Abstract

In Machine Learning and Optimization community there are two main approaches for convex risk minimization problem. The first approach is Stochastic Averaging (SA) (online) and the second one is Stochastic Average Approximation (SAA) (Monte Carlo, Empirical Risk Minimization, offline) with proper regularization in non-strongly convex case. At the moment, it is known that both approaches are on average equivalent (up to a logarithmic factor) in terms of oracle complexity (required number of stochastic gradient evaluations). What is the situation with total complexity? The answer depends on specific problem. However, starting from work [Nemirovski et al. (2009)] it was generally accepted that SA is better than SAA. Nevertheless, in case of large-scale problems SA may run out of memory problems since storing all data on one machine and organizing online access to it can be impossible without communications with other machines. SAA in contradiction to SA allows parallel/distributed calculations. In this paper we show that SAA may outperform SA in the problem of calculating an estimation for population (μ-entropy regularized) Wasserstein barycenter even for non-parallel (non-decentralized) set up.

Keywords: empirical risk minimization, population Wasserstein barycenter, stochastic gradient descent.

1. Introduction

We consider the problem of finding a mean of probability measures. Observing a sample of probability measures \( \nu_1, \nu_2, \nu_3, \ldots \) from a some probabilistic family, we are interested in their population mean. Since the geometric structure of the problem is not Euclidean we refer to optimal transport (OT) problem, formulated long time ago and solved by G. Monge [Monge (1781)] and then improved by L. Kantorovich Kantorovich (1942)]. Nowadays, OT is a popular framework using in clustering Ho et al. (2017), text classification Kusner et al. (2015), image retrieval [Rubner et al. (2000)], computer vision [Ni et al. (2009)], economics and finance Beiglböck et al. (2013); Rachev et al. (2011)]. Inspired by the problem of OT, distance function was introduced which is usually named by Wasserstein distance, or Monge–Kantorovich distance. This distance allows to measure how one object is defer from the other one even for non-linear objects such as probability measures or histograms. To define the notion of barycenter we consider 2-Wasserstein distance between two probability...
measures $\mu$ and $\nu$ supported on complete metric space $\mathcal{X}$ with metric $d : \mathcal{X} \times \mathcal{X} \to \mathbb{R}_+$

$$W_2(\mu, \nu) = \left( \min_{\pi \in \Pi(\mu, \nu)} \int_{\mathcal{X} \times \mathcal{X}} d^2(x, y) d\pi(x, y) \right)^{1/2},$$

(1)

where $\Pi(\mu, \nu)$ is the set of probability measures $\pi$ on the product space $\mathcal{X} \times \mathcal{X}$ with respective marginals $\mu$ and $\nu$. In the Wasserstein space of all probability measures with metric $W_2$ we define the Fréchet mean which is a generalization of usual mean for non-linear space [Fréchet (1948)]

$$\mu^* = \arg \min_{\mu \in \mathcal{X}} \mathbb{E}_\nu W_2^2(\mu, \nu) = \arg \min_{\mu \in \mathcal{X}} \int_{\mathcal{X}} W_2^2(\mu, \nu) d\mathbb{P}(\nu),$$

(2)

where $W_2(\mu, \nu)$ is the 2-Wasserstein distance. We refer to minimizer (2), which is also a probability measure, as the population (Fréchet) mean. In this work, we consider the specific case where measures $\nu_1, \nu_2, \nu_3, \ldots$ are discrete measures with finite support of size $n$ to reduce the problem (1) to finite linear program requiring $\tilde{O}(n^3)$ arithmetic iterations for solving it. Approximation of a probability measures by a measure with finite support were studied in [Genevay et al. (2018); Mena and Weed (2019); Panaretos and Zemel (2019); Weed et al. (2019)]. To tackle the problem of computational complexity for solving linear program there were proposed an entropic regularization [Cuturi (2013)]. It helps to reduce the computational complexity to $n^2 \min\{\tilde{O}(\frac{1}{\varepsilon}), \tilde{O}(\sqrt{n})\}$. Moreover, entropic regularization improves statistical properties of Wasserstein distance itself [Klatt et al. (2018); Bigot et al. (2019)]. This regularization shows good results in generative models [Genevay et al. (2017)], multi-label learning [Frogner et al. (2015)], dictionary learning [Rolet et al. (2016)], image processing [Cuturi and Peyré (2016); Rabin and Papadakis (2015)], neural imaging [Gramfort et al. (2015)]. A nice survey of OT and Wasserstein barycenter presents in [Peyré and Cuturi (2018)].

In this paper we are aim at constructing an $\varepsilon$-approximation for population Wasserstein barycenter. To do so, we estimate the number of sampled measures to get $\varepsilon$-precision in function value. We consider online and offline algorithms with providing comparison study for their convergence rates. Both types of approaches (online and offline) have the pros and the cons depending on specific of the problem which covering by this paper. Generally, starting from the work [Nemirovski et al. (2009)] SA (Stochastic Averaging) was considered to be better than SAA (Stochastic Average Approximation). On the example of population Wasserstein barycenter problem we demonstrate superiority of SA under SAA with definite values of regularization parameter. The main reason for that is the observation that gradient of dual function for $W$ has the complexity $\tilde{O}(n)$ times smaller than primal one. We emphasize that the transition to a dual function is possible only in SAA approach.

Furthermore, in our paper we study an $\varepsilon$-confidence interval for population Wasserstein barycenter defined w.r.t. entropic-regularized OT. Our choice of entropic regularization is due to it ensures strong convexity of OT that allows to write $\varepsilon$-convergence in argument.

1. The estimate $n^2 \min\{\tilde{O}(\frac{1}{\varepsilon}), \tilde{O}(\sqrt{n})\}$ is the best theoretical known estimate for solving OT problem [Blanchet et al. (2018); Jambulapati et al. (2019); Lee and Sidford (2014); Quanrud (2018)].
1.1 Related work

Consistency of the empirical barycenter to its population counterpart as the number of measures tends to infinity was considered in many papers, e.g., Le Gouic and Loubes (2015); Panaretos and Zemel (2019); Le Gouic and Loubes (2017); Bigot and Klein (2012); Rios et al. (2018)]. In [Bigot et al. (2017)] convergence of the empirical barycenter to its population counterpart in Wasserstein metric was also studied. However, they do not provide any rates of convergence. The rate of convergence can be found in paper Boissard et al. (2015)] for the problem of template estimation. Authors provide a confidence interval for population barycenter, approximating it by iterated barycenter in Wasserstein space. However, they only consider probability measures obtained by template deformations with definite properties, e.g., the expectation of a function of deformation from admissible deformations family is identity. Our aim is refusing this particular conditions on is identity. Without any assumptions of generating process for observing measures one can find the rate of convergence for empirical Wasserstein barycenter towards its population counterpart in [Bigot et al. (2018)]. However, it is only valid when measures has one-dimensional support.

Our approaches for constructing a confidence interval significantly use the results of the paper [Shalev-Shwartz et al. (2009)] for stochastic convex optimization.

1.2 Contribution

We summarize our contribution as follows. To the best of our knowledge, this is the first paper which provides a confidence interval for population Wasserstein barycenter with specifying the rates of convergence to calculate its approximation.

Our first result is that SAA gets better rates of convergence in comparison with SA for the problem of approximating of the population Wasserstein barycenter defined w.r.t. entropy-regularized OT with the proper value of regularization parameter. We comment on its value in Section 6

Our second result is providing new regularization in SAA approach for the problem of calculating of the population Wasserstein barycenter (Section 5). To the best of our knowledge, this regularization contributes to improving convergence bounds compared to the state-of-the-art regularization from [Shalev-Shwartz et al. (2009)] for general convex function.

Finally, we show that for the problem of calculating an approximation for population Wasserstein barycenter, stochastic mirror descent and risk minimization approach with our new regularization show better complexity bounds in comparison with SA and SAA.

1.3 Paper organization

The structure of the paper is the following. Sections 3 and 4 presents SA and SAA approaches respectively to find the confidence interval for barycenter w.r.t. regularized OT. In Section 5 we estimate barycenter w.r.t. OT involving some other algorithm with particular structure on regularization constant, including zero constant. In Section 6 we compare the rates of convergences. Finally, we present concluding remarks.
2. Wasserstein distance and Wasserstein barycenter: Notations and Properties

In this paper we consider discrete probability measures given in the probability simplex

\[ S_1(n) = \{ a \in \mathbb{R}^n_+ : \sum_{i=1}^n a_i = 1 \} . \]

Measures \( p \) and \( q \) are discrete if they can be presented in the form

\[ p = \sum_{i=1}^n p_i \delta_{x_i} \text{ and } q = \sum_{j=1}^n q_j \delta_{x_j}, \]

where \( \delta_x \) is the Dirac measure at point \( x \); \( p \in S_1(n) \) and \( q \in S_1(n) \) are histograms. Let \( p, q \in S_1(n) \), then we define transportation polytope

\[ \Pi(p, q) = \{ \pi \in \mathbb{R}^{n \times n} : \pi \mathbf{1}^T = p, \pi \mathbf{1} = q \} . \]

We define optimal transport (OT) problem between discrete probability measures \( p, q \in S_1(n) \) as follows

\[ W(p, q) = \min_{\pi \in \Pi(p, q)} \langle C, X \rangle = \min_{\pi \in \Pi(p, q)} \sum_{i,j=1}^n C_{ij} \pi_{ij} . \]

Here \( C \) is the cost matrix: \( C_{ij} \) is the cost to move the unit mass from point \( x_i \) to point \( x_j \). When \( C_{ij} = d(x_i, x_j)^2 \), where \( d(x_i, x_j) \) is the distance on support points \( x_i, x_j \) \( (i, j = 1, \ldots, n) \) of probability measures \( p, q \), then \( W(p, q)^{1/2} \) is known as 2-Wasserstein distance on \( S_1(n) \). We consider entropic OT, introduced in [Peyré and Cuturi (2018)]

\[ W_{\mu}(p, q) = \min_{\pi \in \Pi(p, q)} \sum_{i,j=1}^n (C_{ij} \pi_{ij} + \mu \pi_{i,j} \ln \pi_{i,j}) . \]

For statistical explanation of such regularization see [Rigollet and Weed (2018)]. Further we define the notion of population barycenter of probability measures w.r.t. regularized OT by using the notion of Fréchet mean

\[ p^*_\mu = \arg \min_{p \in S_1(n)} \int W_{\mu}(p, q) d\mathbb{P}(q) = \arg \min_{p \in S_1(n)} \mathbb{E}_q W_{\mu}(p, q) . \]

We refer to empirical barycenter as the empirical counterpart of \( p^*_\mu \)

\[ \hat{p}^m_\mu = \arg \min_{p \in S_1(n)} \sum_{k=1}^m W_{\mu}(p, q^k) . \]

If \( \mu = 0 \), then \( p^* := p^*_\mu=0 \) is population Wasserstein barycenter (i.e. w.r.t. OT) and \( \hat{p}^m := \hat{p}^m_\mu=0 \) its empirical counterpart.

For our convenience we also define the following notation

\[ W_\mu(p) = \mathbb{E}_q W_{\mu}(p, q) . \]

We refer to \( \mathcal{O}(\cdot) \) when we want to indicate the complexity hiding constants and the logarithms.

2. We omit the sub-index 2 for simplicity.
2.1 Dual formulation and properties

The structure of $W_\mu(p, q)$ allows us to write Lagrangian dual function with dual variables $\lambda$ and $\nu$ to the constraints $\pi \mathbf{1} = p$ and $\pi^T \mathbf{1} = q$ respectively

$$W_\mu(p, q) = \min_{\pi \in \Pi(p, q)} \sum_{i,j=1}^{n} (C_{ij}\pi_{i,j} + \mu\pi_{i,j}\ln\pi_{i,j})$$

$$= \max_{\lambda, \nu \in \mathbb{R}^n} \left( \langle \lambda, p \rangle + \langle \nu, q \rangle - \mu \sum_{i,j=1}^{n} \exp \left( \frac{-C_{ij} + \lambda_i + \nu_j}{\mu} - 1 \right) \right)$$

$$= \max_{\lambda \in \mathbb{R}^n} \left( \langle \lambda, p \rangle - \mu \sum_{j=1}^{n} q_j \ln \left( \frac{1}{q_j} \sum_{i=1}^{n} \exp \left( \frac{-C_{ij} + \lambda_i}{\mu} \right) \right) \right)_{D_q(\lambda)}.$$  (3)

Here we denoted by $D_q(\lambda)$ the Lagrangian dual function for $W_\mu(p, q)$.

Let $\lambda^*$ be a solution of problem (3), then since dual function $D_q(\lambda)$ is strictly convex we have

$$\gamma \simeq \lambda_{\min}(\nabla^2 D_q(\lambda^*)) > 0,$$

where $\lambda_{\min}(A)$ is the smallest eigenvalue of positive semi-definite matrix $A$. Note, that from the theoretical point of view we do not know any accurate bounds from below for $\gamma$ better than exponentially small of $n$.

Moreover,

$$\nabla_p W_\mu(p, q) = \lambda^*, \quad \text{where} \quad \langle \lambda^*, \mathbf{1} \rangle = 0. \quad (4)$$

We use denotation $\nabla_p$ for gradient w.r.t. $p$.

**Proposition 1** ($W_\mu(p, q)$ properties) Entropy-regularized Wasserstein distance $W_\mu(p, q)$ is

1. $\mu$-strongly convex in $p$ w.r.t 2-norm: for any $p, p' \in S_1(n)$

$$W_\mu(p, q) \geq W_\mu(p', q) + \langle \nabla W_\mu(p', q), p - p' \rangle + \frac{\mu}{2}\|p - p'\|^2_2.$$

2. $M$-Lipschitz in $p$ w.r.t 2-norm: for any $p, p' \in S_1(n)$

$$|W_\mu(p, q) - W_\mu(p', q)| \leq M\|p - p'\|_2, \quad (5)$$

where $M \leq \sqrt{n}M_\infty$ ($M_\infty$ is Lipschitz constant w.r.t. $\infty$-norm, $M_\infty = \tilde{O}(\|C\|_\infty)$).

**Proof** The first proposition follows from [Kakade et al. (2009); Nesterov (2005)]. Indeed, according to [Peyré and Cuturi (2018); Nesterov (2005)] the gradient of function $D_q(\lambda)$ in (3) is $(1/\mu)$-Lipschitz continuous in 2-norm. From [Kakade et al. (2009)] we may conclude that $W_\mu(p, q)$ in this case is $\mu$-strongly convex w.r.t. $p$ in 2-norm [Nesterov (2005)].
The second proposition follows from [Dvurechensky et al. (2018); Kroshnin et al. (2019b); Lin et al. (2019)]. Note, that this result assumes some additional assumptions about the separability of considered measures from zero. But without loss of generality we can reduce general case to the desired one [Dvurechensky et al. (2018); Kroshnin et al. (2019b)].

The next two sections present constructing an \( \varepsilon \)-confidence interval for population barycenter \( p^* \mu \) defined w.r.t regularized Wasserstein distance.

3. Population barycenter with respect to regularized OT. Online (SA) approach

In this section we assume that probability measures \( q_1, q_2, q_3, \ldots \) come in online regime. One of the benefits of online approach is no need to fix the number of measures that allows to regulate the precision for calculated barycenter. Moreover, a problem of storing a large number of measures in a computing node is not present if we have an access to online oracle, e.g., some measuring device. Using online to batch conversions [Shalev-Shwartz et al. (2009)] we build the confidence interval for population barycenter defined w.r.t. regularized OT and provide complexity bounds to do it.

The following algorithm calculate online sequence of measures \( p^1, p^2, p^3, \ldots \) by online stochastic gradient descent, that at each iteration \( k \) call Sinkhorn algorithm to compute an approximation for the gradient of entropic-regularized Wasserstein distance \( W_\mu(p^k, q^k) \).

**Algorithm 1** Online Stochastic Gradient Descent (SGD)

**Input:** Starting point \( p^1 \in S_n(1) \)

1: for \( k = 1, 2, 3, \ldots \) do
2: \( \eta_k = \frac{1}{\mu^k} \),
3: \( p^{k+1} = \Pi_{S_1(n)}(p^k - \eta_k \nabla^\delta W_\mu(p^k, q^k)) \),
4: where \( \nabla^\delta W_\mu(p^k, q^k) \) is \( \delta \)-subgradient [Polyak (1987)] calculated by Sinkhorn algorithm,
5: \( \Pi_{S_1(n)} \) is the projection onto \( S_1(n) \), \( \Pi_{S_1(n)}(p) = \min_{v \in S_1(n)} \| p - v \|_2 \)

In Algorithm 1 we define \( \delta \)-subgradient \( \nabla^\delta W_\mu(p, q) \) using (4) as \( \nabla^\delta W_\mu(p, q) := \lambda^K \) where

\[
\| \lambda^K - \lambda^* \|_2 \leq \delta,
\]

where \( \lambda^K \) is an output of Sinkhorn algorithm [Dvurechensky et al. (2018); Pevré and Cuturi (2018)] after \( K \) iterations.

To approximate population barycenter \( p^*_\mu \) by the outputs of Algorithm 1 we use online to batch conversions [Shalev-Shwartz et al. (2009)] and define \( \hat{p}^N \) as the average of online outputs \( p^1, \ldots, p^{N+1} \) from Algorithm 1

\[
\hat{p}^N = \frac{1}{N+1} \sum_{k=1}^{N+1} p^k.
\]
Next we formulate two theorems which indicates the precision of $\tilde{p}^N$ as an approximation for population barycenter $p_\mu^*$ in function value and in argument.

**Theorem 2** With probability $\geq 1 - \alpha$ for the $\tilde{p}^N$ from (7) the following holds

$$W_\mu(\tilde{p}^N) - W_\mu(p_\mu^*) = O\left(\frac{M^2 \ln(N/\alpha)}{\mu N} + \delta RN\right),$$

where $R = \|p^1 - p_\mu^*\|_2 = O(1)$.

**Proof** The proof follows from proof in [Kakade and Tewari (2009)] accounting the error accumulation for inexactness of the gradient.

**Theorem 3 (Barycenter confidence interval)** With probability $\geq 1 - \alpha$ for $\tilde{p}^N$ from (7) the following holds

$$\|\tilde{p}^N - p_\mu^*\|_2 = O\left(\sqrt{\frac{M^2 \ln(N/\alpha)}{\mu^2 N}} + \frac{\delta RN}{\mu}\right).$$

**Proof** The proof follows directly from Theorem 2, strong convexity of $W_\mu(p, q)$ and $W_\mu(p)$.

**Remark 4** Using (not online) algorithm from [Juditsky and Nesterov (2014)] instead of online algorithm allows to avoid accumulation of inexactness $\delta$: the term $\delta RN$ in Theorems 2, 3 can be replaced by $\delta R$.

From Theorem 3 we can immediately conclude that the number of probability measures $q^1, q^2, q^3, \ldots$ taking as inputs of Algorithm 1 and $\delta$ which is the precision for Sinkhorn algorithm performing at each iteration of Algorithm 1.

**Corollary 5 (Number of probability measures and auxiliary precision)** To get the $\varepsilon$-confidence region:

$$\|\tilde{p}^N - p_\mu^*\|_2 \leq \varepsilon \quad \text{with probability} \quad \geq 1 - \alpha \quad (8)$$

it suffices to take the following number of probability measures (iterations)

$$N = \tilde{O}\left(\frac{M}{\mu \varepsilon}\right)^2$$

and the following $\delta$-precision

$$\delta = \tilde{O}\left(\frac{\mu^3 \varepsilon^4}{M^2 R}\right) = \tilde{O}\left(\frac{\mu^3 \varepsilon^4}{M^2}\right).$$

If we use restarted SGD from [Juditsky and Nesterov (2014)] instead of Algorithm 1, then

$$\delta = O\left(\mu \varepsilon^2\right).$$
Now we are ready to provide the complexity bounds for calculating \( \tilde{p}^N \) that guarantee (8).

**Theorem 6** The total complexity of restarted SGD from [Juditsky and Nesterov (2014)] to guarantee (8) is

\[
\tilde{O}\left( \left( \frac{Mn}{\mu \varepsilon} \right) \min \left\{ \exp \left( \frac{\|C\|_\infty}{\mu} \left( \frac{\|C\|_\infty}{\mu} + \ln \left( \frac{\|C\|_\infty}{\gamma \mu^2 \varepsilon^4} \right) \right) \right), \sqrt{\frac{n}{\gamma \mu^3 \varepsilon^4}} \right\} \right),
\]

(9)

where we use \( \delta = O \left( \mu \varepsilon^2 \right) \).

**Proof** The proof follows from the complexity of Sinkhorn algorithm. To state the complexity of Sinkhorn we firstly define \( \tilde{\delta} \) as (see also (6))

\[
D_q(\lambda^K) - D_q(\lambda^*) \leq \tilde{\delta}.
\]

From (2.1) we can conclude that \( \tilde{\delta} \) is proportionally to \( \gamma^2 \delta^2 \). Using this we formulate the complexity of Sinkhorn [Kroshnin et al. (2019b); Stonyakin et al. (2019)]

\[
\tilde{O}\left( \exp \left( \frac{\|C\|_\infty}{\mu} \left( \frac{\|C\|_\infty}{\mu} + \ln \left( \frac{\|C\|_\infty}{\tilde{\delta}} \right) \right) \right) \right).
\]

The complexity for Accelerated Sinkhorn can be improved [Guminov et al. (2019)]

\[
\tilde{O}\left( \sqrt{\frac{n}{\mu \tilde{\delta}}} \right)
\]

Multiplying both of this estimates by the number of measures \( N \) (iterations), taking the minimum and using Corollary 5 we get the statement of the theorem. \( \blacksquare \)

**Remark 7** Suppose that after \( K \) iterations of Sinkhorn algorithm we get approximate dual solutions \( \lambda^K \) and \( \nu^K \). According to [Franklin and Lorenz (1989)] there is a convergence of calculated variables \( \lambda^K \) and \( \nu^K \) (see (3)) to the true variables \( \lambda^* \) and \( \nu^* \) in Hilbert–Birkhoff metric \( \rho \):

\[
\rho((\lambda^K, \nu^K), (\lambda^*, \nu^*)) \leq \delta'.
\]

(10)

Since all norms are equivalent in finite spaces we can obtain by proper choosing \( K \) (6). The number of iterations \( K \) will be proportional to \( \ln(1/\delta') \) [Franklin and Lorenz (1989)], however, in general theoretical constant before logarithm can be too big to get good theoretical results. But accurate calculations allows to obtain here the result like (10), where \( \tilde{\delta} \) can be replaced by \( O(\delta/n^\beta) \) for some \( \beta \geq 0 \). This means that in (9) we may consider \( \gamma \) to be \( n^{-\tilde{\beta}} \). That is better than direct bound from the definition.
4. Barycenter with respect to regularized OT: Offline (SAA) approach

In this section we suppose that we sample measures \( q_1, \ldots, q_N \) in advance. We construct the confidence interval for population barycenter calculating the approximation for the empirical barycenter. Moreover, we also provide the total complexity bounds to do it. This offline setting can be relevant when we are interested in parallelization or decentralization.

We refer to \( \hat{p}_{\varepsilon'} \) as the approximated empirical barycenter of \( \tilde{p}_\mu^m \) if it satisfies the following inequality for some precision \( \varepsilon' \)

\[
\frac{1}{m} \sum_{k=1}^{m} W_\mu(\hat{p}_{\varepsilon'}, q^k) - \frac{1}{m} \sum_{k=1}^{m} W_\mu(\tilde{p}_\mu^m, q^k) \leq \varepsilon'.
\] (11)

Now suppose that we somehow find \( \hat{p}_{\varepsilon'} \). The following theorem estimates the precision for approximation \( \hat{p}_{\varepsilon'} \) of \( p_*^\mu \) in function value.

**Theorem 8** For \( \hat{p}_{\varepsilon'} \) from (11) with probability \( \geq 1 - \alpha \) the following holds

\[
W_\mu(\hat{p}_{\varepsilon'}) - W_\mu(p_*^\mu) \leq \sqrt{\frac{2M^2}{\mu} \left( \frac{1}{m} \sum_{k=1}^{m} W_\mu(\hat{p}_{\varepsilon'}, q^k) - \frac{1}{m} \sum_{k=1}^{m} W_\mu(\tilde{p}_\mu^m, q^k) \right)} + \frac{4M^2}{\alpha \mu m}.
\]

**Proof** Consider for any \( p \in S_n(1) \) the following difference

\[
W_\mu(p) - W_\mu(p_*^\mu) \leq W_\mu(\hat{p}_\mu^m) - W_\mu(p_*^\mu) + W_\mu(p) - W_\mu(\hat{p}_\mu^m). \tag{12}
\]

From Theorem 6 from [Shalev-Shwartz et al. (2009)] with probability at least \( 1 - \alpha \) for the empirical minimizer \( \hat{p}_\mu^m \) the following holds

\[
W_\mu(\hat{p}_\mu^m) - W_\mu(p_*^\mu) \leq \frac{4M^2}{\alpha \mu m}. \tag{13}
\]

Then from (12) and (13) we have

\[
W_\mu(p) - W_\mu(p_*^\mu) \leq \frac{4M^2}{\alpha \mu m} + W_\mu(p) - W_\mu(\hat{p}_\mu^m).
\]

From Lipschitz continuity of \( W_\mu(p) \) we have

\[
W_\mu(p) - W_\mu(\hat{p}_\mu^m) \leq M \| p - \hat{p}_\mu^m \|_2. \tag{14}
\]

From strong convexity of \( W_\mu(p, q) \) we get

\[
\| p - \hat{p}_\mu^m \|_2 \leq \sqrt{\frac{2}{\mu} \left( \frac{1}{m} \sum_{k=1}^{m} W_\mu(p, q^k) - \frac{1}{m} \sum_{k=1}^{m} W_\mu(\tilde{p}_\mu^m, q^k) \right)}. \tag{15}
\]
By using (14) and (15) for (13) and taking \( p = \hat{p}_{\varepsilon'} \) we get the first inequality of the theorem.

Then using strong convexity of function we formulate the results of convergence in argument.

**Theorem 9 (Barycenter confidence interval)** For \( \hat{p}_{\varepsilon'} \) from (11) with probability at least \( \geq 1 - \alpha \)

\[
\| \hat{p}_{\varepsilon'} - p^*_\mu \|_2 \leq \frac{2}{\mu} \left( \sqrt{\frac{2M^2}{\mu}} \left( \frac{1}{m} \sum_{k=1}^{m} W_\mu(\hat{p}_{\varepsilon'}, q^k) - \frac{1}{m} \sum_{k=1}^{m} W_\mu(\hat{p}^*_\mu, q^k) \right) + \frac{4M^2}{\alpha \mu m} \right)
\]

\[
\leq \frac{2}{\mu} \left( \sqrt{\frac{2M^2}{\mu} \varepsilon' + \frac{4M^2}{\alpha \mu m}} \right)
\]

**Proof** The proof consists in application of strong convexity of \( W_\mu(p) \) for Theorem 8.

From Theorem 9 we estimate the number of measures \( q^1, q^2, q^3, \ldots \) and auxiliary precision \( \varepsilon' \) of fidelity term (11) to get \( \varepsilon \)-confidence interval \( \| \hat{p}_{\varepsilon'} - p^*_\mu \|_2 \) with probability \( \geq 1 - \alpha \)

**Corollary 10 (Number of probability measures and auxiliary precision)** To get the \( \varepsilon \)-confidence region:

\[
\| \hat{p}_{\varepsilon'} - p^*_\mu \|_2 \leq \varepsilon \quad \text{with probability} \quad \geq 1 - \alpha
\]

it suffices to take the following number of probability measures

\[
m = O \left( \frac{1}{\alpha} \left( \frac{M}{\mu \varepsilon} \right)^2 \right) \quad (16)
\]

and auxiliary \( \varepsilon' \)-precision in (11):

\[
\varepsilon' = O \left( \frac{\mu^3 \varepsilon^4}{M^2} \right).
\]

Next theorem estimates the complexity for calculating \( \hat{p}_{\varepsilon'} \) which is an approximation for population barycenter \( p^*_\mu \).

**Theorem 11** The total complexity per each node of offline algorithm from [Kroshnin et al. (2019b)] is

\[
O \left( \frac{\kappa}{\sqrt{m}} \left( \frac{nM}{\mu \varepsilon} \right)^2 \right) \quad (17)
\]
where $\kappa$ is the parameter of the architecture:

$$
\kappa = \begin{cases}
1 & \text{in fully parallel } m \text{ nodes architecture} \\
\sqrt{m} & \text{in parallel } \sqrt{m} \text{ nodes architecture} \\
m & \text{if we have only one node (machine)} \\
d & \text{in centralized } m \text{ nodes architecture} \quad (d \text{ is the communication network diameter}) \\
\sqrt{\chi} & \text{in decentralized } m \text{ nodes architecture} \quad (\sqrt{\chi} \text{ is the condition number for the network}).
\end{cases}
$$

Moreover, for one node architecture (without parallelization) the complexity can be simplified

$$
O \left( \left( \frac{M}{\mu \varepsilon} \right)^{3} \frac{n^2}{\sqrt{\alpha}} \right).
$$

(18)

**Proof** To calculate the total complexity we refer to the Algorithm 6 in the paper [Kroshnin et al. (2019b)] providing $\hat{p}_{\varepsilon'}$. For the readers convenience we repeat the the scheme of the proof. This algorithm relates to the class of Fast Gradient Methods for Lipschitz smooth functions and, consequently, has the complexity $O \left( \sqrt{\frac{LR^2}{\varepsilon'}} \right)$ [Nesterov (2018)]. Here $L$ is the constant for dual function $D_q(\lambda)$ from (3) ($L = 1/\mu$ from the proof of Proposition 1) and $R$ is the radius for dual solution (Lemma 8 from [Kroshnin et al. (2019b)]). Combining all of this we get the following number of iterations

$$
\hat{N} = \kappa \cdot \sqrt{\frac{M^2}{m \varepsilon' \mu}},
$$

where we denoted by $\kappa$ the parameter of the architecture. Multiplying by the complexity of calculating the gradient for the dual function (which is $n^2$) and using Corollary 10 for definition of $\varepsilon'$ we get the following complexity per each node

$$
O \left( n^2 \hat{N} \right) = O \left( n^2 \frac{\kappa \sqrt{M^2}}{m \varepsilon' \mu} \right) = O \left( \frac{\kappa}{\sqrt{m}} \left( \frac{nM}{\mu \varepsilon} \right)^2 \right).
$$

Using Corollary 10 for the number of measures we get the first statement of the theorem. By using $\kappa$ for one-machine architecture we get the second statement and finish the proof.

**Remark 12** From the recent results [Feldman and Vondrák (2015)] we may expect that the dependence on $\alpha$ in (16) and (18) is indeed much better (logarithmic). But, unfortunately, as far as we know in general (not small $\mu$) it’s still a hypothesis.

In the next section we construct confidence interval for population Wasserstein barycenter $p^*$. 

\[11\]
5. Population Wasserstein barycenter problem

In previous sections we were aim at constructing the confidence interval for population barycenter defined w.r.t regularized OT $W_{\mu}(p, q)$. Now we refuse the regularization of OT and seek to find population barycenter $p^*$ w.r.t OT $W(p, q)$. To do so, we firstly use the results from Sect. 3 and 4 (SA and SAA algorithms), then we consider another two methods, one of them is based on our new regularization. Since $W(p, q)$ is not strongly convex, in this section we construct $\varepsilon$-confidence interval in function value.

Thought this section we use the following notation $W(p) = \mathbb{E}_q W(p, q)$.

5.1 SA and SAA

We start with application of the results obtained by SA in Sect. 3. We regularize $W(p, q)$ by entropy with the definite regularization parameter $\mu = \frac{\varepsilon}{4 \ln n}$. Here $\varepsilon$ is a desired accuracy in function value [Dvurechensky et al. (2018); Peyrée and Cuturi (2018); Weed (2018)]

$$W(p) - W(p^*) \leq \varepsilon.$$ 

Then we use the following statement from [Gasnikov et al. (2015); Kroshnin et al. (2019b); Peyrée and Cuturi (2018)]

$$W(p) - W(p^*) \leq W_{\mu}(p) - W_{\mu}(p^*) + 2\mu \ln n \leq W_{\mu}(p) - W_{\mu}(p^*) + 2\mu \ln n, \quad \forall p \in S_n(1)$$

Taking regularization parameter $\mu = \frac{\varepsilon}{4 \ln n}$. we ensure the following

$$W(p) - W(p^*) \leq W_{\mu}(p) - W_{\mu}(p^*) + \frac{\varepsilon}{2}, \quad \forall p \in S_n(1)$$

The last inequality allows us to modify Theorem 6 and get the complexity of calculating $\hat{p}^N$ as an $\varepsilon$-approximation for $p^*$ in function value.

**Theorem 13** To ensure $W(\hat{p}^N) - W(p^*) \leq \varepsilon$ for $\hat{p}^N$ from (7) with probability $\geq 1 - \alpha$, it suffices to take the following number of probability measures (iterations) in restarted SGD from [Juditsky and Nesterov (2014)]

$$N = \tilde{O} \left( \frac{M^2}{\mu \varepsilon} \right) = \tilde{O} \left( \frac{M^2}{\varepsilon^2} \right)$$

and the following auxiliary $\delta$-precision $\delta = O(\varepsilon)$.

The total complexity will be

$$\tilde{O} \left( \left( \frac{M n}{\varepsilon} \right)^2 \min \left\{ \exp \left( \frac{\|C\|_{\infty} \ln n}{\varepsilon} \right) \left( \frac{\|C\|_{\infty} \ln n}{\varepsilon} + \ln \left( \frac{\|C\|_{\infty} \ln n}{\gamma \varepsilon^2} \right) \right), \sqrt{\frac{n}{\gamma \varepsilon^3}} \right\} \right).$$

Similarly we use the results of SAA (Theorem 11) to state the complexity bounds for calculating an approximation for $p^*$.

For simplicity we provide only results for only one-machine architecture.
Theorem 14 To ensure \( W(\hat{p}_\varepsilon) - W(p^*) \leq \varepsilon \) with probability \( \geq 1 - \alpha \) it suffices to take the following number of probability measures

\[
m = \tilde{O} \left( \frac{M^2}{\alpha \mu \varepsilon} \right) = \tilde{O} \left( \frac{M^2}{\alpha \varepsilon^2} \right)
\]

and the following auxiliary \( \varepsilon' \)-precision

\[
\delta = \tilde{O} \left( \frac{\varepsilon^3}{M^2} \right).
\]

The total complexity of algorithm form [Kroshnin et al. (2019b)] on one machine (without parallelization/decentralization) is

\[
\tilde{O} \left( \sqrt{\frac{1}{\alpha}} \frac{n^2 M^3}{\varepsilon^3} \right).
\]

5.2 Stochastic Mirror Descent

Another approach to construct \( \varepsilon \)-confidence interval in function value is refusing any regularization and using stochastic mirror descent\(^3\) with 1-norm and KL-prox structure, see, e.g., [Hazan et al. (2016); Nemirovski et al. (2009); Orabona (2019)], for inexact case see, e.g., [Gasnikov et al. (2016); Juditsky and Nemirovski (2012)].

Algorithm 2 Stochastic Mirror Descent

**Input:** Starting point \( p^1 \in S_n(1) \), \( N \) – number of measures \( q^k \)

1: \( \eta = \sqrt{\frac{2 \ln n}{M \cdot \sqrt{N}}} \)

2: for \( k = 1, \ldots, N \) do

3: \[
p_i^{k+1} = \frac{p_i^k \exp \left( -\eta \nabla_{p,i} W(p^k, q^k) \right)}{\sum_{j=1}^n p_j^k \exp \left( -\eta \nabla_{p,j} W(p^k, q^k) \right)},
\]

where indices \( i, j \) denote the \( i \)-th (or \( j \)-th) component of a vector, \( \nabla_{p,i} W(p^k, q^k) \) is calculated with \( \delta \)-precision (e.g., by Simplex Method or Interior Point Method)

**Output:** \( \hat{p}^N = \frac{1}{N+1} \sum_{k=1}^{N+1} p^k \)

From [Gasnikov et al. (2016); Juditsky and Nemirovski (2012)] we have with probability \( \geq 1 - \alpha \)

\[
W(\hat{p}^N) - W(p^*) = O \left( \sqrt{\frac{M^2 \ln(n/\alpha)}{N}} + \delta R \right) = O \left( \sqrt{\frac{M^2 \ln(n/\alpha)}{N}} + \delta \right), \quad (19)
\]

3. By using Dual Averaging scheme [Nesterov (2009)] we can rewrite Algorithm 2 in online regime without including \( N \) in the step-size policy. Note, that Mirror Descent and Dual Averaging schemes are very close to each other [Juditsky et al. (2019)].
where $M_\infty = \tilde{O} (\|C\|_\infty)$, see [Dvurechensky et al. (2018); Kroshnin et al. (2019b); Lin et al. (2019)]. Bound (19) is $\tilde{O} (\sqrt{n})$-times better the bound for Stochastic Gradient Descent with Euclidean set up [Nemirovski et al. (2009); Shalev-Shwartz et al. (2009)].

We also notice that the smoothed complexity of finding exact $\nabla_p W(p^k, q^k)$ is $\tilde{O}(n^3)$, see [Dadush and Huiberts (2018)] and references there in.

**Theorem 15** To ensure $W(\hat{p}^N) - W(p^*) \leq \varepsilon$ with probability $\geq 1 - \alpha$ it suffices to make the following number of iterations of Algorithm 2

$$N = \tilde{O} \left( \frac{M_\infty^2}{\varepsilon^2} \right).$$

The total complexity is

$$\tilde{O}(n^3 N) = \tilde{O} \left( \left( \frac{nM}{\varepsilon} \right)^2 \right).$$

**5.3 Empirical Risk Regularization**

In offline approach with Euclidean set up one may use regularization trick from [Shalev-Shwartz et al. (2009)]

$$4$$

We introduce $\frac{\lambda}{2} \|p - p^1\|_2^2$ composite term in r.h.s of equation (2) ($p^1$ is some initial vector from $S_1(n)$)

$$\hat{p}^m = \arg \min_{p \in S_n(1)} \left\{ \frac{1}{m} \sum_{k=1}^m W(p, q^k) + \frac{\lambda}{2} \|p - p^1\|_2^2 \right\}. $$

Assume that $\hat{p}_{c'}$ such that

$$\frac{1}{m} \sum_{k=1}^m W(\hat{p}_{c'}, q^k) + \frac{\lambda}{2} \|\hat{p}_{c'} - p^1\|_2^2 - \min_{p \in S_n(1)} \left\{ \frac{1}{m} \sum_{k=1}^m W(p, q^k) + \frac{\lambda}{2} \|p - p^1\|_2^2 \right\} \leq \varepsilon'. \quad (20)$$

Then the main result of Theorem 8 can be rewritten as follows [Shalev-Shwartz et al. (2009)]

$$5$$

for $\hat{p}_{c'}$ from (20) with probability $\geq 1 - \alpha$

$$W(\hat{p}_{c'}) - W(p^*) \leq \sqrt{\frac{2(M + \lambda R)^2}{\lambda}} \varepsilon' + \frac{\lambda}{2} R^2 + \frac{4(M + \lambda R)^2}{\alpha \lambda m}. $$

Consider $m$ to be big enough, we choose (like in [Shalev-Shwartz et al. (2009)]) approximately $\lambda \simeq \sqrt{\frac{M^2}{2R^2m}}$ and obtain with probability $\geq 1 - \alpha$

$$W(\hat{p}_{c'}) - W(p^*) = O \left( \sqrt{M R \sqrt{m} \varepsilon'} + \sqrt{\frac{M^2 R^2}{\alpha m}} \right). \quad (21)$$

4. In the same paper [Shalev-Shwartz et al. (2009)] one can find an explanation why do we need regularization in offline approach for non strongly convex case. The problems of SAA approach for non strongly convex case are also discussed in Guigues et al. (2017); Shapiro and Nemirovski (2005). For more complete understanding see [Shapiro et al. (2009); Sridharan (2012)].

5. Note, that in [Shalev-Shwartz et al. (2009)] instead of $(M + \lambda R)$ it was used simple $M$. For the moment we do not know how to justify this replacement. That is why we write $(M + \lambda R)$. Fortunately, when $m$ is big enough it doesn’t matter.
Remark 16 Recently, it was shown [Feldman and Vondrák (2015)] that dependence on \( \alpha \) in (21) can be improved to logarithmic.

Another type of regularization allows to improve (21). We refer to Bregman divergence \( \lambda B_d(p, p^1) \) ([Ben-Tal and Nemirovski (2015)])

\[
B_d(p, p^1) = d(p) - d(p^1) - (\nabla d(p^1), p - p^1), \quad d(p) = \frac{1}{2(a-1)} \| p \|_{a}^{2}, \quad a = 1 + \frac{1}{2 \ln n}.
\]

We notice that \( B_d(p, p^1) \) is 1-strongly convex in 1-norm and \( \tilde{O}(1) \)-Lipschitz continuous in 1-norm on \( S_n(1) \). In [Bigot et al. (2017)] there proposed to use entropy as regularizer. For entropy we have the same strong convexity properties in 1-norm on \( S_n(1) \), but we loose limitation from above on a Lipschitz constant.

Using this we redefine \( \hat{p}^m \) as follows

\[
\hat{p}^m = \arg \min_{p \in S_n(1)} \left\{ \frac{1}{m} \sum_{k=1}^{m} W(p, q^k) + \lambda B_d(p, p^1) \right\}.
\]

(22)

Assume that \( \hat{p}_\varepsilon \) such that

\[
\frac{1}{m} \sum_{k=1}^{m} W(\hat{p}_\varepsilon, q^k) + \lambda B_d(\hat{p}_\varepsilon, p^1) - \min_{p \in S_n(1)} \left\{ \frac{1}{m} \sum_{k=1}^{m} W(p, q^k) + \lambda B_d(p, p^1) \right\} \leq \varepsilon'.
\]

(23)

Consider \( m \) to be big enough, we choose approximately \( \lambda \simeq \sqrt{\frac{8M^2}{\alpha R^2 m}} \), where \( \tilde{R} \simeq B_d(p^*, p^1) = \tilde{O}(1) \), and obtain for \( \hat{p}_\varepsilon \) from (23) with probability \( \geq 1 - \alpha \)

\[
W(\hat{p}_\varepsilon) - W(p^*) = O \left( \sqrt{M\infty \tilde{R} \sqrt{m \varepsilon'}} + \sqrt{\frac{M^2 \infty \tilde{R}^2}{\alpha m}} \right).
\]

(24)

To prove this estimate we use the same arguments as in [Shalev-Shwartz et al. (2009)], but replace strong convexity and smoothness from 2-norm to 1-norm. Since \( M/M_{\infty} \simeq \sqrt{n} \) we may conclude that (24) is \( \tilde{O}(\sqrt{n}) \)-times better than (21).

Note, that if we choose \( \lambda \simeq \sqrt{\frac{8M^2}{R^2 m}} \) then (24) can be written as follows:

\[
\mathbb{E} [W(\hat{p}_\varepsilon)] - W(p^*) = O \left( \sqrt{M\infty \tilde{R} \sqrt{m \varepsilon'}} + \sqrt{\frac{M^2 \infty \tilde{R}^2}{m}} \right).
\]

This fact can be easily extract from [Shalev-Shwartz et al. (2009)], see formula (21) of this work in the proof of Claim 6.2. The same thing one can say about (21).

We summarize the result in the next theorem.

6. Note, that to solve (22) we may use the same dual distributed tricks like in [Kroshnin et al. (2019a)] if we put composite term in a separate node. But before, we should regularized \( W \rightarrow W_\mu \) with \( \mu = \frac{1}{4 \ln m} \). The complexity in terms of \( O(\cdot) \) will be the same as in Theorem 11.
Theorem 17 To ensure $W(\hat{p}_{\varepsilon'}) - W(p^*) \leq \varepsilon$ with probability $\geq 1 - \alpha$ we need to take the following number of probability measures

$$m = O \left( \frac{M^2 \tilde{R}^2}{\alpha \varepsilon^2} \right) = O \left( \frac{M^2}{n \alpha \varepsilon^2} \right)$$

and find $\hat{p}_{\varepsilon'}$ satisfy (23) with

$$\varepsilon' = \frac{\varepsilon^2}{M \tilde{R} \sqrt{m}} = \frac{\varepsilon^2}{M \sqrt{\frac{n}{m}}} = \frac{\varepsilon^2 n \sqrt{\alpha}}{M^2}.$$ 

The total complexity of properly corrected algorithm form [Kroshnin et al. (2019b)] on one machine (without parallelization/decentralization) is

$$\tilde{O} \left( \frac{n M^3}{\varepsilon^3 \alpha^{3/2}} \right).$$

Remark 18 From the recent results [Feldman and Vondrak (2019)] we may expect that the dependence on $\alpha$ in Theorems 14, 17 is indeed much better (logarithmic). For the moment we don’t possess an accurate prove of it, but we suspect that original ideas in [Feldman and Vondrak (2015)] allow to prove it.

6. Comparison

In this section we compare approaches from Sections 3, 4, 5. For the reader convenience we skip the details about high probability bounds. The first reason is we can fixed $\alpha$, say as $\alpha = 0.05$, and consider it to be a fixed parameter in all the bounds. The second reason is an intuition (goes back to [Shalev-Shwartz et al. (2009)]) that all the bounds in this paper have logarithmic dependence on $\alpha$ in fact and up to a $\tilde{O}(\cdot)$ denotation we can ignore the dependence on $\alpha$.

The main result is proving the possible superiority of SAA under SA for population ($\mu$-entropy regularized) Wasserstein barycenter estimation even in non-parallel case (and non-decentralized). For this purpose we provide Table 1, where we used (5), to compare the total complexity of the algorithms. Here $\varepsilon$-precision is the precision in argument.

<table>
<thead>
<tr>
<th></th>
<th>Complexity</th>
</tr>
</thead>
<tbody>
<tr>
<td>SA</td>
<td>$\tilde{O} \left( n^3 \left( \frac{|C|<em>{\infty}}{\mu \varepsilon} \right)^2 \min \left{ \exp \left( \frac{|C|</em>{\infty}}{\mu} \right) \left( \frac{|C|<em>{\infty}}{\mu} + \ln \left( \frac{|C|</em>{\infty}}{\gamma \mu \varepsilon^4} \right) \right), \frac{1}{\mu \varepsilon^2 \sqrt{\frac{n}{\gamma \mu}}} \right} \right)$</td>
</tr>
<tr>
<td>SAA</td>
<td>$\tilde{O} \left( n^{3.5} \left( \frac{|C|_{\infty}}{\mu \varepsilon} \right)^3 \right)$</td>
</tr>
</tbody>
</table>

Table 1: Complexity bounds for constructed confidence interal for population barycenter w.r.t. regularized OT. $\varepsilon$ is the precision in argument.

When $\mu$ is not too large, SA has the complexity according to the second term under the minimum. In this case we have obvious advantage of SAA since its complexity about in $\tilde{O} \left( \varepsilon \sqrt{\mu} \right)$ times less that SA complexity.
Next, we compare the results complexity with proper regularization of OT (with definite $\mu$ or $\mu = 0$). Table 2 presents the results. Here $\varepsilon$ is the precision in function value.

<table>

</tr>
</tbody>
</table>

Table 2: Complexity bounds for constructed confidence interval for population barycenter w.r.t. OT. $\varepsilon$ is the precision in function value.

We do not make any conclusions about comparison of Stochastic MD and Regularized ERM since it depends on comparison $\sqrt{n}$ and $1/\varepsilon$. However, both of these methods are definitely outperform (according to complexity results) SA and SAA approaches based on entropy regularization of OT.

**Remark 19** The conclusions of advantages SAA approach vs SA approach can be reinforced by using parallelization or distributed calculations. For that we can use estimate (17) instead of (18). The same we can say about the following formulas that we used in Section 5.
