Abstract

Lead halide perovskites are a fascinating class of materials for a wide range of applications because of their unique optoelectronic features. In spite of the recent discussions on the strong electron-phonon coupling of halide perovskites, its effects on the excitonic properties are not yet completely understood. Here, we investigate the exciton binding energies of CH$_3$NH$_3$PbX$_3$ [X = I, Br, and Cl] under weak magnetic fields below 7 T where the cyclotron energy is sufficiently small compared with LO phonon energy and exciton Rydberg energy. Highly sensitive magneto-reflectance spectroscopy was employed to detect the high-order exciton Rydberg states and Landau levels. The larger reduced masses and smaller exciton binding energies under the lower magnetic field suggest the strong exciton-phonon coupling. We discuss the field-dependent excitonic properties in terms of phonon screening effect and derive the polaronic and excitonic material parameters that can account for the magneto-optical properties of lead halide perovskites.
Organic–inorganic hybrid lead halide perovskites $\text{CH}_3\text{NH}_3\text{PbX}_3 \ [\text{X} = \text{I, Br, and Cl}]$ are a novel class of high-quality semiconductor materials that are anticipated for use in solar cells [1,2], light-emitting devices [3,4], sensors [5], and other optoelectronic devices [6]. Furthermore, these materials may constitute the base of future semiconductor physics and innovative devices beyond conventional semiconductors. The combination of wide tunability of the bandgap energy and high photoluminescence (PL) quantum yields makes the lead halide perovskites unique semiconductor materials [7-10], and the high PL yields enable remarkable phenomena such as laser-induced cooling [11] and photon recycling [12-14]. This outstanding performance of the lead halide perovskites might be enabled by its defect-tolerant nature, which is reflected in high formation energy of deep defect states.

Recently, polaron formation through strong electron-phonon coupling has been discussed as a critical feature of halide perovskites to account for the long carrier lifetime and relatively small carrier mobility. Some research groups proposed large polaron formation induced by conventional Fröhlich mechanism or ferroelectric-like dielectric response [15,16] and small polaron formation coupled with local structural lattice distortions [17,18]. However, the impact of electron-phonon interaction on band-edge optical properties remains unclear.

Magneto-reflectance spectroscopy is one of the most powerful tools to derive the band-edge optical parameters of semiconductors, including exciton binding energy, reduced mass, effective dielectric constant, etc. Previous magneto-optical studies on lead halide perovskites have estimated the exciton binding energies by employing extremely strong pulsed magnetic fields up to 130 T [19,20]. It is known that the magnetic-field dependence is characterized by the field strength parameter $\gamma = \hbar \omega_c/(2 R^*)$, where $\hbar \omega_c$ and $R^*$ are cyclotron energy and exciton Rydberg energy [21]. Under such intense magnetic fields ($\gamma \gg 1$), the optical properties are dominated by the splitting of Landau levels, whose observation enables studying exciton properties even in samples with low crystalline quality. However, careful interpretation is required in the case of materials with strong exciton-phonon coupling: theoretical studies have demonstrated that the phonon contribution to the screening is
reduced as the magnetic fields become stronger [22]. This means that the electron-phonon interaction differently contributes to the optical properties under strong and weak magnetic field. Consequently, measurements with high-quality crystals under weak magnetic fields are essential for an accurate estimation to reveal the band-edge optical properties in the low-field limit, which is more relevant to the actual device operation and materials research on halide perovskites.

Here we report the exciton binding energy of CH$_3$NH$_3$PbX$_3$ [$X = $I, Br, and Cl] single crystals at low temperatures, obtained by highly sensitive magneto-reflectance measurements with relatively weak magnetic fields up to 7 T, corresponding to $\gamma < 1$ regime. Under such weak magnetic field, the relation of $\hbar\omega_{LO} > R^* > \hbar\omega_c$ is satisfied for CH$_3$NH$_3$PbI$_3$ and CH$_3$NH$_3$PbBr$_3$, where $\hbar\omega_{LO}$ is the LO phonon energy, and the phonon screening effect plays an essential role. The observation of the Landau levels and higher-order exciton Rydberg states enables precise estimation of the reduced mass and exciton binding energies. We report 4.3, 11, and 67 meV for CH$_3$NH$_3$PbI$_3$, CH$_3$NH$_3$PbBr$_3$, and CH$_3$NH$_3$PbCl$_3$, respectively. These values are much smaller than those obtained under intense magnetic field [19,20,23]. We discuss such discrepancies in terms of magnetic-field dependent phonon screening, which highlights the significance of the exciton-phonon interaction on the band-edge optical properties of lead halide perovskites.

We fabricated CH$_3$NH$_3$PbI$_3$, CH$_3$NH$_3$PbBr$_3$, and CH$_3$NH$_3$PbCl$_3$ single crystals (see Supplemental Material for crystal growth method) and used their cleaved surfaces for the optical measurements. We conducted the reflectance measurements at 1.5 K with a Helmholtz superconducting magnet in the Faraday configuration. Note that all the crystals we used are in orthorhombic phase at cryogenic temperature [24], where the motion of CH$_3$NH$_3^+$ cation is frozen out. This means that we can neglect the impact of CH$_3$NH$_3^+$ dipole orientation on polaronic and excitonic features, which would be essential in high-temperature tetragonal and cubic phase [25,26]. The continuous magnetic field up to 7 T allows long data acquisition times, which enables us to detect minute optical responses such as higher-order exciton resonances. Using a linear polarizer and a liquid crystal variable retarder, we generated either right- or left-circular polarized white light from the laser-driven light source (EQ-
99X, Energetiq Technology, Inc.). The circularly polarized light was focused onto the crystal surface (spot size ~ 100 μm), and the spectrum of the reflected light was measured by a monochromator with a CCD camera. The spectral resolution was 0.24 meV at 2.27 eV. We calculated the degree of circular polarization from the difference between the reflectance intensities measured for right- and left-circular polarized light, which enables us to detect small structures in the reflectance spectrum with high sensitivity.

The reflectance spectra of the CH$_3$NH$_3$PbI$_3$ single crystal at 1.5 K under different magnetic field strengths with left- (σ$^+$) and right-circular polarized (σ$^-$) light are shown in Fig. 1a and 1b, respectively. The spectrum without applied magnetic field exhibits an inflection point at around 1.637 eV, which corresponds to the 1s exciton resonance energy. The broadening of the 1s exciton (that is, energy separation between positive and negative peaks indicated with the arrowheads in Fig. 1a) is 1.3 meV, which is much narrower than that in previous reports [20,23,27].

The 1s exciton resonance slightly shifts to the higher energies under applied magnetic fields. In addition, we observe three small peaks at the high-energy side for finite magnetic field strengths as well as a peculiar feature just below the 1s exciton resonance. An enlarged view of the high-energy side is displayed in the inset of Fig. 2a. The peaks appear at regular intervals and thus are assigned to the Landau levels. The dependences of the peak energies on the magnetic field strength are summarized in Fig. 2a. The 1s exciton resonance energy is also plotted in the same figure for reference. The peak energies of the Landau levels linearly depend on the magnetic field in accordance with the theoretical prediction of the energies of the Landau levels which are described by

$$E_g + \left( N + \frac{1}{2} \right) \hbar \omega_c \pm \frac{1}{2} g_{\text{eff}} \mu_B B,$$

where $N = 0, 1, 2, \ldots$ is the quantum number, $\omega_c = \frac{eB}{\mu}$ is the cyclotron frequency, and $g_{\text{eff}}$, $\mu_B$, and $B$ are the effective g-factor, Bohr magneton, and magnetic field strength, respectively. The observation of this Landau fan enables us to estimate $g_{\text{eff}}$ of 1.68 and a reduced mass $\mu$ of 0.15 (±0.01) $m_0$ ($m_0$ is the electron rest mass), which determines the cyclotron frequency. It should be noted that the reduced mass is enhanced with respect to that reported in high-field experiments ($\mu \sim 0.1 m_0$) [19].
We plotted the 1s exciton resonance energies for both excitation conditions as a function of the magnetic field in Fig. 2b. Note that the scale of the vertical axis is about ten times smaller than that of Fig. 2a. The 1s exciton energy is determined by the diamagnetic shift and Zeeman splitting, and thus obeys the function $C_0B^2 \pm \frac{1}{2} g_{ex} \mu_B B$, where $C_0$ and $g_{ex}$ are the diamagnetic constant and exciton g-factor. Using a global fitting procedure that accounts for both $\sigma^+$ and $\sigma^-$ excitation conditions, we estimate $C_0 = 15.9 (\pm 0.1) \mu$eV/T$^2$ and $g_{ex} = 1.63$, which is consistent with the effective g-factor estimated from the Landau levels.

In Wannier-Mott exciton model, the diamagnetic constant is related to the exciton binding energy $R^*$, effective dielectric constant $\varepsilon_{eff}$, and exciton Bohr radius $a_B$ via the following three equations:

$$
\frac{R^*}{R_y} = \left( \frac{\varepsilon_H}{\varepsilon_{eff} \varepsilon_0} \right)^{\frac{1}{2}}, \quad \frac{a_B}{a_H} = \left( \frac{\varepsilon_{eff} \varepsilon_0}{\varepsilon_H} \right)^{\frac{1}{2}}, \quad \frac{\mu}{m_0} = \left( \frac{\varepsilon_{eff}^2 \varepsilon_H}{C_0} \right)^{\frac{1}{2}}.
$$

Here, we use the values for hydrogen, i.e., the Bohr radius $a_H = 0.53 \AA$, diamagnetic coefficient $C_H$ of $1.23 \times 10^{-10}$eV/T$^2$, and Rydberg constant $R_y = 13.6$ eV. Under assumption of Wannier-Mott exciton model, we obtain the following values for the exciton binding energy, dielectric constant, and Bohr radius in CH$_3$NH$_3$PbI$_3$: $R^* = 4.7 (\pm 0.6)$ meV, $\varepsilon_{eff} = 21 (\pm 2)$, and $a_B = 74 (\pm 3) \AA$.

The estimated exciton binding energy is consistent with that obtained from the simple interpolation of Landau energies ($\sim 4.3 (\pm 0.3)$ meV, see Fig. 1a), suggesting that Wannier-Mott exciton model is almost applicable in CH$_3$NH$_3$PbI$_3$. These parameters estimated above are quite different from those obtained for $\gamma \gg 1$ regime (c.f. $R^* = 16$ meV reported in thin films [19] and single crystals [23]), which will be discussed later.

Now we provide a brief comment on the feature just below the 1s free exciton energy. This additional resonance at about 1.636 eV exhibits a quadratic dependence on the magnetic field strength, which is similar to the behavior of the 1s exciton, as shown in Fig. 2b. It is worth noting that high-energy $\sigma^+$ component is much stronger than low-energy $\sigma^-$ one for positive applied magnetic field, which is quite
different from the case of 1s exciton. Such magnetic-field dependence has been observed in charged exciton [28,29]; low-energy state (j = −1/2) is occupied for the case of charged exciton and thus σ− excitation hardly occurs (see the inset). However, we need more elaborated researches to draw a conclusion, and the further discussion is beyond the scope of this study.

It is significant to investigate the halogen-dependence of the excitonic properties. In the following, we discuss the data obtained from the magneto-reflectance measurements on a CH₃NH₃PbBr₃ single crystal. The reflectance spectra of CH₃NH₃PbBr₃ single crystal at 0 and 7 T are shown in Fig. 3a. A clear 1s exciton resonance appears at 2.254 eV. By applying a magnetic field, the exciton resonance energy shifts only marginally due to Zeeman splitting. The degree of the shift depends on the excitation polarization. We observed linear dependence of energy separation on the magnetic field and estimate g-factor $g_{ex} = 2.30$. In addition, a small dip appears below 1s exciton energy by applying magnetic field, as indicated by an arrow in Fig.3a. Similar to the case in CH₃NH₃PbI₃, this spectral feature is observed only under σ+ excitation. However, the signal is so small for the further discussion.

To accurately determine the exciton energy structure, we investigate the differences in the reflectance spectra obtained for σ+ and σ− excitation. We define the degree of the circular polarization $p$ with

$$p = \frac{\sigma^+ - \sigma^-}{\sigma^+ + \sigma^-}, \quad (2)$$

where σ+ and σ− are the measured reflectance intensities under excitation with left- and right-circular polarized light, respectively. When the Zeeman splitting is small, the circular polarization spectrum $p$ corresponds to the first derivative of the reflectance spectrum and exhibits a peak at the exciton resonance energy accompanied by two small opposite peaks on both sides. This enables us to resolve even small structures in the reflectance spectrum such as higher-order exciton resonances, because common noise is canceled out according to Eq. (2).

Figure 3b shows the circular polarization spectra $p$ for different magnetic field strengths. We confirm a strong peak at 2.254 eV, which agrees well with previous reports and can be assigned to the 1s free exciton resonance [30,31]. The 1s peak energy shows very small diamagnetic shift compared
with CH$_3$NH$_3$PbI$_3$, and the diamagnetic coefficient is estimated to be $C_0 = 2.30(\pm 0.01) \ \mu$eV/T$^2$ (see Supplemental Material). In the energy region above the 1s free exciton, a small peak is found at around 2.265 eV, which shows blueshift with an increase in the absolute magnitude of the magnetic field. We assign this peak as 2s exciton state based on the magnetic-field dependence of the resonance energy. (see Supplemental Material). A magnification of the data for a magnetic field equal to 7 T in the range between 2.263 and 2.286 eV is provided in Fig. 3c. A tiny dip is also observed at 2.267 eV, which is probably attributable to 2p or 3s exciton state.

Above 2.27 eV, we observe clear spectral structures with regular intervals, which correspond to Landau levels rather than higher-order excitons. Since the circular polarization spectrum is the first derivative of reflectance spectrum, Landau energy corresponds to the inflection point with negative slope as indicated by dotted lines in Fig. 3c.

Figure 3d summarizes the exciton Rydberg states and Landau levels of CH$_3$NH$_3$PbBr$_3$ as a function of the magnetic field. According to the magnetic-field dependence of Landau levels, the reduced mass is estimated to be $\mu = 0.21 (\pm 0.01) \ m_0$. In addition, we obtain the bandgap energy of 2.265 eV by the linear extrapolation of Landau levels to 0 T ($N = 1, 2, 3, 4$; dotted lines). Thus, the 1s exciton binding energy of 11 (±1) meV is determined. We estimate the 1s and 2s exciton resonance energies at zero magnetic field as 2.254 and 2.264 eV, respectively. Apparently, simple Wannier-Mott model ($E_{X,n} = E_g - R^*/n^2$) cannot reproduce the experimental results, as shown in the inset of Fig. 3d; the smaller exciton binding energy is observed for the larger quantum number compared with Wannier-Mott model. Such deviation from Wannier-Mott model is usually observed when the polaron radius is close to or larger than the 1s exciton Bohr radius because the phonon screening is more significant for the higher-order excitons possessing larger Bohr radius [32]. Here, the polaron radii for electron and hole, $r_{e,h}^p$, are given by $r_{e,h}^p = (\hbar/2m_{e,h}^*\omega_{LO})^{1/2}$, where $m_{e,h}^*$ are electron and hole band masses for rigid lattice.

Although simple Wannier model cannot describe the series of exciton resonance energies in CH$_3$NH$_3$PbBr$_3$, it is useful to estimate the excitonic parameters for 1s exciton on the basis of Eq. (1). We obtain effective dielectric constant $\varepsilon_{eff} = 16(\pm 1)$, exciton Bohr radius $a_B = 41(\pm 3) \ \AA$ and $C_0$
\( = 3.5(\pm 0.5) \text{ \mu eV/T}^2 \), if we substitute \( R^* = 11 \text{ meV} \) and \( \mu = 0.21 \text{ } m_0 \) to Eq. (1). The effective dielectric constant locates nearly at the middle point between the high-frequency (5.2) and low-frequency (28) values [33]. This is consistent with the deviation of high-order exciton resonance energy from the Wannier-Mott model.

Similar to the case in CH$_3$NH$_3$PbI$_3$, these parameters estimated above are quite different from those previously reported under intense magnetic field \( (R^* = 25 \text{ meV}, \mu = 0.117 \text{ } m_0, \) and \( \epsilon_{\text{eff}} = 7.5 \text{ } \) in thin film CH$_3$NH$_3$PbBr$_3$ [20]). We consider that such discrepancy is due to magnetic-field dependent screening by LO phonons.

We schematically show the exciton Rydberg energy, cyclotron energy, and LO phonon energy of CH$_3$NH$_3$PbX$_3$ \([X = I, \text{ Br, and Cl]}\) in Figure S5 in Supplemental Material, where the cyclotron energies in our experiment and previous intense-field data are compared [19,20]. The data on a CH$_3$NH$_3$PbCl$_3$ single crystal is also shown in Supplemental Material. Obviously, the relation of \( \hbar \omega_c \gg R^*, \hbar \omega_{LO} \) is satisfied in previous reports under intense magnetic field, meaning that LO phonon screening hardly contributes to the cyclotron resonance. As previously demonstrated by theoretical work, the phonon screening is reduced with an increase in applied magnetic field [22]. In other words, the polaron effect becomes essential in the framework of Fröhlich interaction when the polaron radius is smaller than the cyclotron radius. Thus, it is considered that the reduced mass estimated from cyclotron frequency under intense field rather reflects the bare carrier mass without electron-phonon interaction. Actually, the lighter effective mass under high magnetic field in the case of \( \hbar \omega_c \gg \hbar \omega_{LO} \) has been reported in other semiconductors, which is attributable to the reduced polaron effects [34].

On the other hand, for our weak-field experiment, \( \hbar \omega_{LO} > R^* \geq \hbar \omega_c \) is satisfied. In this regime, polaron mass enhancement occurs due to strong electron-phonon interaction. We consider that the polaron mass renormalization is the origin of different reduced mass and exciton binding energy observed under intense and weak magnetic field.

For more quantitative discussion, we consider the polaron effect based on Haken potential [35]. The effective dielectric constant, \( \epsilon_{\text{eff}} \), is given by
\[
\frac{1}{\varepsilon_{\text{eff}}} = \frac{1}{\varepsilon_0} - \left(\frac{1}{\varepsilon_\infty} - \frac{1}{\varepsilon_0}\right) \left(1 - \frac{\exp(-r_{eh}/r_{lh}^p) + \exp(-r_{eh}/r_{hp}^p)}{2}\right),
\]

where \(\varepsilon_0\) and \(\varepsilon_\infty\) are low- and high-frequency dielectric constants, respectively, and \(r_{eh}\) is the distances between electron and hole [27,35]. The renormalized masses (polaron mass) for electrons and holes are \(m_{e,h}^{\text{pol}} = m_{e,h}^* \left(1 + \frac{\alpha_{e,h}}{6}\right)\), where the coupling constant, \(\alpha_{e,h}\), is given by \(\alpha_{e,h} = \frac{e^2}{8\pi\hbar \omega_{LO}} \left(\frac{2m_{e,h} \omega_{LO}}{\hbar}\right)^{1/2} \left(\frac{1}{\varepsilon_\infty} - \frac{1}{\varepsilon_0}\right)\). It should be noted that we neglect anisotropy effect and multiple LO phonon modes in orthorhombic phase in the following calculation for simplicity. It has been demonstrated that anisotropy effect is negligible when considering exciton [36]. In addition, we previously demonstrated that single LO mode approximation is applicable if we use weighted average of LO phonon frequencies [37].

We adopted the literature values of free carrier electron and holes masses without consideration of electron-phonon interaction reported by Bokdam et al. [38], since the reduced masses derived from these parameters are close to those obtained from high-field experiments (0.104 \(m_0\) for CH\(_3\)NH\(_3\)PbI\(_3\) and 0.117 for CH\(_3\)NH\(_3\)PbBr\(_3\) [20]), which should correspond to the bare band masses. Based on the above equations, we calculated the effective dielectric constant, polaron mass, coupling constant, and other related parameters for CH\(_3\)NH\(_3\)PbX\(_3\) [X = I, Br, and Cl] as displayed in Table 1. Here we consider the electron-hole distance, \(r_{eh}\), as exciton Bohr radius, and solved Eq. (3) with the relation of Bohr radius and effective dielectric constant \(r_{eh} = \frac{4\pi\varepsilon_{\text{eff}}}{\mu e^2}\) simultaneously. Besides, we calculated the exciton Rydberg energy from \(R_y^* = \frac{\mu}{m_{e,h}^{\text{eff}} e^2}\), where the reduced mass is given by \(\mu = \frac{1}{m_e^{\text{pol}}} + \frac{1}{m_h^{\text{pol}}}\).

The calculated exciton binding energy and polaron reduced mass show better agreement with our experimental results rather than those under intense magnetic field. This indicates that the Fröhlich-type electron-phonon coupling gives dominant contribution to the band-edge optical properties.

On the other hand, it is obvious that simple Fröhlich large polaron model cannot provide complete picture of mass enhancement by polaronic effect in halide perovskites: mass enhancement is given by \((1+\alpha/6)\) in the framework of Fröhlich model where halide perovskites display \(\alpha\sim2\), while the reduced mass in our low-field experiment shows a 50 % (75 %) increase in CH\(_3\)NH\(_3\)PbI\(_3\) (CH\(_3\)NH\(_3\)PbBr\(_3\))
compared with the previous high-field experiments. This discrepancy indicates the stronger electron-phonon coupling compared with that predicted from conventional Fröhlich polaron model, and suggest that other polaron mechanism, such as small polaron, is required to gain thorough understanding of mass enhancement. Theoretical calculations have demonstrated small polaron formation in halide perovskites[17,39]. As we demonstrated in this work, a study of polaron mass enhancement by magneto-optical spectroscopy can be a powerful tool to discuss the polaron formation mechanism.

In summary, we investigated the excitonic properties of CH$_3$NH$_3$PbX$_3$ perovskite single crystals under weak magnetic field. The estimated exciton binding energy is much smaller than that reported in high-field experiments. We clarified the discrepancy of excitonic magneto-optical properties between the low- and high-field regimes in terms of phonon screening, which is dependent on the magnetic field strength in the presence of strong electron-phonon interaction. In addition, we showed the polaronic and excitonic material parameters that can account for the high- and low-field magneto-optical properties. Our data provide the low-field excitonic parameters, which are more relevant to the device operation and required for a quantitative discussion of the physics in lead halide perovskite semiconductors.

Single crystal growth

The CH$_3$NH$_3$PbBr$_3$ single crystals were prepared from a N, N-dimethylformamide (DMF) solution. Purified lead bromide and MA bromide with a 1:1 molar ratio were dissolved in dry DMF (10 mL). The resulting solution is poured into a screwcap vial, which is then placed on a hot plate at 90 °C for 2 days to produce clear-faceted polyhedral single
crystals with a few millimeters in size. We used a cleaved surface for the optical measurements. Using atomic force microscopy, we confirmed that the surface contains atomically-flat terraces with steps extending more than 5 mm.

**Magneto-reflectance**

We conducted the reflectance measurements at 1.5 K with a Helmholtz superconducting magnet in the Faraday configuration. The continuous magnetic field up to 7 T allows long data acquisition times (in this work we integrated over 10 s), which enables us to detect minute optical responses such as higher-order exciton resonances. Using a linear polarizer and a liquid crystal variable retarder, we generated either right- or left-circular polarized white light from the laser-driven light source (EQ-99X, Energetiq Technology, Inc.). The circular polarized light was focused onto the crystal surface (spot size ~ 100 mm) and the spectrum of the reflected light was measured by a monochrometer with a CCD camera. The spectral resolution was 0.24 meV at 2.27 eV. We calculated the degree of circular polarization from the difference between the reflectance intensities measured for right- and left-circular polarized light, which enables us to detect small structures in the reflectance spectrum with high sensitivity.

**Surface characterization**

The atomic force microscopy (AFM) images in Fig. S1 show the atomically flat surface obtained by cleaving the single crystal samples. To obtain the reflectance spectrum, the sample was illuminated with white light and the reflected light was analyzed with a monochrometer.
Figure S1

Magnetoreflectance of CH$_3$NH$_3$PbCl$_3$

As shown in Fig. S2, the reflectance spectrum of a CH$_3$NH$_3$PbCl$_3$ single crystal shows the 1s exciton resonance at 3.23 eV. In addition, we observed a small structure at 3.28 eV, which will correspond to 2s excitons. If we assume the Wannier-Mott model, the exciton binding energy is estimated to be 67 meV. This value is much larger than that of
CH$_3$NH$_3$PbI$_3$ and CH$_3$NH$_3$PbBr$_3$, which suggests the smaller phonon screening in CH$_3$NH$_3$PbCl$_3$. It should be noted that the high-order exciton resonance energy will deviate from Wannier-Mott model in CH$_3$NH$_3$PbCl$_3$ because the phonon energy is lower than exciton Rydberg energy. In this situation, the degree of phonon screening is dependent on the principal quantum number of exciton. As a result, it is expected that the exciton binding energy is above 67 meV. The diamagnetic shift for 1s exciton is quite small and below the spectral resolution of our measurements, as will be mentioned below. The expected diamagnetic coefficient based on the parameters listed in Table 1 in the main text is 0.3 meV/T$^2$, which is one- or two-orders magnitude smaller than CH$_3$NH$_3$PbBr$_3$ and CH$_3$NH$_3$PbI$_3$.

Degree of circular polarization of reflectance spectrum of a CH$_3$NH$_3$PbCl$_3$ single crystal under different magnetic fields. The inset shows the reflectance spectra under 0 T and 7
T mangetic field.

1s and 2s exciton resonance energy as a function of the magnetic field

Figure S3 shows the 1s exciton resonance energy as a function of applied magnetic field for CH$_3$NH$_3$PbI$_3$, CH$_3$NH$_3$PbBr$_3$, and CH$_3$NH$_3$PbCl$_3$, which are estimated from the first derivative of circular-polarization-resolved reflectance spectra. The solid curves are for eye guiding. The averaged exciton resonance ($\frac{\sigma^+ + \sigma^-}{2}$) and Zeeman splitting ($\sigma^+ - \sigma^-$) are also plotted. The dotted curves are fitting results by quadratic and linear function. The estimated diamagnetic coefficient and g-factor are indicated in the figure. For CH$_3$NH$_3$PbCl$_3$, the diamagnetic shift was not clearly observed because of large fitting error. We can confirm that CH$_3$NH$_3$PbI$_3$ has a much larger diamagnetic coefficient than CH$_3$NH$_3$PbBr$_3$ and CH$_3$NH$_3$PbCl$_3$. 
**Figure S3**

Magnetic field dependences of the 1s exciton resonance energy under $s^+$ and $s^-$ exciton for (a) CH$_3$NH$_3$PbI$_3$, (b) CH$_3$NH$_3$PbBr$_3$, and (c) CH$_3$NH$_3$PbCl$_3$. Solid curves are for eye guiding. Averaged exciton energy and Zemman splitting for (a) CH$_3$NH$_3$PbI$_3$, (b) CH$_3$NH$_3$PbBr$_3$, and (c) CH$_3$NH$_3$PbCl$_3$ are also shown. The dotted curves are the fitting results by a quadratic and linear function.

We also plot 2s exciton resonance energy for CH$_3$NH$_3$PbBr$_3$ and CH$_3$NH$_3$PbCl$_3$ in Figure S4. For CH$_3$NH$_3$PbI$_3$, we could not observe 2s exciton resonance. 2s exciton energies show
quadratic dependence on the magnetic field. We performed the curve fitting of averaged
2s exciton energy with \( E = E_0 + C_{2s}B^2 \), and obtained \( C_{2s} = 20.0 \) and \( 3.0 \) meV/T² for
\( \text{CH}_3\text{NH}_3\text{PbBr}_3 \) and \( \text{CH}_3\text{NH}_3\text{PbCl}_3 \), respectively. In a simple three-dimensional Wannier
model, the diamagnetic energy shift of the \( n \)th s exciton Rydberg state, \( \Delta E_d(B) \), is given
by
\[
\Delta E_d(B) = \frac{n^2(5n^2+1)}{6} C_0 B^2, \tag{S1}
\]
with \( n \) being a non-zero integer number [S1]. It is evident that the diamagnetic shift
becomes significantly large for high \( n \). Therefore, the diamagnetic shift for 2s exciton is
14 times larger than that of 1s exciton in Wannier-Mott exciton model. The diamagnetic
coefficient of 2s peak is 7-times larger than that of 1 excitons for \( \text{CH}_3\text{NH}_3\text{PbBr}_3 \). Such
discrepancy appears because the Wannier-Mott exciton model is not applicable in
\( \text{CH}_3\text{NH}_3\text{PbBr}_3 \), as described in the main text.
For \( \text{CH}_3\text{NH}_3\text{PbCl}_3 \), we can roughly estimate the diamagnetic coefficient, \( C_0 \sim 0.21 \)
meV/T², according to eq. (S1) by assuming Wannier-Mott exciton model. This value is
consistent with that estimated in the main text (\( \sim 0.3 \) meV/T²).
Figure S4

Magnetic field dependences of the 2s exciton resonance energy under $s^+$ and $s^-$ exciton for (a) CH$_3$NH$_3$PbBr$_3$ and (b) CH$_3$NH$_3$PbCl$_3$. Solid curves are for eye guiding. Averaged exciton energy and Zeman splitting for (c) CH$_3$NH$_3$PbBr$_3$ and (d) CH$_3$NH$_3$PbCl$_3$ are also shown. The dotted curves are the fitting results by a quadratic and linear function.
Figure S5

Schematic energy diagram of exciton Rydberg energy ($R^*$), LO phonon energy ($\hbar\omega_{LO}$), and cyclotron energy ($\hbar\omega_c$) for CH$_3$NH$_3$PbI$_3$, CH$_3$NH$_3$PbBr$_3$, and CH$_3$NH$_3$PbCl$_3$. Cyclotron energy for this work corresponds to the magnetic of 4 – 7 T and is calculated using $m = 0.15m_0$ and $0.21m_0$ for CH$_3$NH$_3$PbI$_3$ and CH$_3$NH$_3$PbBr$_3$. For comparison, cyclotron energy of previous high-field experiments (Refs. 19 and 20 in main text for CH$_3$NH$_3$PbI$_3$ and CH$_3$NH$_3$PbBr$_3$) were also indicated. The LO phonon energy is from Ref. 37 in the main text.
