal{H}_A$ we define the computational basis $\{|s\rangle : s \in \mathcal{X}\}$ in which outputs will be written. The system at time $t$ can be described using the joint Hilbert space $\mathcal{H}_{A_1} \otimes \mathcal{H}_{A_2} \otimes \mathcal{H}_S$, where each $\mathcal{H}_{A_k}$ is unitarily equivalent to $\mathcal{H}_A$, and the state is:

$$\rho_\theta(t) := \sum_{x_1, x_2} |x_1 \ldots x_t\rangle \langle x_1 \ldots x_t| \otimes K^{(x_t \ldots x_1)} \rho_\pi K^{(x_t \ldots x_1)\dagger},$$

where $K^{(x_t \ldots x_1)} = K^{(x_t)} \ldots K^{(x_1)}$ and $|x_1 \ldots x_t\rangle = |x_1\rangle_1 \otimes \cdots \otimes |x_t\rangle_{A_t}$. From this we get the process generated by the $\epsilon$-machine and quantum generator in terms of the Kraus operators as:

$$\text{Pr}_\theta (x_1 \ldots x_t) := \text{Tr} \left[ K^{(x_t \ldots x_1)} \rho_\pi K^{(x_t \ldots x_1)\dagger} \right].$$

The preceding material was, in fact, review. Now, we identify several key properties of quantum generators that will aid in our proof. The first is a result about memory synchronization in $\epsilon$-machines that we adapt to their quantum implementations.

**Proposition 5** (Synchronization of quantum generators). Let $\rho_{x_1 \ldots x_t} := \text{Pr}_\theta (x_1 \ldots x_t)^{-1} K^{(x_t \ldots x_1)} \rho_\pi K^{(x_t \ldots x_1)\dagger}$ be the state of the memory system after seeing the word $x_1 \ldots x_t$. Further, let $\hat{s}(x_1 \ldots x_t) := \text{argmax}_s \text{Pr}(s|x_1 \ldots x_t)$ be the most likely memory state after seeing the word $x_1 \ldots x_t$ and let $F(x_1 \ldots x_t) := \text{F}(\rho_{x_1 \ldots x_t}, |s\rangle |\psi_s\rangle \langle \psi_s|)$ be the fidelity between the quantum state of the memory system and the most likely encoded state. Then, there exist $0 < \alpha < 1$ and $K > 0$ such that, for all $t$:

$$\text{Pr} \left( F(x_1 \ldots x_t) > 1 - \alpha^t \right) \leq K \alpha^t.$$

This shows that the quantum state of the memory system converges to a single encoded state with high probability.

This follows straightforwardly from a similar statement about $\epsilon$-machines [36, 50, 51]. Let $Q(x_1 \ldots x_t) := 1 - \text{Pr}(\hat{s}|x_1 \ldots x_t)$ be the probability of not being in the most likely state after word $x_1 \ldots x_t$. Then there exist $0 < \alpha <
1 and $K > 0$ such that, for all $t$:

$$\Pr \left( Q(x_1 \ldots x_t) < \alpha^t \right) \leq K \alpha^t.$$  

Note that, from the Kraus operator definition, the quantum state of the memory system after word $x_1 \ldots x_t$ is:

$$\rho_{x_1 \ldots x_t} = \sum_{s_t} \Pr(s_t|x_1 \ldots x_t) |\psi_{s_t}\rangle \langle \psi_{s_t}|.$$  

Now, the fidelity can be computed as:

$$F(x_1 \ldots x_t) = \text{Tr} \left[ \sqrt{|\psi_s\rangle \langle \psi_s|} \rho_{x_1 \ldots x_t} \sqrt{|\psi_s\rangle \langle \psi_s|} \right]^2$$

$$= \langle \psi_s|\rho_{x_1 \ldots x_t}|\psi_s\rangle$$

$$= \Pr(\delta|x_1 \ldots x_t)$$

$$+ \sum_{s_t \neq \delta} \Pr(s_t|x_1 \ldots x_t) |\psi_{s_t}| \langle \psi_{s_t}|^2$$

$$\geq 1 - Q(x_1 \ldots x_t).$$

And, from the synchronization theorem for $\epsilon$-machines, we have:

$$\Pr \left( F(x_1 \ldots x_t) > 1 - \alpha^t \right) \leq K \alpha^t$$

for all $t$. \ (\Box)

The second notion we must introduce is a simple partition that may be constructed on the memory states of the $\epsilon$-machine for a given quantum implementation. Specifically, we define the maximal commuting partition on $\mathcal{S}$ to be the most refined partition $\{B_0\}$ such that the overlap matrix $\langle \psi_s|\psi_s\rangle$ is block-diagonal. That is, $\{B_0\}$ is such that $\langle \psi_r|\psi_s\rangle = 0$ if $r \in B_0$ and $s \in B_0$ for $\theta \neq \theta'$. From this partition we construct the maximally commuting local measurement required to define sufficient statistics.

**Proposition 6.** Let $\rho_\Theta(t)$ be the state of the system $A_1 \ldots A_tS_t$ at time $t$. Let $\Theta$ be the projective measurement on $\mathcal{H}_S$ corresponding to the MCP of the quantum generator. Then, for sufficiently large $t$, $\Theta$ is the MLCM of $S_t$. Similarly, $X_t\Theta$ is the MLCM of $A_tS_t$.

By Prop. 2, the MLCM must leave each $\rho_{x_1 \ldots x_s}$ unchanged, for all $t$. This is true for $\Theta$. The question is if any refinement of $\Theta$ can do so. Now, realize that for any $\epsilon > 0$, there is sufficiently large $t$, so that for each state $s$ there must be at least one word $x_1 \ldots x_s$ satisfying $F(\rho_{x_1 \ldots x_s}, |\psi_s\rangle \langle \psi_s|) > 1 - \epsilon$. Then, for sufficiently large $t$, it must be the case that there exists a word $x_1 \ldots x_s$ such that $Y$ modifies $\rho_{x_1 \ldots x_s}$, so $Y$ cannot be a commuting local measurement. Therefore, $\Theta$ is the maximal commuting local measurement. \ (\Box)

Let us now briefly discuss the thermodynamic properties of quantum generators, homing in on our main result about conditions for their efficiency. The previous section discussed how a process, to be generated, requires the minimal work rate $W_{\text{min}} = -K B T \ln 2 h_\epsilon$. However, this is not typically achievable for classical generators, as the same principle holds for quantum generators: since they act temporally locally, the true cost at time $t$ is bounded by $W_{\text{loc}} = W_{\text{min}} + \Delta S_{\text{loc}}$ and the locality dissipation $\Delta S_{\text{loc}}$ has the same form:

$$\Delta S_{\text{loc}} = k_B T \ln 2 \left( I(S_t : A_1 \ldots A_t) - I(S_{t+1}A_{t+1} : A_1 \ldots A_t) \right).$$

There are two crucial differences, though. First, the mutual information $I$ above is the quantum mutual information derived from the von Neumann entropy; i.e., $I(S_t : A_1 \ldots A_t) := D(\rho_\Theta(t)||\rho_\Theta \otimes \rho_{A_1 \ldots A_t})$. Second, even the work rate $W_{\text{loc}}$ is not necessarily achievable in the single-shot case [48]. However, it may be attained for asymptotically parallel generation [15]. We will not concern ourselves with this second problem here. Our intent is to focus, as in the previous section, on the necessary and sufficient conditions for $\Delta S_{\text{loc}} = 0$.

Our result on thermodynamically-efficient quantum generators is as follows.

**Theorem 5** (Maximally-efficient quantum generator). Let $\mathcal{S} = (S,X,\{T^{x}_{s}\})$ be a given process’ $\epsilon$-machine. Suppose we build from it a quantum generator with encoding $\{\psi_s\}$ and Kraus operators $\{K^{(s)}\}$. Let $\mathcal{B} := \{B_0\}$ be the largest commuting partition of $\mathcal{S}$. Then the quantum generator has $\Delta S_{\text{loc}} = 0$ if and only if the partition $\mathcal{B}$ is maximal—in that $|B_0| = 1$ for each $\theta$—and the retrodictively state-merged generator $\Theta^P$ of $\mathcal{S}$ is co-unifilar.

We define $\rho^{(\theta)}(t) := \Pi^{(\theta)} \rho_\Theta(t) \Pi^{(\theta)}$, so that $\rho_\Theta(t) = \bigoplus_\theta \rho^{(\theta)}(t)$. For the equivalence relation we say that $\theta \sim \theta'$ if $\rho^{(\theta)}(t) \equiv_S \rho^{(\theta')}(t)$. This defines a partition $\mathcal{P} = \{[\theta]_S\}$, labeled by $\sigma$, over the set $\{B_0\}$.

The quantum channel:

$$\mathcal{E}(\rho) := \sum_x K^{(x)} \rho K^{(x)}| \otimes |x\rangle \langle x|$$

has Kraus operators $L^{(x)} := K^{(x)} \otimes |x\rangle$. The MLCM of $A_tS_t$ is $X_t\Theta$. Now, Thm. 3 demands that the Kraus operators $L^{(x)}$ have the form:

$$L^{(x)} = \bigoplus_{\theta,\theta'} \sqrt{\Pr(\theta',x|\theta)} U^{(x,\theta')|\theta}$$

$$= \bigoplus_{\theta,\theta'} \sqrt{\Pr(\theta',x|\theta)} |x\rangle \otimes U^{(x)}_{\theta,\theta'}. $$

This implies that the quantum generator Kraus operators
have the form:

$$K(x) = \bigoplus_{\theta, \theta'} \sqrt{\Pr(\theta', x|\theta)} U_{\theta \to \theta'}^{(x)}.$$  \hspace{1cm} (14)

The channel \(\Pr(\theta', x|\theta)\) must be positive only when \(\theta' \sim \theta\).

Now, we note that this means there is a machine \((\mathcal{B}, \mathcal{X}, \{T_{\theta, \theta'}^{(x)}\})\) with transition probabilities \(T_{\theta', \theta}^{(x)} := \Pr(\theta', x|\theta)\) that generates the process. This merged machine must have the property that merging its retrodictively equivalent states results in a co-unifilar machine. However, there is more to consider here. We assumed starting with a process’ \(\epsilon\)-machine. This means each state \(s_t\) must have a unique prediction of the future \(\Pr(x_{t+1} \ldots x_{t}|s_t)\). In fact, we can relate these predictions to the partition:

\[
\begin{align*}
\Pr(x_{t+1} \ldots x_{t}|s_t) &= \text{Tr} \left[ K(x_{t+1} \ldots x_{t+1}) |\psi_{s_t}\rangle \langle \psi_{s_t}| K(x_{t+1} \ldots x_{t+1}) \right] \\
&= \sum_{\theta_{t+1} \ldots \theta_t} \Pr(\theta_{t+1}, x_{t+1}|\theta(s_t)) \ldots \Pr(\theta_t, x_t|\theta_{t-1}).
\end{align*}
\]

Which, we see, only depends on the partition index \(\theta\). Then any two \(s_t, s_t' \in B_\theta\) with \(s_t \neq s_t'\) have the same future prediction, which is not possible for an \(\epsilon\)-machine. Then, it must be the case that each partition has only one element: \(|B_\theta| = 1\) for all \(\theta\). The remainder of the theorem follows directly. \(\square\)

This is a profound result on the efficiency of quantum memory compression. We previously found that, in the limit of asymptotically parallel generation, a quantum generator is always more thermodynamically efficient than its corresponding \(\epsilon\)-machine, in that it has a lower dissipation \([15]\). Yet this does not imply dissipation can be made to vanish for quantum generators of a process. Unlike the classical case, where Thm. 4 established that certain generators do achieve zero dissipation, Thm. 5 implies that only certain processes have zero-dissipation quantum generators and those particular processes achieve no memory compression. The memory states, being orthogonally encoded, take no advantage of the quantum setting to reduce their memory cost.

IX. CONCLUDING REMARKS

We identified the conditions under which local operations circumvent the thermodynamic dissipation \(\Delta S_{\text{loc}}\) that arises from destroying correlation. We started by showing how a useful theorem can be derived using recent results on the fixed points of quantum channels. We applied it to the setting of local operations to determine the necessary and sufficient conditions for vanishing \(\Delta S_{\text{loc}}\) in classical and quantum settings, with the aid of a generalized notion of quantum sufficient statistic. We employed this fundamental result to review and extend previous results on the thermodynamic efficiency of generators of stochastic processes. We confirmed a recent conjecture regarding the conditions for vanishing \(\Delta S_{\text{loc}}\) in a classical generator. And, then, we showed the exact same conditions hold for quantum generators, even to the point of requiring orthogonal encoding of memory states. This implies the profound result that quantum memory compression and perfect efficiency \((\Delta S_{\text{loc}} = 0)\) are incompatible.

It is appropriate here to recall the lecture by Feynman in the early days of thinking about quantum computing, in which he observed that quantum systems can only be simulated in classical (even probabilistic) computers with great difficulty, but on a fundamentally-quantum computer they could be more realistically simulated \([3]\). Here, we considered the task of simulating a classical stochastic process by two means: one by using fundamentally-classical but probabilistic machines and the other by using a fundamentally-quantum machine. Previous results generally indicated quantum machines are advantageous in memory for this task, in comparison to their classical counterparts. Historically, this led to a much stronger notion of “quantum supremacy” than Feynman proposed: quantum computers may be advantageous in all tasks \([52]\).

However, the quantum implementation we examined, though advantageous in memory, requires nonzero dissipation in order to cash in on that advantage. Furthermore, not every process necessarily has a quantum generator that achieves zero dissipation. This is in sharp contrast to the classical outcome. And so, this returns us to the spirit of Feynman’s vision for simulating physics, in which it may sometimes be the case that the best machine to simulate a classical stochastic process is a classical stochastic computer—at least, thermodynamically speaking.

To further exercise these results, extensions must be made to the standard form of quantum generators. We must determine if the exclusive relationship between compression and zero dissipation continues to hold in such extensions. We pursue this question in forthcoming work.
