ABSTRACT: We detect the diffuse thermal Sunyaev-Zeldovich (tSZ) effect from the gas filaments between the Luminous Red Galaxy (LRG) pairs using a new approach relying on stacking the individual frequency maps. We apply and demonstrate our method on 88000 LRG pairs in the SDSS DR12 catalogue selected with an improved selection criterion that ensures minimal contamination by the Galactic CO emission as well as the tSZ signal from the clusters of galaxies. We first stack the *Planck* channel maps and then perform the Internal Linear Combination method to extract the diffuse y_{sz} signal. Our *Stack First* approach makes the component separation a lot easier as the stacking greatly suppresses the noise and CMB contributions while the dust foreground becomes homogeneous in spectral-domain across the stacked patch. Thus one component, the CMB, is removed while the rest of the foregrounds are made simpler even before component separation algorithm is applied. We obtain the WHIM signal of $y_{\text{whim}} = (3.78 \pm 0.37) \times 10^{-8}$ in the gas filaments, accounting for the electron overdensity of ~ 13 . We estimate the detection significance to be $\gtrsim 10.2\sigma$. This excess y_{sz} signal is tracing the warm-hot intergalactic medium and it could account for most of the missing baryons of the Universe. We show that the *Stack First* approach is more robust to systematics and produces a cleaner signal compared to the methods relying on stacking the y -maps to detect weak tSZ signal currently being used by the cosmology community.

1 Introduction

According to the standard Λ CDM model of Cosmology, our Universe is composed of approximately 5% baryonic matter with the rest 95% of the total energy density in the form of dark matter and dark energy. The current most precise measurement of the baryonic energy density parameter, $\Omega_b h^2 = 0.02225 \pm 0.00016$, where $h = H_0/(100 \text{ km/s/Mpc})$ and H_0 is the Hubble constant, is derived from the cosmic microwave background (CMB) measurements [1] and thus tells us the amount of baryons present at the time of recombination at redshift $z \approx 1100$ [2, 3]. However, observations of the low redshift Universe show that the baryon fraction today falls below the expected universal value from CMB for almost all regions (except for the massive haloes) [4]. It has been known for sometime now that almost all of the baryons at high redshifts ($z \gtrsim 2$) are accounted for in the Lyman- α absorption forest [5]. In contrast, at low redshifts ($z \lesssim 2$) we see that even after accounting for the baryons in stars, galaxies, Lyman- α forest gas along with broad Lyman- α and OVI absorbers, and hot gas in clusters of galaxies, almost half of the baryons are still missing [6]. This apparent discrepancy between the direct observations spanning the electromagnetic spectrum

from radio to X-rays and the predicted baryonic mass in the standard model of cosmology and the galaxy formation theories need to be resolved by locating ‘*the missing baryons*’.

The gravitational instability of small initial Gaussian density fluctuations results in anisotropic collapse [7, 8] forming sheets (Zeldovich pancakes) and filaments that make up a web like structure, the cosmic web [9–14]. Galaxies and galaxy clusters, embedded in the knots of the web (also known as dark matter haloes), are therefore connected by large-scale filamentary structures. It has been long known from simulations that a large fraction of the baryons are in the seemingly empty regions of the universe, i.e. outside the gravitationally bound haloes [15]. The haloes are highly overdense regions, but there are regions which are mildly overdense but span a much larger volume. These relatively low density and high volume spanning regions of sheets and filaments could be a rich reservoir of the missing baryons as they go undetected by the conventional methods. The gas in these filaments or the intergalactic medium (IGM) have a density of the order of ten times the mean baryon density and temperatures between $10^5 - 10^7$ K. Hydrodynamical simulations suggest that this warm hot intergalactic medium (WHIM) could contain 30 – 50 % of all baryons today [16, 17], even though the filaments occupy only 6 % of the total volume [18]. The high ionization degree would have prevented these baryons from being detected in absorption line surveys in the radio and optical bands while the low density and temperature would have prevented them from being detected in either emission lines or in the X-ray surveys targeting thermal X-ray emission, making them an ideal candidate for the *missing baryons*. The efforts for the detection of these missing baryons have been ongoing. Most of the campaigns targeting WHIM have focused on the detection of hot gas using X-rays from individual filaments [19] or from the absorption spectra of quasars [6]. These methods are however able to probe only a part of the phase space of WHIM leaving about $\sim 30\%$ of the baryons still unobserved [6, 20]. There has been a recent work on X-ray detection of filamentary structures near cluster Abell 2744 [21], albeit their work probes the hotter and denser end of the WHIM, and quote a small fraction of baryons in that state. Recent observations of OVII absorption lines in the X-ray spectra of a $z = 0.48$ blazar provide some evidence for a significant fraction of baryons to be present in $\sim 10^6$ K gas at $z \sim 0.4$ [22] leading to the claim by the authors that the missing baryons have been found, albeit in just two systems very close to a single blazar. There have been detections of kinetic Sunyaev Zeldovich (kSZ) effect from the baryons in the dark matter halos (galaxies and clusters of galaxies) [23–26], which is sensitive to peculiar motion of the baryons with non zero velocities. Recently, it was shown that the cross-correlation of angular fluctuations of galaxy redshifts with the kSZ effect in CMB temperature maps [27] can be sensitive to baryons in regions with overdensities consistent with those of the filaments and sheets in the cosmic web.

The elastic scattering of hot free electrons in the WHIM with the CMB photons boosts the energy of the CMB photons resulting in a characteristic spectral distortion of the CMB, the thermal Sunyaev Zeldovich (tSZ) effect [28]. The tSZ effect provides a way to study WHIM through multifrequency experiments, such as *Planck*, which can separate the tSZ effect from the CMB and foreground emissions [29–31]. The magnitude of tSZ distortion, denoted by y_{sz} , is a function of both the gas density and the temperature of the medium [32] and is given by (using *Planck* 2018 cosmological parameters [33] and fully ionized primordial gas)

$$\begin{aligned} y_{\text{sz}} &= \int ds n_e \sigma_T \frac{k_B T_e}{m_e c^2} \\ &\approx \tau_T \frac{k_B T_e}{m_e c^2} \\ &\approx 7.6 \times 10^{-8} \left(\frac{\delta}{10} \right) \left(\frac{T_e}{10^7 \text{ K}} \right) \left(\frac{r}{10 \text{ Mpc}} \right), \end{aligned} \quad (1.1)$$

where n_e is the free electron number density, T_e is the electron temperature, σ_T is the Thomson

cross section, k_B is the Boltzmann constant, m_e is the mass of electron, c is the speed of light, the integral is over the line of sight distance, s , through the WHIM, $\delta = \rho/\rho_b$ is the overdensity, ρ is the filament baryon density, ρ_b is the average baryon density, r is the length of filament along the line of sight and τ_T is the Thomson optical depth through the WHIM or the filament along the line of sight. If we take the filament baryon density to be $10\times$ average baryon density ($\delta = 10$), we get an optical depth of $\tau_T \sim 4.5 \times 10^{-6}/\text{Mpc}$ at $z = 0$. For a temperature of $T_e \sim 10^7$ K, we will get a tSZ signal of $\sim 7.6 \times 10^{-8}$ or a Rayleigh-Jeans temperature decrement of $2y_{sz} \sim 0.1 \mu\text{K}$ after integrating over $r = 10$ Mpc along the line of sight. This signal is much smaller than the noise in the current best CMB experiments, and in particular much smaller compared to the sensitivity of *Planck*. Therefore, it is not possible at present to detect the individual filaments. We can however beat down the noise by stacking hundreds of thousands of filaments, improving the signal to noise ratio, S/N , by a factor of hundreds. The y_{sz} signal from the WHIM in the stacked objects would be detectable in the *Planck* data if we can remove the contamination from the CMB as well as Galactic foregrounds with the same accuracy.

The approach of stacking to improve the S/N has been used previously to detect the faint tSZ signatures. The stacking of the tSZ signal in the maps released by the *Planck* collaboration [29] on the positions of known galaxy pairs of massive luminous red galaxy (LRGs) [34, hereafter T19] as well as constant mass (CMASS) galaxy samples [35, hereafter G19] from the Sloan Digital Sky Survey (SDSS) has been performed in an effort to find the missing baryons. In this technique, the selected close galaxy pairs within a certain radial and tangential distance are stacked up coherently in the y_{sz} map created from the Planck data by a component separation algorithm. G19 claim a detection of around $\sim 11\%$ of the baryons with 2.9σ detection of the tSZ signal, leaving $\sim 18\%$ of the baryons still unaccounted for. A stacking of tSZ maps around superclusters was done in [36], in which the authors claim a detection of 17% of missing baryons in the intercluster gas in superclusters with the tSZ effect detected at 2.5σ significance.

We present a new algorithm for detection of WHIM through tSZ effect in multifrequency CMB data sets. Although the individual steps of our algorithm are similar to T19 and G19, the order in which the steps are performed is completely new. It turns out that just reordering the steps makes a huge difference. The main essence of our algorithm is to *first stack* the individual frequency maps at source locations and then extract the y_{sz} component from the multifrequency stacked data using standard component separation algorithms. Our new algorithm is motivated and described in Sec. 2. In Sec. 3, we introduce the *Planck* data products and the sky masks used in this paper. Section 4 introduces the main data analysis part of the paper to extract the y_{sz} signal at the location of LRG pairs from the stacked *Planck* maps. The modelling of y_{sz} signal expected from individual halo contribution and its subtraction from the total y_{sz} signal to see the signature of WHIM in the filament region is discussed in Sec. 5. In Sec. 6, we discuss the null test and the error estimate of the excess y_{sz} signal. Finally we present our conclusions in Sec. 9.

2 A new algorithm to detect weak tSZ signals in *Planck* data

In the previous attempts at detecting the WHIM through tSZ effect [34, 35], there is ambiguity as to what might be the true signal. In the conventional method, stacking of sources is done on preprocessed publicly available *Planck* y_{sz} maps obtained from Needlet Internal Linear Combination (NILC) [37] and Modified Internal Linear Combination Algorithm (MILCA) [38] algorithms. The residual contamination by the other foreground emissions (dust, CO, free-free, synchrotron and CMB leakage) after component separation in the y_{sz} maps is much larger compared to the signal we are interested in [31, 39]. Thus, when we stack a large number of galaxy pairs, there will be

Figure 1: The normalized distribution of the y_{sz} maps in the region between the LRG pairs selected as described in Sec. 3 in MILCA, NILC and LIL y_{sz} maps. The local average background around the LRG pairs is subtracted to get the correct zero level for each galaxy pair in the y_{sz} maps.

some cancellation between the positive and negative contamination leaving a net residual systematic which can be either positive or negative. This can be seen in the probability distribution functions (PDFs) of y_{sz} in NILC, MILCA and Linearized Iterative Least-squares (LIL) maps in Fig. 1 for the pixels which lie in-between the galaxies in a galaxy pair. The selection procedure is explained in the next section. We see that there is significant positive as well as negative excess over the Gaussian noise. The negative excess is contamination while the positive excess is contamination + y_{sz} signal. In particular, the contamination signal is more than a factor of 100 larger compared to the y_{sz} signal we are interested in. There is no guarantee that the positive contamination is equal to the negative contamination, and there would be large unknown systematic bias in the y_{sz} signal obtained in this way.

We propose a new method of extracting the y_{sz} signal from the filaments connecting the galaxy pairs. We begin by first stacking the individual *Planck* frequency maps at the positions of the LRG pairs. We then perform the component separation using Internal Linear Combination (ILC) [40–42] algorithm on the stacked frequency maps to extract out the y_{sz} signal. By doing *stacking first* and component separation later, we achieve a number of advantages over the conventional method of stacking the y_{sz} map [34, 35]:

1. We suppress the instrumental noise before doing ILC. Thus even the noisy 70 GHz and 100 GHz channel are utilized efficiently. In conventional method, these channels are down-weighted as the ILC tries to strike a compromise between reducing noise and reducing foregrounds in the final map.

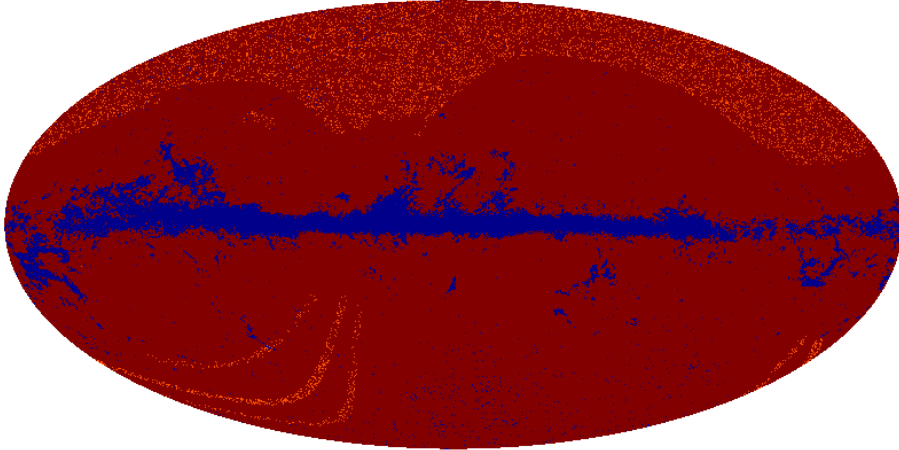

Figure 2: The eK86 mask used in our analysis. The orange points over the eK86 mask represents the LRG locations in the SDSS12 survey.

2. The Gaussian random CMB fluctuations, uncorrelated with the positions of the galaxies, are suppressed. Thus we have one less component even before we begin the ILC.
3. Since Galactic foregrounds are also uncorrelated with the galaxy positions, by stacking the frequency maps, we are homogenizing the foregrounds in amplitude as well as in spectral shape across our stacked patch. That is, in every pixel in the final stacked map after stacking patches of interest from different parts of the sky, we should expect a sum of foreground contamination from a large number of sources, essentially sampling the whole foreground parameter space. Every pixel should end up with a very similar foreground contribution, effectively summing the complicated foregrounds comprising of many different components varying across the sky to a single foreground component across our patch.

The full power of ILC is therefore concentrated in eliminating the foregrounds, as noise and CMB is eliminated in the pre-ILC stage. The foreground spatial structure is also simplified by stacking the frequency maps. In particular, the dust emission has spectrally smooth behaviour in the stacked frequency images, with negligible variation across the image, as a result of averaging. In our approach, since we are suppressing noise before doing ILC, we can work at higher resolution compared to the conventional method. We will demonstrate this by doing analysis at $8'$ resolution although most of our results would be derived at $10'$ resolution.

3 Data and masks

3.1 SDSS and *Planck* data

We use SDSS data release 12 (DR12) with the same criteria as T19 to make a catalog of LRGs with stellar mass $M_\star > 10^{11.3} M_\odot$ [43]. We take the stellar mass estimate based on a principal component analysis method from [44]. Next, we construct a sample of LRG pairs with the radial distance between the galaxies of a pair $\leq 6h^{-1}$ Mpc and the tangential distance in the range $6 - 10h^{-1}$ Mpc. We adopt a Λ CDM cosmology with $\Omega_m = 0.3$, $\Omega_\Lambda = 0.7$, and $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$ for calculation of the comoving distances from the redshift (z) information. If two or more LRG pairs fall within

Figure 3: The $\chi^2_{\text{CO}-y_{\text{sz}}}$ distribution at the location of LRG pairs. Right panel shows a zoomed-in version. The vertical lines represent different $\chi^2_{\text{CO}-y_{\text{sz}}}$ thresholds used in our stacking analysis.

30' in the projected sky coordinates (Galactic latitude and longitude), then we only keep the higher average mass LRG pairs in the sample. We find roughly 161000 LRG pairs satisfying both of the distance criteria in the SDSS DR12 sample. The angular separation between the selected LRG pairs lies between 19' and 203'.

We will use the *Planck* 2015 intensity maps from 70 to 857 GHz and IRIS 100 μm (or 3000 GHz) map [45] for our analysis. The temperature data has not changed significantly between 2015 and 2018 releases. We rebeam the *Planck* HFI maps to a common beam resolution of 10' full width half maximum (FWHM), taking into account the effective beam function of each map and reduce to a HEALPix resolution of $N_{\text{side}} = 1024$ from the original $N_{\text{side}} = 2048$ to make computations faster. While smoothing to 10' beam resolution, we only retain the scales up to $\ell_{\text{max}} = 4000$ for *Planck* HFI channels and $\ell_{\text{max}} = 2048$ for *Planck* 70 GHz LFI channel. As a validation step, we also produce *Planck* maps at a common beam resolution of 8' FWHM with $\ell_{\text{max}} = 3000$ for *Planck* HFI channels and keeping 70 GHz LFI channel $\ell_{\text{max}} = 2048$.

We will use the MILCA and NILC y_{sz} maps from the *Planck* Legacy Archive¹ for comparison. The MILCA y_{sz} maps were produced using all of the *Planck* High Frequency Instrument (HFI) intensity maps (100 – 857 GHz). The NILC method uses in addition the Low Frequency Instrument (LFI) data (30 – 70 GHz) at large angular scales ($\ell < 300$). The angular resolution of both of these y_{sz} maps is 10' FWHM. We downgrade the original y_{sz} maps from $N_{\text{side}} = 2048$ (pixel size=1.7') to $N_{\text{side}} = 1024$ (pixel size=3.4') for computational efficiency.

3.2 Sky masks and sample selection

We will use the sky mask obtained in [31, hereafter K86 mask] specifically for the tSZ studies with an unmasked sky fraction $f_{\text{sky}} = 86\%$ as the baseline. This mask specifically tries to minimize the CO line emission contamination and also covers strong point sources. We will also use the masks provided by the *Planck* collaboration, in particular the Galactic + point source mask with $f_{\text{sky}} = 48\%$ (henceforth PL48 mask) to compare with the T19 results.

As we estimated in the last section, we expect the IGM in the filaments between the galaxies to give a very weak tSZ signal, much below the noise level of the *Planck* for individual objects. Thus, in addition to the regions of strong CO line contamination [31], we also want to avoid the strong tSZ signal coming from much hotter and denser gas in the clusters of galaxies in the foreground or background, i.e. we want to select only those pairs of galaxies for which, in the individual objects,

¹<https://www.cosmos.esa.int/web/planck/pla>

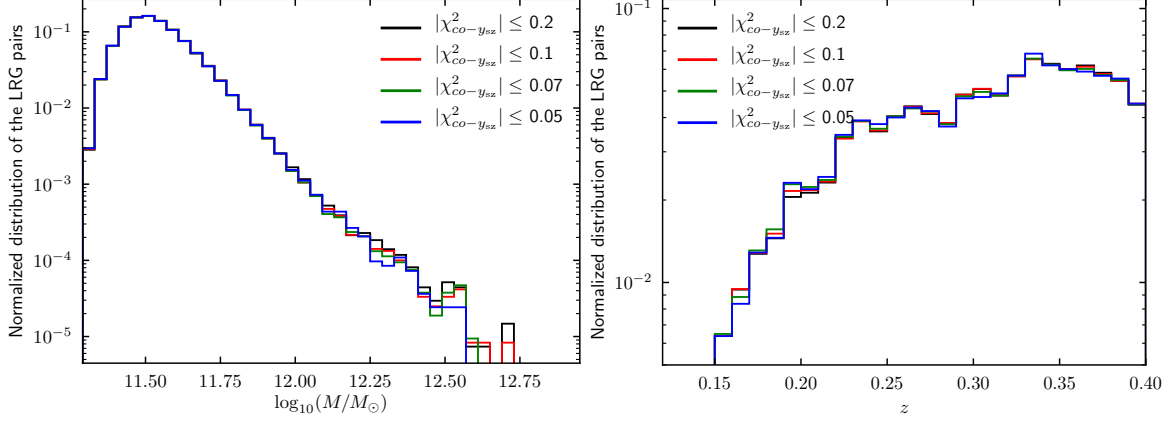

Figure 4: *Left panel:* the normalized distribution of the mean mass of the LRG pairs for four different $\chi^2_{\text{CO}-y_{\text{SZ}}}$ thresholds. *Right panel:* the normalized distribution of mean redshift distribution of the LRG pairs as a function of $\chi^2_{\text{CO}-y_{\text{SZ}}}$ thresholds.

the y_{SZ} signal is undetectable and we are dominated by the instrumental noise. To accomplish this, we use the fact that CO emission is also a weak signal in the *Planck* data, of similar strength to the y_{SZ} signal but with a different spectrum. We can fit a model consisting of CMB + Dust + tSZ signal to the *Planck* HFI data as well as a model consisting of CMB + Dust + CO emission, and compare the χ^2 of the two models (which have the same number of parameters). In the regions where CO emission is stronger than the tSZ, we will have smaller χ^2 for the CO model and the difference between the χ^2 for the two models $\chi^2_{\text{CO}-y_{\text{SZ}}}$ will be negative. In the opposite case, when we have stronger tSZ signal, $\chi^2_{\text{CO}-y_{\text{SZ}}}$ will be positive. We want to avoid both these cases. We want to select galaxies such that we are noise dominated and unable to distinguish between the two models, i.e. $\chi^2_{\text{CO}-y_{\text{SZ}}} \sim 0$. These model fits were performed in [31] and we will use the $\chi^2_{\text{CO}-y_{\text{SZ}}}$ map obtained in [31] to further prune our galaxy sample. For each LRG pair, we attribute a $\chi^2_{\text{CO}-y_{\text{SZ}}}$ value by computing the average $\chi^2_{\text{CO}-y_{\text{SZ}}}$ of the sky pixels that lies within $20'$ radius from the centre of LRG location. We have $\sim 99.6\%$ of our sample with a $|\chi^2_{\text{CO}-y_{\text{SZ}}}| < 5$ and $\sim 96.6\%$ of our sample with a $|\chi^2_{\text{CO}-y_{\text{SZ}}}| < 0.5$. We can thus use aggressive thresholds in $\chi^2_{\text{CO}-y_{\text{SZ}}}$ removing the most contaminated galaxy pairs but still loose only a small fraction of the sample.

We first extend the K86 mask by masking the sky pixels where the $\chi^2_{\text{CO}-y_{\text{SZ}}}$ values are either highly negative or highly positive, i.e. $|\chi^2_{\text{CO}-y_{\text{SZ}}}| > 5$. This extended K86 mask, hereafter eK86, is shown in Fig. 2. This extension masks the *Planck* detected 1653 clusters [46], SZ dominated regions and molecular clouds from our concerned sample. If either of the two LRGs of the pair falls in the masked region, then we exclude that LRG pair from our stacking analysis. The PDF of average $\chi^2_{\text{CO}-y_{\text{SZ}}}$ for all galaxy pairs in our sample, after applying the eK86 mask, is plotted in Fig. 3. The skewness towards positive values in the distribution of $\chi^2_{\text{CO}-y_{\text{SZ}}}$ with eK86 mask towards the positive side shows that in the concerned sky regions y_{SZ} signal dominates over the foreground CO emission. To get an even cleaner sample, we further eliminate the galaxies in the tails of the PDF and consider only those LRG pairs for stacking for which $|\chi^2_{\text{CO}-y_{\text{SZ}}}| < 0.2$, marked by vertical lines in Fig. 3. We can get cleaner samples by further reducing the $\chi^2_{\text{CO}-y_{\text{SZ}}}$ threshold. Also in order to test that the $\chi^2_{\text{CO}-y_{\text{SZ}}}$ threshold does not affect our results, we will consider samples with thresholds of $|\chi^2_{\text{CO}-y_{\text{SZ}}}| \leq 0.2, 0.1, 0.07$, and 0.05 containing 144930, 128528, 113374, and 88001 LRG pairs respectively. We show in Fig. 4 the distributions of mean mass ($\log(M/M_{\odot})$) and mean redshift of the LRG pairs for the four $\chi^2_{\text{CO}-y_{\text{SZ}}}$ thresholds. We see that the mass and redshift distributions are insensitive to the $\chi^2_{\text{CO}-y_{\text{SZ}}}$ thresholds. The $\chi^2_{\text{CO}-y_{\text{SZ}}}$ thresholds, therefore, do not introduce any bias

in our sample.

4 Stacking analysis

We use the following procedure to stack the *Planck* sky maps at each frequency. The angular separation between the LRG pairs in our sample spans from $19'$ to $203'$. We first project a given LRG pair from the spherical coordinates onto a normalized tangent plane centered at the midpoint of the line joining the pair such that one LRG is placed at $(-1, 0)$ and the other LRG at $(1, 0)$ [47]. We interpolate the tangent plane projections of all the LRG pairs to an equal size grid. For our analysis we project the tangent plane to a grid of 301×301 pixels. The angular resolution of each pixel in the grid concerned varies from pair to pair. The two LRGs are always placed 50 pixels apart in the grid, the pixel resolution varies from $\sim 0.4'$ for the pair with least angular separation to $\sim 4.3'$ for the largest. We then stack on the equal sized grids. We interchange the one LRG location from $(-1, 0)$ to $(1, 0)$ and other vice versa to produce the symmetric stacked signal on both LRG positions. We perform the stacking for the four $\chi^2_{\text{CO}-y_{\text{sz}}}$ selected samples as discussed in the previous section for all of the *Planck* HFI maps and the 70 GHz LFI map at $8'$ and $10'$ FWHM resolutions. We note that these are slightly finer compared to the native 70 GHz channel resolution and therefore the noise in 70 GHz maps gets boosted. However, the noise is suppressed again when we stack and we can thus hope that the 70 GHz channel (as well as 100 GHz channel at $8'$) will contribute to the y_{sz} signal.

We show the stacked *Planck* frequency maps in Fig. 5. The stacked maps show an increase in foreground contamination as we increase the $|\chi^2_{\text{CO}-y_{\text{sz}}}|$ thresholds from 0.05 to 0.2. We see the unmistakable signatures of the hot gas in the filament region due to the tSZ effect in Fig. 5, i.e. a negative signal at 143 GHz and lower frequencies with respect to the average ambient background around the galaxies and a positive signal for $\nu > 217$ GHz. This signature becomes slightly less prominent for higher $\chi^2_{\text{CO}-y_{\text{sz}}}$ thresholds. We will be using our cleanest sample with $|\chi^2_{\text{CO}-y_{\text{sz}}}| < 0.05$ for our baseline analysis. The signal at the position of galaxies is dominated by the radio and infrared emission from the galaxies themselves. We expect this galactic contamination to become subdominant as we go away from the centers of the galaxies to the intergalactic medium. We fit the modified blackbody spectrum to every pixel in the stacked image from 217 to 3000 GHz. The dust temperature in the fit is fixed to 18 K. The fitted dust amplitude normalised at 353 GHz has the same morphology as the 353 GHz stacked *Planck* map. After taking into account the color correction factors due to the *Planck* bandpasses, the fitted dust spectral indices are close to 1.4 over the entire stacked patch. We can conclude that the dust emission has spectrally smooth behaviour as a result of averaging of dust spectral energy distribution over the different line of sights. We will need to remove the galactic contamination from the LRGs themselves to get an unbiased estimate of the y_{sz} signal from the intergalactic medium.

4.1 Blind component separation

We will use the ILC method [40–42] on the stacked *Planck* maps to extract the y_{sz} signal. The ILC is a blind component separation method used to extract the signal of interest, whose spectrum is known, from multifrequency observations without assuming anything about the frequency dependence of unwanted foreground contamination. It has been used extensively in the CMB data analysis in the past to extract the CMB signal from multifrequency *Wilkinson Microwave Anisotropy Probe* (WMAP) sky observations. The ILC method can be applied over distinct regions of the sky in pixel space [42, 48], domains in harmonic space [49], or domains in needlet space [50]. The NILC and MILCA component separation methods used by the *Planck* collaboration to extract the y_{sz} signal from the multifrequency *Planck* maps are also based on the ILC method with additional constraints [37, 38].

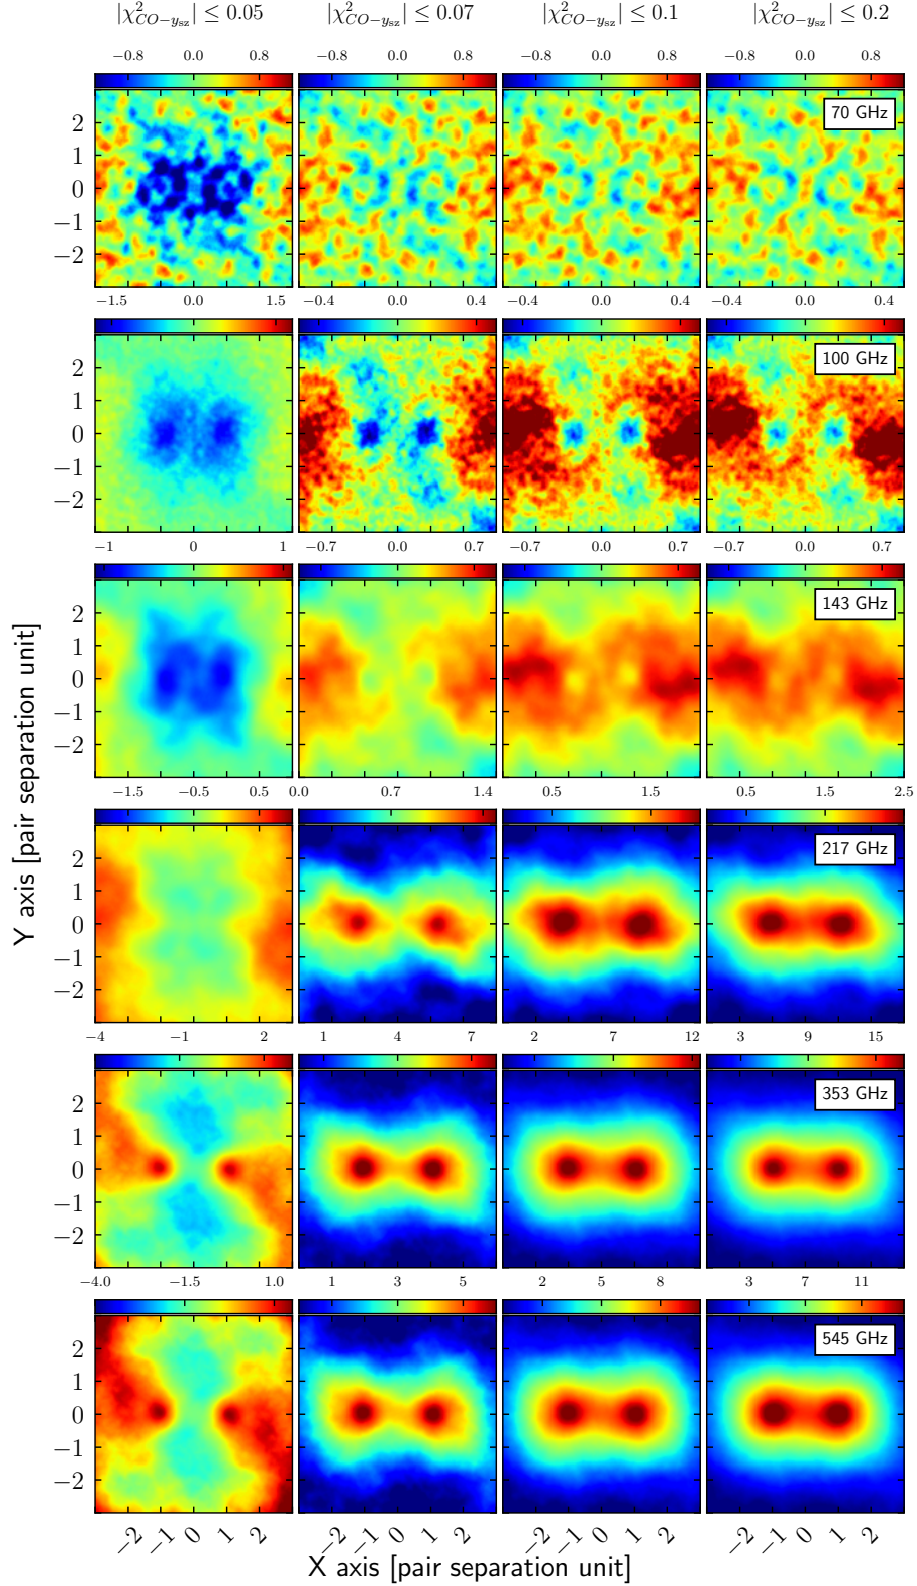

Figure 5: The stacked *Planck* maps smoothed at common $10'$ FWHM beam resolution for different $\chi^2_{\text{CO}-y_{\text{sz}}}$ thresholds: $|\chi^2_{\text{CO}-y_{\text{sz}}}| \leq 0.05$ (column 1), $|\chi^2_{\text{CO}-y_{\text{sz}}}| \leq 0.07$ (column 2), $|\chi^2_{\text{CO}-y_{\text{sz}}}| \leq 0.1$ (column 3), and $|\chi^2_{\text{CO}-y_{\text{sz}}}| \leq 0.2$ (column 4). The top to bottom rows represent different *Planck* channels starting from 70 GHz (top row) to 545 GHz (bottom row). All the *Planck* maps from 70 to 353 GHz are expressed in μK_{cmb} units and 545 GHz map is in kJy/sr. The zero level of the stacked *Planck* channels is adjusted such a way that the stacked signal in the range $-3 < X < 3$ and $0.05 < Y < 0.05$ is set to 0.

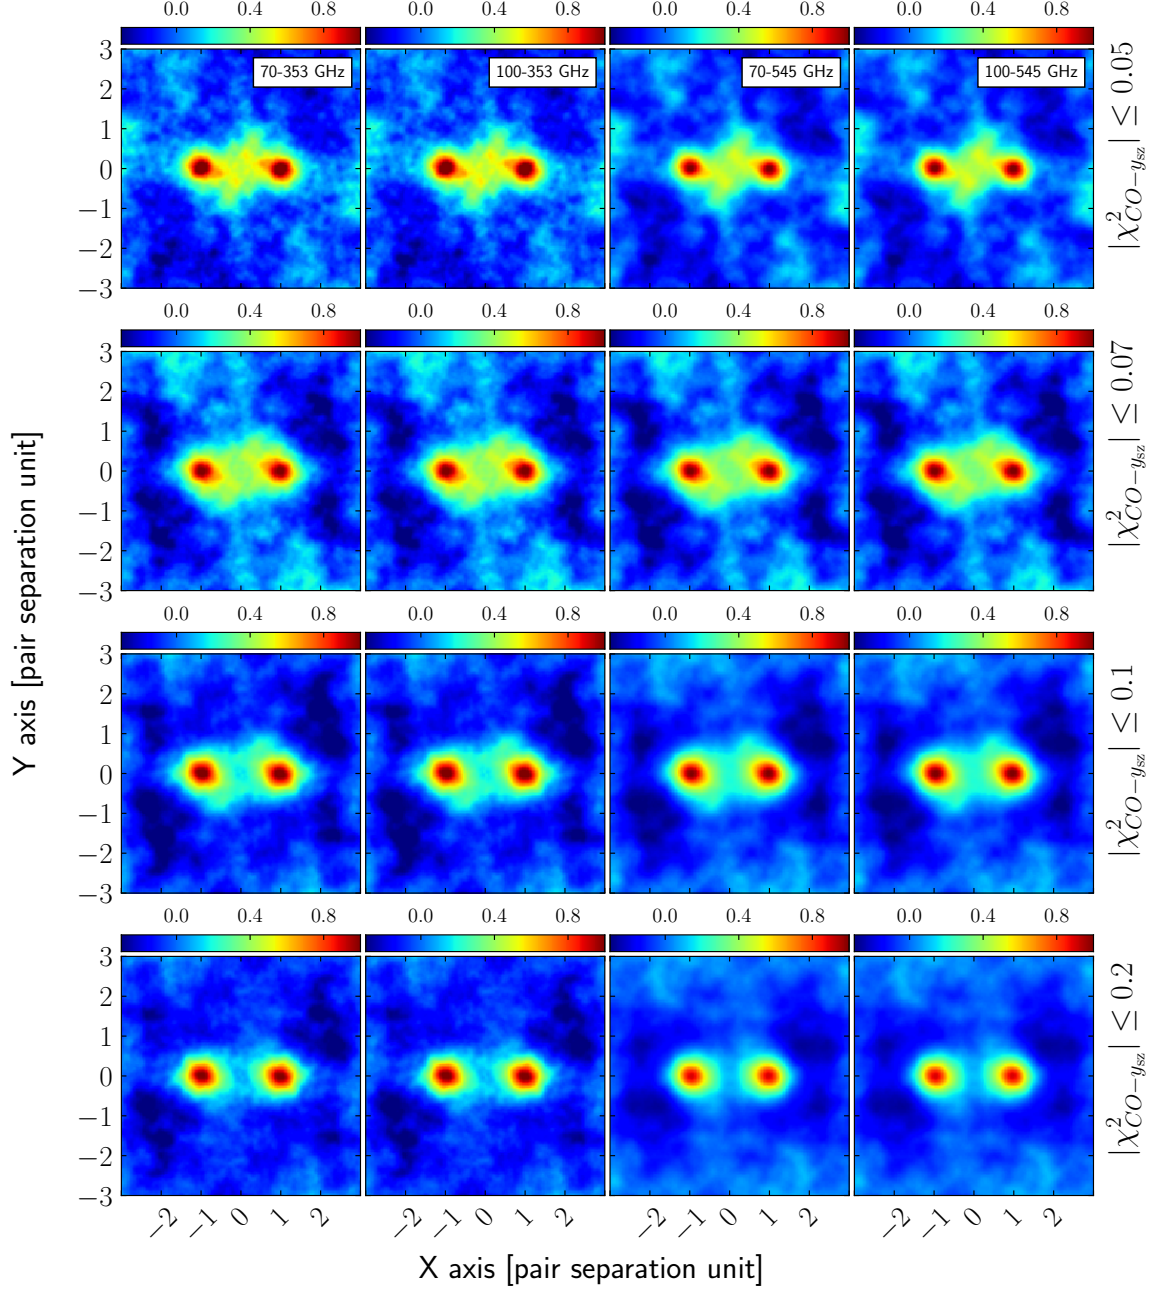

Figure 6: The stacked ILC \hat{y}_{sz} signal expressed in units of 10^{-7} extracted from the stacked common $10'$ FWHM beam resolution *Planck* maps at $N_{\text{side}} = 1024$ for the four different thresholds: $|\chi^2_{\text{CO}-y_{sz}}| \leq 0.05$ (column 1), ≤ 0.07 (column 2), ≤ 0.1 (column 3), and ≤ 0.2 (column 4). The top to bottom rows represent combination of different *Planck* channels used to extract the stacked ILC y_{sz} signal: 70 – 353 GHz (row 1), 100 – 353 GHz (row 2), 70 – 545 GHz (row 3) and 100 – 545 GHz (row 4).

The ILC is a multifrequency linear filter that minimizes the variance of the reconstructed y_{SZ} map. We assume the stacked maps (x) in each *Planck* channels as a superposition of y_{SZ} signal, foreground (f) and noise (n), written as $x_i(p) = a_i y_{\text{SZ}}(p) + f_i(p) + n_i(p)$, where the index p labels the pixels in the stacked map. The coefficients a_i contains the relative strength of the y_{SZ} signal in the different *Planck* channels. The ILC solution for the tSZ signal, $\hat{y}_{\text{SZ}}(p)$ is given by $\hat{y}_{\text{SZ}}(p) = \sum_i w_i x_i(p)$. The weights, w_i , are found by minimizing the variance of $\hat{y}_{\text{SZ}}(p)$ subjected to the constraint that the y_{SZ} signal is preserved, i.e. $\sum_i a_i w_i = 1$ [37, 38]. We use the ILC method in pixel space to reconstruct the stacked y_{SZ} signal from the stacked *Planck* maps. We show the y_{SZ} map for our four LRG pair samples with different $\chi^2_{\text{CO}-y_{\text{SZ}}}$ thresholds and using different frequency channel combinations in Fig. 6.

The ILC \hat{y}_{SZ} maps are quite robust w.r.t to the changing $\chi^2_{\text{CO}-y_{\text{SZ}}}$ thresholds as well as the number of frequency channels. We will use the reconstructed ILC map derived from the frequency range 70 – 545 GHz for our fiducial analysis. The ILC weights obtained from our analysis with K86 mask and selection criterion $\chi^2_{\text{CO}-y_{\text{SZ}}} \leq 0.05$ are quoted in Table 1 and compared with the ILC weights obtained for unstacked maps. We see from Fig. 6 that removing 70 GHz and/or 545 GHz channels does not make a significant difference, implying that the ILC has converged as far as the number of frequency channels is concerned. The strong signal at the galaxy positions is indicative of residual contamination from the emissions of the stacked galaxies themselves which needs to be estimated and removed.

Since we are doing ILC on a small number of pixels, there maybe ILC bias coming from chance correlations between the noise, y_{SZ} signal, and foregrounds [40, 51, 52]. To check for the ILC bias we half the size of the patch around the LRG pairs from $N \times N$ arcmin to $N/2 \times N/2$ arcmin and the number of interpolated pixels from 301×301 to 151×151 . The results of comparison are shown in Fig. 7. We also do the analysis at original HEALPix resolution of $N_{\text{side}} = 2048$. We see no significant evidence for ILC bias. At higher resolution of $N_{\text{side}} = 2048$, the signal is a little smoother, but otherwise consistent with $N_{\text{side}} = 1024$ results.

We also validate our stack first approach on simulations of realistic sky simulations in Appendix A and show that our stack first + ILC approach recovers the WHIM tSZ signal without bias or significant foreground contamination. We note that since we are not interested in the mean background signal, we implement the standard ILC in which the cost function that is minimized is the variance of the reconstructed y map [48, 51] i.e. the fluctuations about the mean are minimized. There are other choices for the cost function possible. An alternative cost function proposed in [53] minimizes L2 norm of the total signal, including the average signal, especially useful when we are interested in the large scale modes. We tried both formulations and found that the two choices of the cost function give consistent results, with the standard ILC giving a slightly stronger detection significance. The fact that the two formulations give results which are similar can be taken as additional evidence that the foregrounds are getting homogenized by stacking as expected.

4.2 Component separation by parameter fitting

In order to use parameter fitting to do component separation, we need an accurate model. However stacking on frequency maps mixes different foreground spectra, in particular mixes dust, CO and low frequency emission. It is therefore difficult to come-up with a foreground that will be accurate enough for our purpose. However, we can still use parameter fitting to learn about the foregrounds and check our assumptions. In particular, we want to check whether the foreground shape is really homogenized over our patch by stacking and that any residual foreground contamination is morphologically different from the SZ signal we are interested in. We employ LIL parametric fitting algorithm developed in [31, 54]. We fit a simple parametric model consisting of either CMB + dust + tSZ or CMB + dust + CO components to 4 HFI channels from 100 GHz to 353 GHz. We model dust by a modified blackbody spectrum with fixed temperature $T_d = 18$ K and fixed line

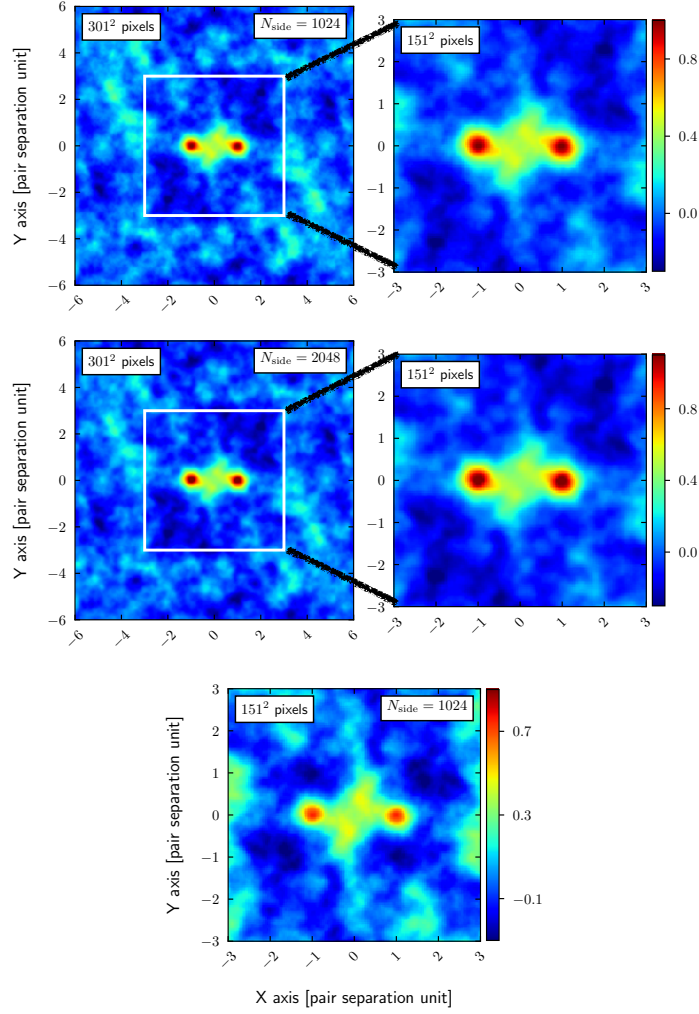

Figure 7: The ILC \hat{y}_{sz} signal expressed in 10^{-7} units extracted from *Planck* 70 – 545 GHz channels at $N_{\text{side}}=1024$ and a patch size of 301×301 pixels (*top panel*), $N_{\text{side}}=2048$ and a patch size of 301×301 pixels (*middle panel*), and $N_{\text{side}}=1024$ and a patch size of 151×151 pixels (*bottom panel*) for the threshold $\chi^2_{\text{CO}-y_{sz}} \leq 0.05$ and K86 mask.

ratios for CO line contribution in different channels, following [31]. The parameters to fit are CMB temperature, tSZ or CO amplitude, dust amplitude and the dust spectral index.

The results of the parameter fitting exercise are shown in Fig. 8. The top panel shows the fitted SZ signal, the CO signal and the dust amplitude (for SZ+dust+CMB model fit) signal. In the bottom panel, we have removed the average background to show the fluctuations. We recover the y_{sz} signal with morphology remarkably similar to the ILC method. We also see that both the dust and the CO signals are quite homogeneous. Comparing the top and bottom panels, we see that the dust amplitude is almost homogeneous over the entire patch with fluctuations of $\lesssim 0.1\%$. For the CO signal also, the fluctuations are smaller by a factor of $\sim 4-5$ compared to the average signal. In particular the CO fluctuations are dominated by noise and are also statistically homogeneous and random, apart from the small leakage from other components at the locations of the galaxies. In particular the CO signal fluctuations are of order few $\times 10^{-3}$ Kkm/s which corresponds to few

Table 1: The ILC weights applied to individual *Planck* stacked maps to reconstruct stacked ILC \hat{y}_{sz} signal over different Galactic sky masks used in our analysis. For comparison we also show the weights with the LRGs selected using PL48 mask and using 6 *Planck* channels. The last column shows the weights when ILC is applied to pixels at the LRG positions in unstacked Planck maps. It is clear that the solution we get for ILC on stacked maps is very different from the one we get for the ILC on unstacked maps.

Frequency in GHz	ILC weights		
	$ \chi^2_{CO-y_{sz}} < 0.05$ with K86	PL48 mask	Unstacked pixels
70	-0.0024	-0.0153	-0.0008
100	0.0182	-0.0857	-0.0057
143	-0.5160	-0.1158	-0.2710
217	0.5861	0.1518	0.2444
353	-0.0808	0.0465	0.0352
545	0.0012	-0.0040	-0.0031

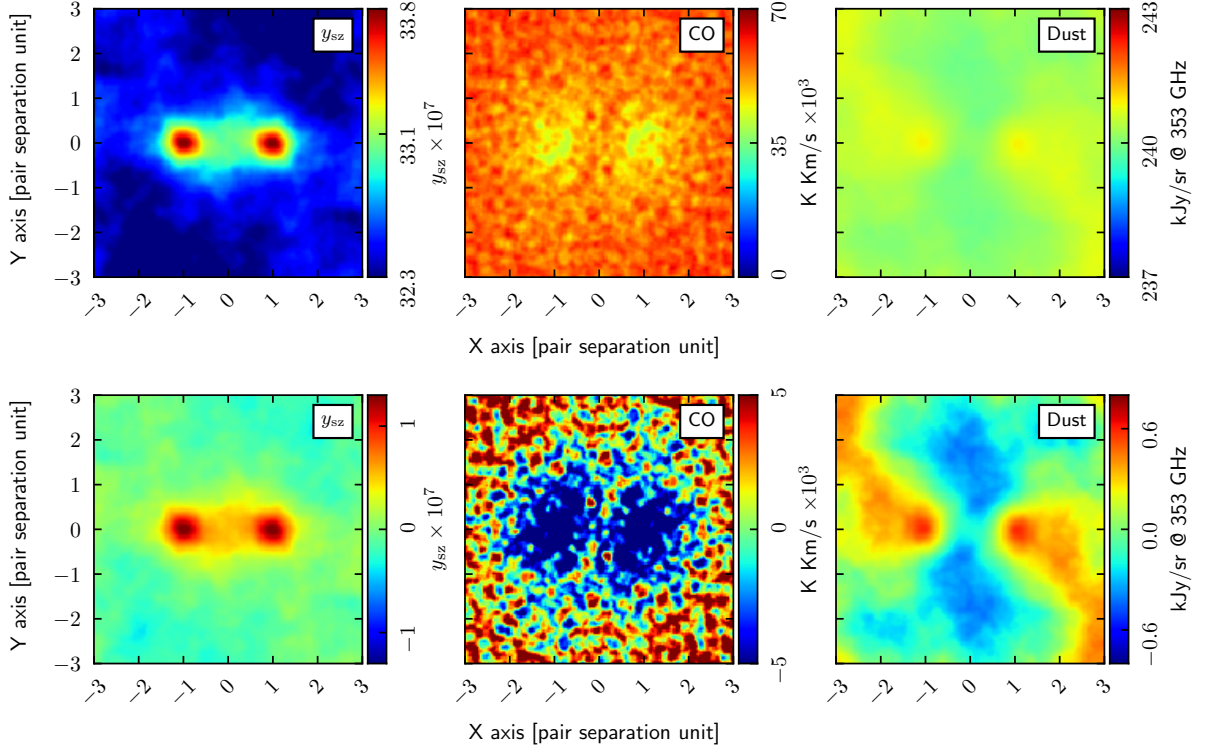

Figure 8: The stacked y_{sz} signal (*left panel*), CO emission (*middle panel*) and dust amplitude (*right panel*) obtained from three-component LIL parameter fitting. *Top panel* is the fitted LIL component maps. In the *bottom panel*, the average level of the y_{sz} map, CO map and the dust amplitude map is subtracted off to accentuate the visibility of the fluctuations.

$\times 10^{-8} K_{CMB}$ in CMB temperature units at 100 GHz [see 54, 55, for conversion factors]. This is approximately the amplitude of the noise after stacking $\sim 10^5$ galaxies in the most sensitive Planck maps with full sky map level sensitivity of $\sim 10^{-5}$ K [56, 57].

We note that CO is already a very weak contamination in Planck maps (see also Appendix A).

We also note that while doing standard ILC [48, 51], we subtract out the average or the monopole part of the signal. Thus 99.9% of the dust and most of the CO contamination would be subtracted out even before we do the ILC. Most of the background SZ signal, seen in the top panel, will also be suppressed. The small correlation in the CO map with the galaxy positions is because when we fit for the CO, our model does not include the SZ component. The SZ component will therefore contaminate all other components and will show up prominently in the weakest component which is the CO [54]. However, even in CO, the SZ contamination is at the level of noise fluctuations in the rest of the map. Most of the foregrounds will thus be removed and suppressed even before we have applied the ILC. The ILC should remove any remaining CO and dust foregrounds from the stacked maps bringing down the contamination to the noise levels. In particular the ILC is most efficient in removing the foregrounds in noiseless maps [see 51, for proof and detailed study of ILC methods]. Stacking before ILC suppresses the noise thus increasing the efficiency of foreground removal. We must still account for the residual contamination and SZ signal from the stacked galaxies themselves. This is however not a big concern. Since the galaxies themselves would be unresolved at Planck resolution, the dust and SZ signals from the galaxies is well approximated by two non-overlapping Gaussian discs and subtracted.

With the parameter fitting exercise, we have therefore quantified the benefits of the *Stack First* approach. We have shown that we have a factor of 1000 suppression in the fluctuating part of the foregrounds, in addition to the suppression of noise, by just stacking the individual frequency maps even before the ILC component separation algorithm is applied.

5 Excess signal

We expect two symmetric peaks in the stacked ILC \hat{y}_{sz} map as we stack the *Planck* frequency maps twice by interchanging the LRG positions. The position of the LRGs may have some remaining dust contamination, since the LRGs themselves are expected to have strong dust emission (as evident by the lower panels in the first column of Fig. 5) and even a small leakage may be significant compared to the tSZ signal. However, the region between the LRGs, where we expect to find the WHIM, is relatively free of dust and leakage from any weak dust emission from the intergalactic medium would be suppressed even further by the ILC. The *middle panel* of Fig. 9 shows the profile of the stacked ILC \hat{y}_{sz} map along $Y=0$ axis. The stacked ILC \hat{y}_{sz} signal for our baseline case has the dominant contributions from the individual LRG halo. The circular model for halos is a good approximation since most of our galaxies are unresolved and any non-circular beam effects will get symmetrized when stacking a large number of objects. T19 have shown that other systematic effects are also small. To extract the excess y_{sz} signal in the filament region connecting the LRG pair, we need to subtract the individual LRG halo contribution.

We exclude the central region $-1 < X < 1$ and fit a Gaussian model to the single-halo signal on both the sides [34]. The blue solid line in the *middle panel* of Fig. 9 is the best-fit Gaussian model to the data, excluding the central LRG region from $-1 < X < 1$. The 2D circular Gaussian model is constructed based on the fit to the data at $Y = 0$. The residuals after fitting the best-fit 2D circular Gaussian model along the $Y=0$ and $X=0$ are shown in the *bottom panel* of Fig. 9. The map representation of the same is shown in the *top panel* of Fig. 9. The amplitude of the excess y_{sz} signal is $\sim 4 \times 10^{-8}$ in the region $-0.5 < X < 0.5$ at $Y=0$. The excess y_{sz} signal peaks in the central filament region between $-0.5 < X < 0.5$ and $-0.5 < Y < 0.5$. The average of the excess y_{sz} signal in the central filament region is $y_{sz} = 3.78 \times 10^{-8}$, which is approximately a factor of three higher than the value reported in T19.

We note that our basic selection criteria is same as T19 however we impose additional thresholds to further prune our samples, making our results more robust to accidental contamination by foreground or background clusters. In order to relate the measured y_{sz} signal to the filament

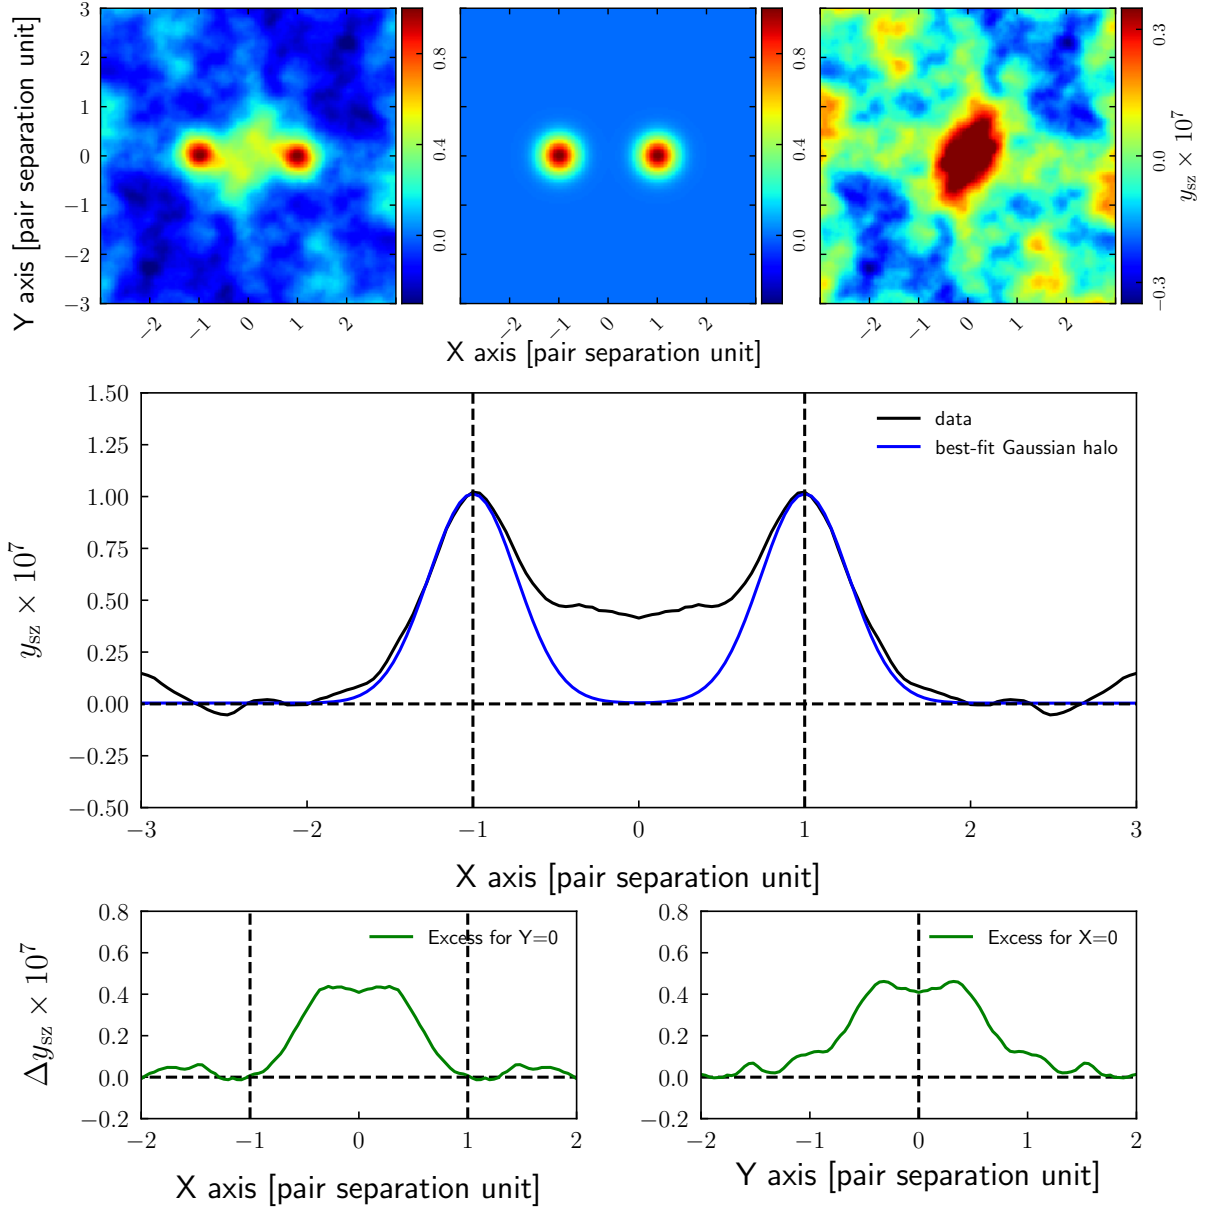

Figure 9: *Top Panel left:* The stacked ILC \hat{y}_{sz} map obtained from the combination of *Planck* LFI and HFI channel maps (70 – 545 GHz) with the threshold criterion $\chi^2_{\text{CO}-y_{sz}} \leq 0.05$ and K86 mask. *Top Panel center:* The best-fit 2D gaussian model for the individual LRG halo contribution. *Top Panel right:* The excess signal in the filament region connecting two LRGs after subtraction of the best-fit 2D Gaussian halo model from the stacked ILC \hat{y}_{sz} map. *Middle panel* shows the y_{sz} profile at $Y=0$, along with the best-fit Gaussian halo profile (blue solid line). *Bottom panel left:* the excess at $Y=0$ after subtraction of best-fit model. *Bottom panel right:* the excess after subtraction of the best fit model at $X=0$.

properties, we use the following density profile for the filament similarly to T19,

$$n_e^z(r) = \frac{n_e^z(0)}{\sqrt{1 + (r/r_c)^2}}, \quad (5.1)$$

where $n_e^z(r)$ is the electron number density of a filament at redshift z and distance r from the filament center along the line of sight, r_c is the core radius of the filament and we will take $r_c = 0.5h^{-1}$ Mpc. The density profile is set to zero at $r > 5r_c$. The mean electron number density as a function of redshift, $\bar{n}_e(z)$ is given by $\bar{n}_e(z) = \frac{\Omega_b \rho_{cr}(1+z)^3}{\mu_c m_p}$, where Ω_b is the baryon density parameter, ρ_{cr} is the critical density of the Universe today, m_p is the proton mass and $\mu_c = 1.14$ is the mean molecular weight of primordial plasma with 76% hydrogen by mass. We also define the overdensity δ at the center of the filament as $\delta = n_e^z(0)/\bar{n}_e(z)$. We assume Planck Λ CDM cosmology [33] giving average electron number density today to be $\bar{n}_e(0) = 2.2 \times 10^{-7} \text{ cm}^{-3}$. The electron number density in filaments, $n_e^z(r)$ can be expressed in terms of overdensity δ by multiplying and dividing Eq. 5.1 by $\bar{n}_e(z)$ as

$$\begin{aligned} n_e^z(r) &= \frac{n_e^z(0)}{\bar{n}_e(z)} \frac{\bar{n}_e(z)}{\sqrt{1 + (r/r_c)^2}} \\ &= \delta \frac{\bar{n}_e(0)(1+z)^3}{\sqrt{1 + (r/r_c)^2}}. \end{aligned} \quad (5.2)$$

Assuming a constant electron temperature T_e and a symmetry along the filament axis, we can express Δy_{sz} as a line of sight integration of the filament density profile ($n_e(r, z)$) as,

$$\begin{aligned} \Delta y_{sz} &= \frac{\sigma_T k_B T_e}{m_e c^2} \int_{-5r_c}^{5r_c} n_e^z(r) dr \\ &= 2 \frac{\sigma_T k_B T_e \delta (1+z)^3 \bar{n}_e(0)}{m_e c^2} \int_0^{5r_c} \frac{1}{\sqrt{1 + (r/r_c)^2}} dr, \\ &= 4.62 r_c \frac{\sigma_T k_B T_e \delta (1+z)^3 \bar{n}_e(0)}{m_e c^2} \end{aligned} \quad (5.3)$$

where $5r_c$ is the cut-off radius of the filaments and r is the parameter for line of sight integration. The mean redshift of each LRG pair in our sample is known. On averaging over all LRG pairs in our fiducial sample, we obtain the average excess y_{sz} signal from the filament for our sample as

$$\Delta y_{sz} = 3.78 \times 10^{-8} \left(\frac{\delta}{13} \right) \left(\frac{T_e}{5 \times 10^6} \right) \left(\frac{r_c}{0.5h^{-1} \text{ Mpc}} \right). \quad (5.4)$$

As the WHIM constitutes a major chunk of the matter in the filaments [58], we can assume an average temperature of 5×10^6 K in order to estimate the density contrast of the filament from the y_{whim} signal. This electron temperature is within the upper bounds obtained from Illustris simulations [58] and in-between the temperatures used by T19 ($T_e = 10^7$ K) and G19 ($T_e = 10^6$ K). Putting the $y_{whim} = 3.78 \times 10^{-8}$, we obtain the mean overdensity in the filament region to be

$$\delta \approx 13 \left(\frac{5 \times 10^6 \text{ K}}{T_e} \right) \left(\frac{0.5h^{-1} \text{ Mpc}}{r_c} \right) \quad (5.5)$$

Our result is in excellent agreement with expectations of overdensity in filaments ($\sim 10 - 40$) [16] from simulations. We also use different electron density profiles to compute the mean over density in the filament region. For electron density profile $n_e(r) = \text{constant}$ ($r < 2r_c$), the mean overdensity is found to be ~ 16 . For $n_e(r) = \frac{n_e(0)}{1 + (r/r_c)^2}$ ($r < 5r_c$) density profile, the mean overdensity is around 23. Irrespective of the electron density profile, the numbers for the overdensity only change by a factor of 2 and are always within the bounds of the expected WHIM overdensity as suggested by simulations.

6 Estimate of error and significance of detection

In order to obtain the significance of our detection we use the null test and the bootstrap method.

6.1 Null test with misaligned stacking

We use misaligned LRG pairs, i.e. randomly chosen positions for the LRG pairs, to estimate the foreground contamination in the measured y_{sz} signal. We make 100 random realizations of the LRG pair catalogue. In each realization, we shift the Galactic longitude of every LRG pair in the real data by a random amount $\in [5^\circ, 25^\circ]$ either in the positive or negative direction, keeping the Galactic latitude fixed (for example, a pair having central coordinated $[l, b]$ could be shifted to $[l + 20^\circ, b]$). The lower bound in the random shift in longitude makes sure that the filament in the new random location does not overlap the original filament and is sufficiently away from it. We keep the original Galactic latitude so that the Galactic foreground contamination is similar as the original location. If indeed there was some contribution from the Galactic foregrounds, this would be of the similar order of magnitude for the shifted pair, and hence would show up as an excess in the misaligned stack too. We repeat the procedure of component separation with ILC and measure the y_{whim} in each of the 100 random realizations of our fiducial catalogue consisting of 88001 galaxy pairs. The results are shown in Fig. 10 (*Left panel*). We find the mean and standard deviation of the WHIM signal to be $y_{whim} = (-0.20 \pm 0.37) \times 10^{-8}$. We thus find the detected y_{whim} signal to be 10.2σ away from zero. Note that the systematic contributed by the mean of random realization, i.e. the background is $\approx 0.5\sigma$ and is negative. We therefore neglect it to get a conservative estimate of the detection significance.

6.2 Bootstrap method

We do an alternate estimate of the errorbar on the reconstructed ILC \hat{y}_{sz} signal using the bootstrap technique. From our sample of $N_{pairs} = 88001$, we randomly select galaxy pairs to build a new sample, allowing each galaxy pair to be sampled more than once, until we again have 88001 galaxy pairs. Because of the random selection, some galaxy pairs would be selected more than once while some would be left out. We thus have a new realization of our galaxy pair catalogue with the same number of pairs as in the original catalogue but each galaxy pair, in general, having a weight different from unity. We make 100 random realizations of our galaxy pair catalogue in this way, and repeat our analysis by stacking, doing ILC component separation and estimating the average y_{whim} signal in the central region $-0.5 < X < 0.5$ and $-0.5 < Y < 0.5$. The standard deviation among the 100 realizations gives us an estimate of the sample variance or the errorbar on the y_{whim} signal. We find the standard deviation for the y_{whim} signal in the region between the LRG pairs, i.e. $-0.5 < X < 0.5$ and $-0.5 < Y < 0.5$, to be 0.44×10^{-8} , consistent with the misalignment method above.

6.3 Non-overlapping misaligned stacking

To address the concerns of the effect oversampling of regions might have on the estimate of our significance of results, we perform the misaligned stacking with mutually independent regions. For each pair in our sample concerned, with centre at $[l, b]$, we choose 100 independent regions by dividing the iso-latitude region into 100 zones separated by 3.5 degrees each. For each LRG pair, we assign values for misalignment such that there is no overlap for the 100 realizations in the entire region for $|X| < 3$ and $|Y| < 3$. For example say the misalignment angle for two realizations for a pair are k and k' , so the patches centered at $[l+k, b]$ and $[l+k', b]$ never have any common region amongst them. The 100 realizations thus obtained for each of the 88000 misaligned LRG pairs are mutually independent. The signal that we obtain from this analysis is consistent within 1σ with our previously quoted values where we did not enforce the samples to be non-overlapping. The excess

Figure 10: *Left panel:* The histogram of the excess y_{sz} signal obtained from random 100 misaligned stacking is shown in blue colour and the black line represents the measurement from the actual data. Our measurement of $y_{whim} = 3.78 \times 10^{-8}$ is 10.2σ away from zero and 10.7σ away from the mean of the misaligned realizations. *Right panel:* Same as the figure on left but with non-overlapping regions for each of the 100 realizations giving a detection significance of 10.8σ .

we obtain from 100 such misalignment samples is $\Delta y_{sz} = (0.00 \pm 0.35) \times 10^{-8}$ and has been shown in Figure 10 (*Right panel*). With this our significance stands at $\sim 10.8\sigma$ consistent with our other estimate in Sec. 6.1. Since in trying to enforce non-overlap, we need to consider regions which are far in longitude from the given galaxy pair, the contamination may be slightly different in these samples giving a slight difference in error estimate compared to Sec. 6.1.

7 Consistency checks and robustness of the excess y_{sz} signal

We perform a number of tests to check the robustness of our results and to check that the excess y_{sz} signal that we observe is indeed coming from the WHIM between the LRGs.

7.1 Robustness w.r.t. resolution, channel combinations and selection criteria

The WHIM signal is diluted to some extent due to the *Planck* beam of $10'$. T19 have shown with BAHAMAS simulations that there is $\sim 15\%$ dilution in WHIM y_{sz} signal from unsmoothed maps to $10'$ smoothed maps. As a consistency check, we repeat our analysis with *Planck* maps rebeamed to $8'$ resolution. We would expect the smaller beam size to confine the spread of LRG halo contribution to a smaller region and thus reduce any contamination in the filament region. We would also expect a slightly higher signal in the filament region between the LRG pairs. We obtain the mean amplitude of the y_{whim} signal in the filament region to be 4.02×10^{-8} at $8'$ resolution. Thus the dilution in the WHIM signal amplitude is $\sim 7\%$ due to beam smoothing from $8'$ to $10'$.

We present the comparison of the WHIM profiles after halo subtraction for different selection of *Planck* channels, different $\chi^2_{CO-y_{sz}}$ thresholds, and resolutions in Fig. 11. The y_{whim} signal along $Y=0$ is consistent for different data selection criteria for $\chi^2_{CO-y_{sz}} \leq 0.05$. As we see from Fig. 5, $\chi^2_{CO-y_{sz}} \leq 0.07$ sample has significantly more contamination than the $\chi^2_{CO-y_{sz}} \leq 0.05$ sample. This is also evident in the residual signal in Fig. 11, where we see that there is slightly smaller excess in-between the LRGs and slightly larger excess on the other sides of LRGs at $X, Y < -1$ and $X, Y > 1$.

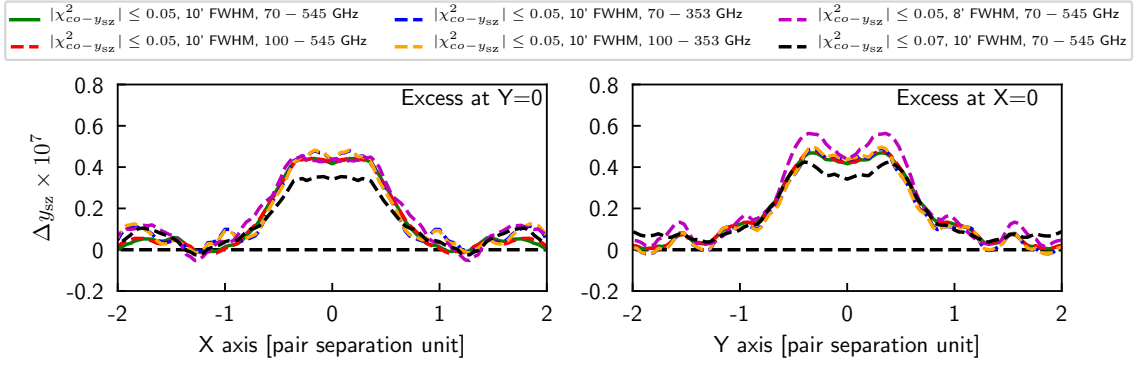

Figure 11: The comparison of the excess \hat{y}_{sz} signals along $X=0$ and $Y=0$ after the halo subtraction from individual LRG for different combinations of *Planck* channels and different beam resolutions.

7.2 Robustness w.r.t choice of point source masks and Galactic masks

The weights given to each frequency map during the ILC could vary significantly due to the presence of strong point sources in some of the regions projected for stacking analysis. Application of the temperature point source masks to these maps helps in removing those possible contaminants. We thus need to check the consistency of our excess by using point masks provided for the frequencies which get a significant weightage during ILC, i.e., the 4 HFI frequencies of 100-353 GHz most important for the y_{sz} extraction. We use the point source mask provided by *Planck* to test the robustness of the signal against contamination from strong radio and infrared point sources. *Planck* provides individual temperature point source mask for both LFI (30 - 70 GHz) and HFI (100 - 857 GHz) [59]. These are binary masks provided at $N_{side}=2048$. We downgrade them to $N_{side} = 1024$ and then select the regions having values >0.9 to ensure a sample free from point source contamination. These masks are then combined with the K86 mask. We expect some variation in y_{whim} and S/N as we are stacking a different number of LRGs with different masks. If there is no contamination then the y_{whim} signal amplitude along $Y=0$ should remain within the sample variance. Indeed, that is what we observe. We also test the robustness with the union of individual frequency channel point masks combined with K86 mask as well. The results with different masks are presented in Fig. 12. We do not see any significant variation in the signal on using different masks.

A point source mask has been provided by *Planck* [29] for SZ studies. However, we note that this is not intended as a general purpose mask but is specifically customized to be used with the NILC and MILCA SZ maps provided by the Planck collaboration. We perform the stacking analysis of the *Planck* LFI and HFI channels with PL48 mask which includes the point source mask. We stack roughly 101000 LRG pairs retained by PL48. The number of LRG pairs allowed by the PL48 mask is roughly the same number as used in our baseline analysis with the threshold criterion $\chi^2_{CO-y_{sz}} \leq 0.05$ with K86 mask. The reconstructed stacked ILC \hat{y}_{sz} map using different combination of *Planck* channels is presented in Fig. 13. The ILC weights for *Planck* frequency channels from 70 to 545 GHz for stacking with the PL48 mask are given in Table 1. We perform all the same steps as we have done for the baseline analysis. The average y_{whim} signal in the central region $-0.5 < X < 0.5$ and $-0.5 < Y < 0.5$ is $(2.4 \pm 0.4) \times 10^{-8}$. The error bar on the measured average y_{whim} signal is derived from the misalignment technique. If we also combine the PL48 mask with K86 mask along with the threshold criterion $\chi^2_{CO-y_{sz}} \leq 0.05$ we retain only ≈ 60000 LRG pairs, i.e. only $\sim 60\%$ of the sample with just PL48 mask. Thus the LRGs selected by our mask vs the PL48 mask are very different with PL48 mask sample giving a signal that is $\sim 36\%$ smaller. Our

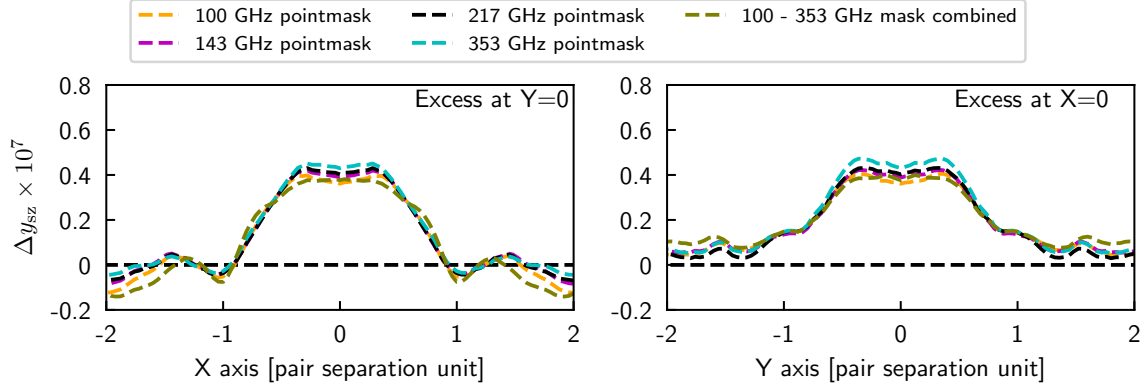

Figure 12: Same as Fig. 11, but for different combinations of *Planck* point source masks along with K86 mask with threshold criterion $|\chi^2_{\text{CO}-y_{\text{sz}}}| \leq 0.05$ and using 70 – 545 GHz *Planck* channels at 10' beam resolution.

Figure 13: The reconstructed ILC \hat{y}_{sz} maps using PL48 mask and different combination of *Planck* channels.

y_{sz} signal with PL48 mask sample is still much larger compared to the previous studies based on stacking of y_{sz} maps and is in particular a 6σ detection.

Table 2: The amplitude of the average y_{whim} signal in the central filament region derived from different combinations of *Planck* channels in the reconstruct the ILC \hat{y}_{sz} map, different $\chi^2_{\text{CO}-y_{\text{sz}}}$ thresholds over K86 and for different FWHMs of the raw *Planck* maps.

Channel combinations	$\chi^2_{\text{CO}-y_{\text{sz}}}$ threshold with K86	FWHM [in arcmin]	y_{whim}
70 – 545	0.05	10	3.78×10^{-8}
100 – 545	0.05	10	3.78×10^{-8}
70 – 353	0.05	10	3.97×10^{-8}
100 – 353	0.05	10	3.97×10^{-8}
70 – 545	0.05	8	4.02×10^{-8}
70 – 545	0.07	10	3.50×10^{-8}

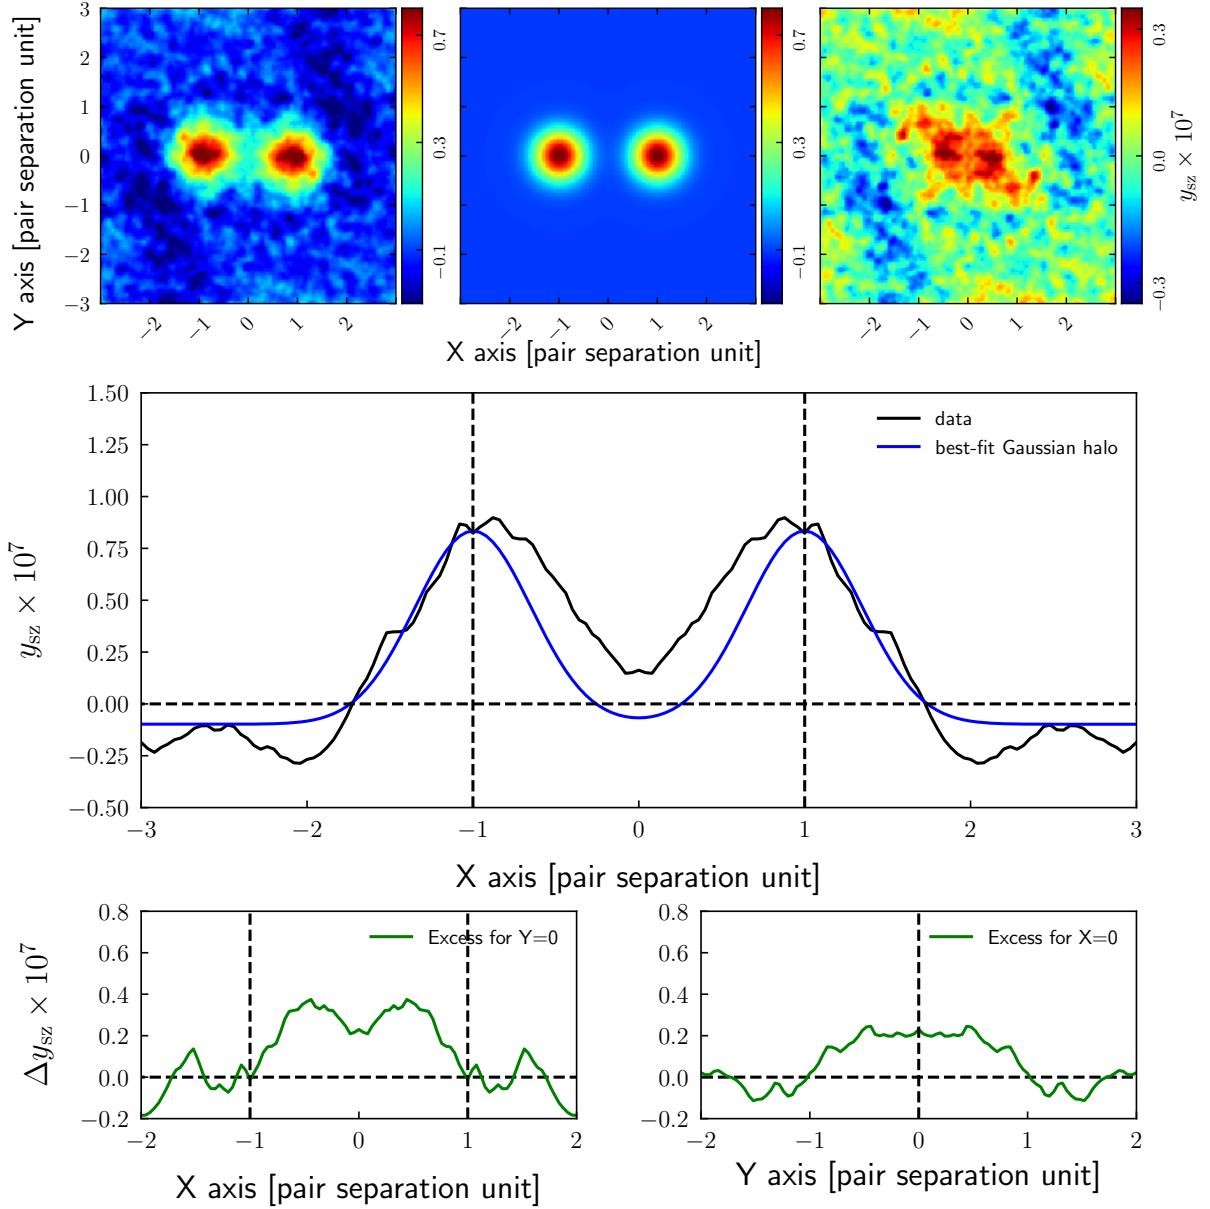

Figure 14: Same as Fig. 9, but for the stacked ILC \hat{y}_{SZ} map using *Planck* HFI channels 70–545 GHz and PL48 mask.

8 Comparison with stacking of *Planck* y_{SZ} maps

Earlier T19 and G19 have stacked the MILCA and NILC y_{SZ} maps at the locations of the LRG pairs. As we argued earlier, the MILCA and NILC y_{SZ} maps (or any other full sky tSZ map created from *Planck* data such as LIL map) have significant contamination (Fig. 1), much higher compared to the signal we are interested in and there is no guarantee that the positive and negative contamination would cancel. As it turns out, there is over-cancellation, resulting in the excess negative contamination decreasing the y_{SZ} signal in the WHIM between two LRGs.

In this section we reproduce their results and in particular show that we get results consistent with T19 and G19 when we also stack the y_{SZ} maps. We stack on the publicly available MILCA,

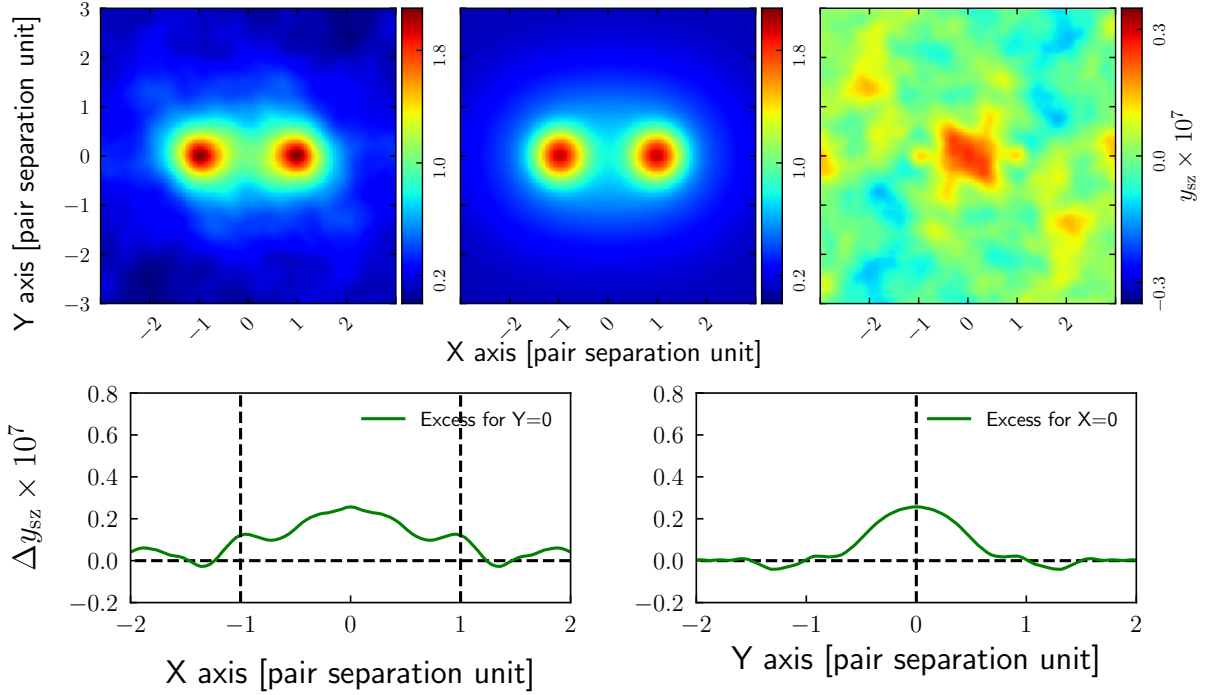

Figure 15: Same as Fig. 9, but for the stacked MILCA y_{sz} map with the threshold criterion $\chi^2_{CO-y_{sz}} \leq 0.05$ and K86 mask.

NILC and LIL y_{sz} maps at the location of LRG pairs with K86 mask and selection threshold of $|\chi^2_{CO-y_{sz}}| < 0.05$. The stacking method for y_{sz} maps is identical to the one we used for the *Planck* frequency channel maps as described in Sect. 4. We estimate the local background signal for each LRG pair in the annular region $9 < r < 10$ ($r^2 = X^2 + Y^2$) and subtract it to get the excess y_{sz} signal above the background. We see two clear peaks at the position of LRGs along with a bridge connecting the two peaks. The extended y_{sz} signal at the peaks is due to the y_{sz} as well as galactic emission from the two LRGs. After subtracting the LRG halo contribution, we get average $y_{whim} \sim (1.88 \pm 0.30) \times 10^{-8}$ in the region between the LRGs, i.e. $-0.5 \leq X \leq 0.5$ and $-0.5 \leq Y \leq 0.5$, from the stacked MILCA y_{sz} map. The 1σ errorbar is derived from the misalignment technique. The result of stacking analysis from MILCA y_{sz} map is shown in Fig. 15. We also use the other two publicly available y_{sz} maps for the stacking analysis. Over the same filament region, we get the average $y_{whim} \sim 1.56 \times 10^{-8}$ from NILC map and $y_{whim} \sim 3.45 \times 10^{-8}$ from LIL map. The WHIM signal we get from the stacking of LIL y_{sz} map is close to the one we obtained from our “*Stack First*” approach.

We also repeat the analysis of T19 by using PL48. The results are presented in Fig. 16. The WHIM y_{sz} signal in the filament region between the LRG pairs is $y_{whim} = (1.55 \pm 0.22) \times 10^{-8}$, consistent with the value we got above with our custom K86 mask and $\chi^2_{CO-y_{sz}}$ based selection criteria. Our results are also consistent within 1σ errorbars to the reported excess y_{sz} signal of $(1.31 \pm 0.24) \times 10^{-8}$ in T19. As argued above, and shown by our results from stacking the individual frequency maps, stacking y_{sz} maps gives biased results due to only partial cancelation of the positive and negative contaminations.

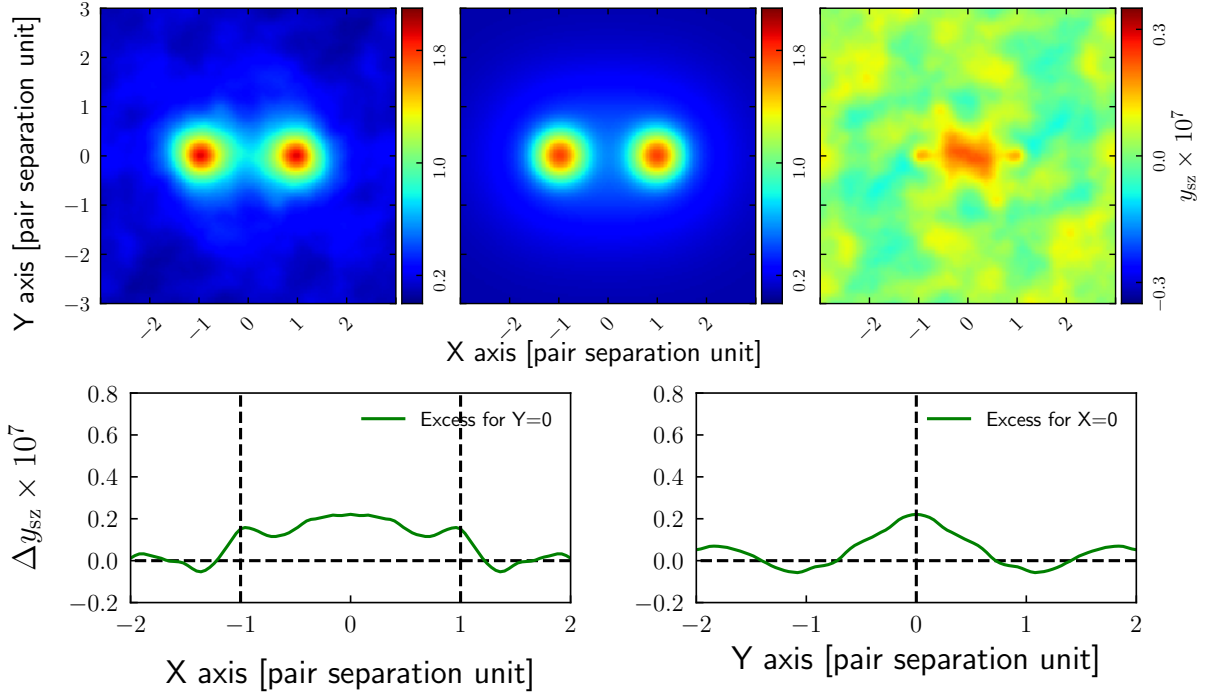

Figure 16: Same as Fig. 15, but for the stacked MILCA y_{sz} map and PL48 mask.

9 Conclusion

We have presented a new *Stack First* approach aimed at detection of weak y_{sz} signals in stacked objects in the *Planck* data. The important new ingredient in our recipe is to *first stack* the individual frequency channel maps and *then* perform blind component separation. In our approach, the component separation problem that the blind separation algorithm should solve is simpler compared to the common method of first doing component separation and then stacking. This is because the noise as well as the CMB contribution is suppressed due to stacking at random locations and the stacked dust signal becomes spatially uniform in its spectrum. In order to avoid regions with CO contaminations, present in all the *Planck* HFI channels excluding 143 GHz, as well as strong background and foreground SZ sources, we use an additional mask based on the $\chi^2_{CO-y_{sz}}$ thresholds. The $\chi^2_{CO-y_{sz}}$ map [31] indicates whether CO emission or y_{sz} signal fits the *Planck* data better in addition to the dust and CMB emission. For the weak, noise dominated, sources we are interested in, we should not be able to distinguish between CO and SZ, and thus choose pixels with $\chi^2_{CO-y_{sz}}$ close to 0. We restrict our analysis to a limited range of $\chi^2_{CO-y_{sz}}$ values, i.e. $|\chi^2_{CO-y_{sz}}| \leq 0.05$ to get a cleaner sample of LRG pairs for the stacking analysis. Our approach is different than T19 and G19, as they consider the stacking of the MILCA and NILC y_{sz} maps at high Galactic latitude without taking into account the residual CO emission and y_{sz} emission from the background/foreground sources in the y_{sz} maps. We present our main conclusions below.

- We find the WHIM signal between the LRG pairs to be $y_{whim} = (3.78 \pm 0.37) \times 10^{-8}$. We have thus detected WHIM at a significance level of ~ 10.2 (10.8σ if we use errorbar from non-overlapping regions).
- We find the signal is robust with respect to using different channel combination and masks.

- Our results are consistent with the expectations for the WHIM from hydrodynamic cosmological simulations [16, 17, 58].
- Our WHIM signal is higher compared to the results of T19 and G19. The difference is most likely coming from incomplete cancelation of positive and negative contamination when directly stacking y_{sz} maps.
- The WHIM (dominant baryonic component in the filaments of the cosmic web), exists in a wide range of temperatures and densities. Assuming an average temperature of 5×10^6 K indicated by simulations, we find that the overdensity in filaments is ~ 13 in agreement with the expectations from simulations of $\sim 10 - 40$ [16].

We therefore conclude that we have detected the missing baryons in the local Universe using the thermal Sunyaev-Zeldovich effect in the *Planck* data at a significance $> 10\sigma$.

A Validation of *Stack First* approach using simulations

In this section, we test the efficacy of the *Stack First* approach for the extraction of the y_{whim} signal in the filament region connection the LRG pairs. For this purpose, we use all-sky LIL y_{sz} map as a proxy for the true tSZ signal and the extracted y_{whim} signal from the stacking of LIL y_{sz} map as our input or true WHIM signal for our fiducial galaxy pair sample (K86 mask and $|\chi^2_{\text{CO}-y_{\text{sz}}}| < 0.05$, see Sect. 8 for details). We prefer LIL y_{sz} map over the MILCA and NILC y_{sz} maps just because of its agreement with the amplitude of y_{whim} signal obtained from the *Stack First* approach.

We simulate realistic sky observed by *Planck* between 70 and 545 GHz by adding various diffuse foreground components to the input y_{sz} signal. We demonstrate that our *Stack First* approach recover back the input y_{whim} signal from the combination of simulated multifrequency *Planck* maps without any significant bias. The total sky intensity at a given frequency ν can be modeled as a linear superposition of tSZ signal, CMB emission, the Galactic contamination and the instrumental

noise,

$$T(\nu, p) = f_{\nu}^{y_{sz}} T_{y_{sz}}(p) + T_{\text{cmb}}(p) + f_{\nu}^{\text{co}} T_{\text{co}}(p) + f_{\nu}^d \tau_{353}(p) \left(\frac{\nu}{353} \right)^{\beta_d(p)} B_{\nu}(T_d(p)) \\ + T_{\text{sy}}(\nu, p) + O_{\text{CIB}}(\nu) + T_N(\nu, p), \quad (\text{A.1})$$

where p corresponds to the pixel index corresponding to **HEALPix** pixel resolution of $N_{\text{side}}=1024$. The different emission components that we included in our simulation are described below.

- **tSZ signal** - We use LIL y_{sz} map as a template for tSZ signal ($T_{y_{sz}}$). The factor $f_{\nu}^{y_{sz}}$ is the spectrum of the y -distortion. It is obtained by integrating the change in intensity ($\Delta I_{\nu} = \frac{2h\nu^3}{c^2} \frac{x e^x}{(e^x - 1)^2} \left(\frac{x(e^x + 1)}{(e^x - 1)} - 4 \right)$) over the *Planck* frequency response [55], where $x = \frac{h\nu}{k_B T}$; h, k_B, T being the Planck's constant, Boltzman constant and CMB monopole temperature (2.725 K) respectively.
- **CMB emission** - We simulate a random gaussian realization of the CMB sky from the theoretical power spectrum of the *Planck* 2018 best-fit model [33] giving the random the CMB sky realization T_{cmb} uncorrelated with our input y_{sz} map.
- **Thermal dust** - To simulate the dust emission, we use *Planck* 2013 dust model [61], which is a modified blackbody fit to *Planck* intensity maps at $\nu \geq 353$ GHz. The model fits the three parameters: dust opacity (τ_{353}), dust spectral index (β_d) and dust temperature (T_d) per sky pixel. We use *Planck* 2013 dust model [61] instead of updated *Planck* 2015 dust model [62] since the 2013 model includes the CIB anisotropies present in the *Planck* maps. In the 2015 dust model, the CIB anisotropies are removed using the generalized linear combination (GNILC) method. As our study is focussed at high Galactic latitude and at small scales, we choose the appropriate dust model that is close to the real *Planck* data. Note that even though dust model in each pixel is quite simple, after stacking we will have superposition of many different spectra in each pixel. The foregrounds in the stacked maps, on which we run ILC, would be very complex and realistic.
- **Synchrotron** - We use the bandpass integrated FFP10 synchrotron templates (T_{sy}) available on PLA¹ for our purpose. It uses the 408 MHz map provided by Haslam [63] and reprocessed by [64] as a synchrotron amplitude and a pixel-dependent single power-law spectral index map, derived by fitting the *WMAP* data [65].
- **CIB offset** - We add the CIB monopole term (O_{CIB}) to our sky simulation. It has a constant value per frequency over the full-sky. The CIB monopole values per *Planck* HFI frequency is given in Table 4 of [66].
- **CO emission** - In absence of any publicly available CO map, we take the *Planck*-derived MILCA 2015 CO ($1 \rightarrow 0$) line emission map [67] as a proxy for the CO emission. We choose Type 1 CO map as it has little contamination from other foregrounds, e.g. dust and y_{sz} emission. We smoothed the CO ($1 \rightarrow 0$) Type 1 map at 10' (FWHM) beam resolution taking into account the effective beam response of the *Planck* CO map and reduced to a **HEALPix** resolution of $N_{\text{side}}=1024$. We then stack the CO map at the location of LRG pairs with K86 mask and the $\chi^2_{\text{CO}-y_{sz}}$ threshold $|\chi^2_{\text{CO}-y_{sz}}| < 0.05$. The left panel of Fig. 17 shows the stacked 10' smoothed CO $J = 1 \rightarrow 0$ map at the location of LRG pairs. The stacked CO ($1 \rightarrow 0$) map has no structure similar to the y_{sz} signal and is completely dominated by the CO noise. This also confirms our expectation using parameter fitting in section 4.2. To increase the

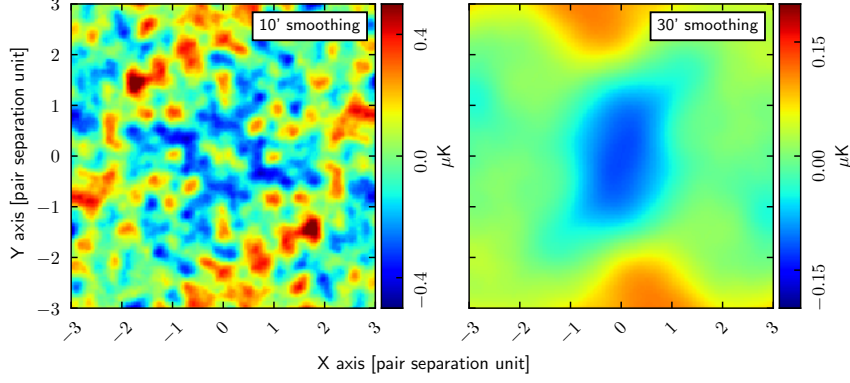

Figure 17: The figure shows the stacked CO ($1 \rightarrow 0$) map at 100 GHz for two different smoothing scales: 10' FWHM (*left panel*) and 30' FWHM (*right panel*) at the location of the LRG pairs for the threshold mask $|\chi_{\text{CO}-y_{\text{sz}}}^2| < 0.05$ with K86 mask. There is no significant correlation between the stacked CO ($1 \rightarrow 0$) maps at two different beam resolutions and the stacked y_{sz} map.

signal-to-noise ratio, we choose to smoothed the CO ($1 \rightarrow 0$) map to a beam resolution of 30' FWHM. The stacking of 30' smoothed CO ($1 \rightarrow 0$) map is presented in the right panel of Fig. 17. The choice of 30' smoothing scale is based on the power spectrum analysis of the CO map at high Galactic latitude [68]. We take 30' smoothed CO ($1 \rightarrow 0$) map as a template for the CO emission (T_{co}). We add CO contribution to 100 and 217 GHz channels only. For 217 GHz channel, we assume the line ratio of $J = 2 \rightarrow 1$ to $J = 1 \rightarrow 0$ as 0.595. The factor f_{ν}^{co} takes into account the spectrum of the CO emission at 100 and 217 GHz. For other frequencies, f_{ν}^{co} is set to zero.

- Instrumental noise - We add a random realization of simulated full focal plane (FFP8) noise map per frequency as an instrumental noise contribution T_N [69]. It captures the dominant instrumental, scanning and map making algorithm and implementation noise effects.

We simulate all-sky simulated maps between 70 and 545 GHz at a common beam resolution of 10' FWHM. These maps are expressed in K_{CMB} units for frequencies between 70 and 353 GHz and MJy/sr for 545 GHz, similar to the real *Planck* data. Figure 18 compares the simulated maps over K86 mask with the real *Planck* data. We then perform the *Stack First* approach i.e. stacking the simulated frequency maps first at the LRG pair location over the threshold mask ($|\chi_{\text{CO}-y_{\text{sz}}}^2| < 0.05$) with K86 mask and then perform the ILC on the stacked maps. Figure 19 shows the comparison between the simulated and the *Planck* stacked maps at frequencies between 70 and 545 GHz. The results and comparison with the stacked input map has been shown in the Figure 20. We find that the y_{whim} signal recovered using the *Stack First* approach indeed resembles the input y_{whim} signal obtained from the direct stacking of the LIL y_{sz} map. This confirms beyond doubt the capabilities of our approach in recovering faint signals by removing contaminations from the stacked frequency maps.

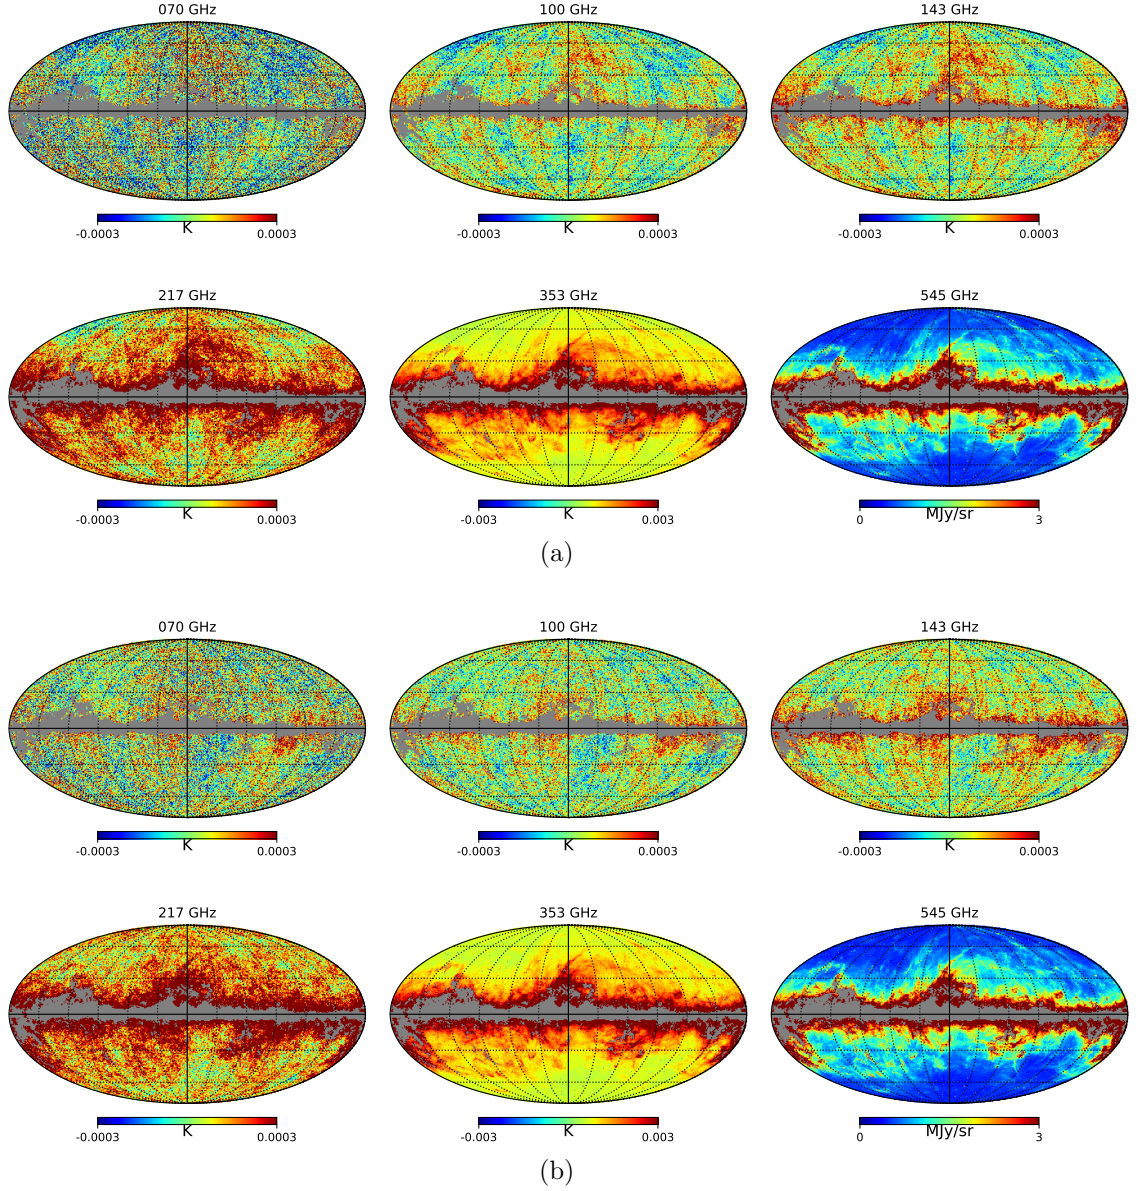

Figure 18: The figure shows the comparison of our simulated sky maps (*panel a*) with the real *Planck* data (*panel b*) in the frequency range between 70 and 545 GHz. All the maps are smoothed to 10' FWHM beam resolution with K86 Galactic mask applied (shown in gray region).

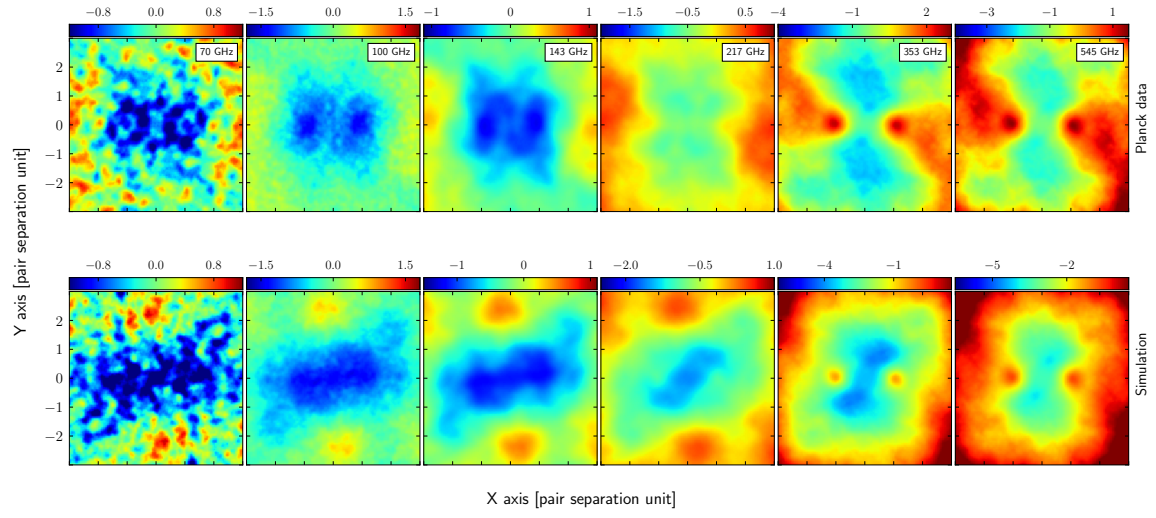

Figure 19: The figure shows the comparison of stacked maps of the *Planck* data (*top panel*) and our simulated dataset (*bottom panel*) for *Planck* frequencies between 70 and 545 GHz.

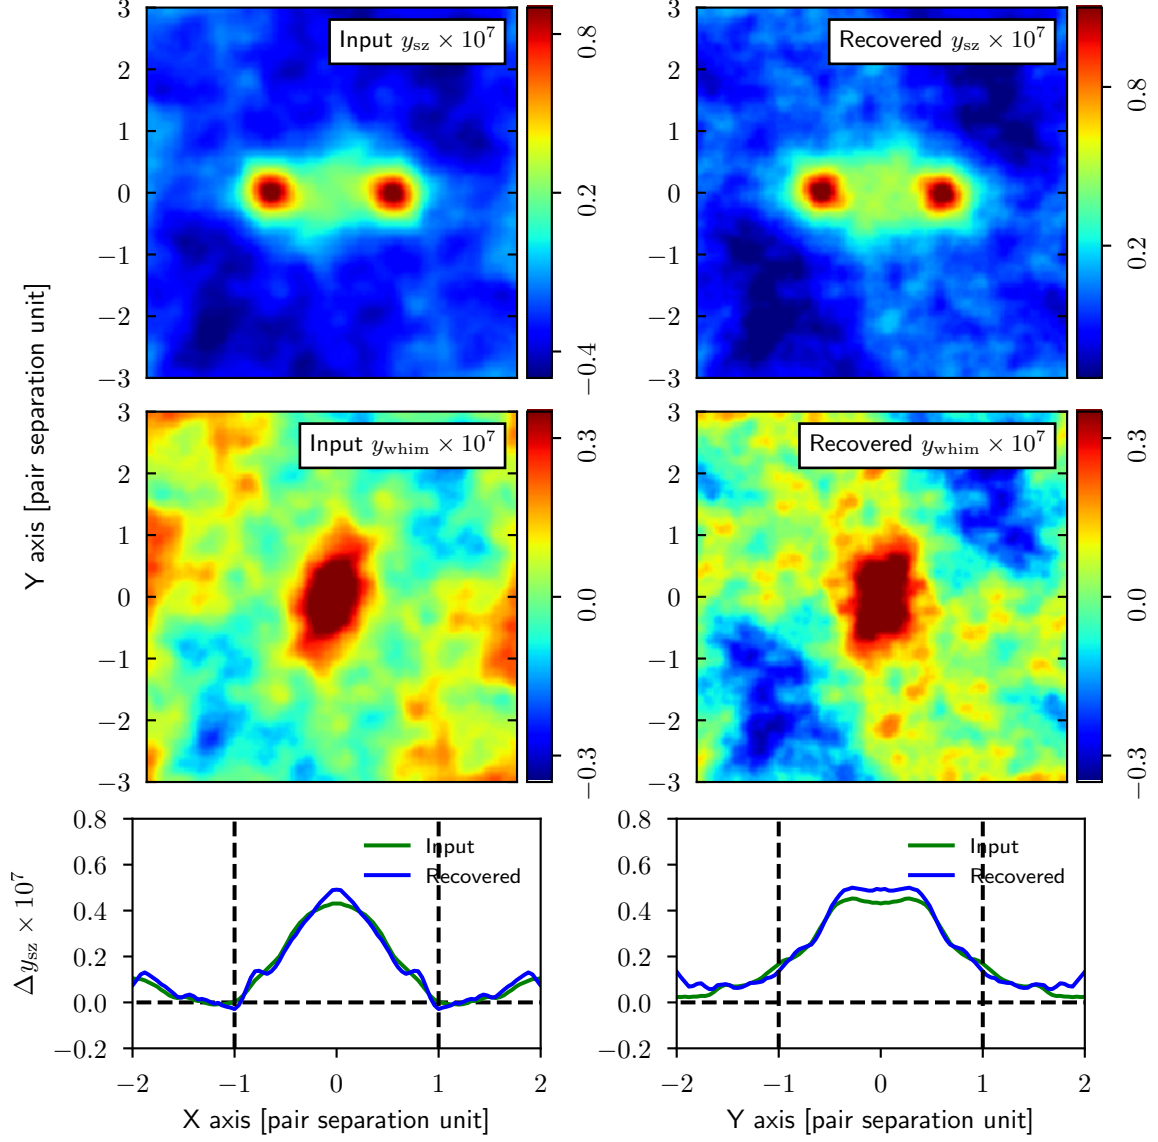

Figure 20: The figure shows the comparison of the stacked input y_{sz} signal (*top left panel*) and the recovered y_{sz} signal after applying the *Stack First* approach (*top right panel*) on the simulated *Planck* maps. The *middle panel* shows the comparison between the input and the recovered y_{whim} signal at the location of LRG pairs after subtraction of the halo contribution. The *bottom panel* shows the profile of the input and recovered y_{whim} signal along $Y=0$ (*left panel*) and $X=0$ (*right panel*). We are able to recover the profile of the y_{whim} signal without any significant bias.
