Introduction— The entanglement entropy (EE) is an important measure of quantum correlations of a quantum many body system that also exhibits the universal properties in the vicinity of a quantum phase transitions[1–3]. For a closed quantum system, the bipartite EE is calculated through the Von-Neumann entropy of the reduced density matrix \( \rho \) for a sub-system of size \( \ell \):

\[
S(\ell) = -\text{Tr}[\rho_{\ell} \ln \rho_{\ell}],
\]

where \( \rho_{\ell} = \text{Tr}_{L-\ell}[\rho_L] \) and \( \rho_L \) is the density matrix of the composite system of size \( L \). If we consider the ground state of a short-range one-dimensional Hamiltonian, the EE follows an area law with a logarithmic correction of the form \( \sim \ln \ell \) when the composite system is at its quantum critical point[5, 6].

Recently, there has been a great interest in studying the temporal evolution of correlations and entanglement entropy during the non-equilibrium dynamics of a closed quantum many body system following a quantum quench in which a parameter of the Hamiltonian is instantaneously changed (globally or locally)[7]. The out-of-equilibrium dynamics of the system results in propagation of quantum correlations over the whole system thus leading to a growth of non-trivial bipartite entanglement even if the initial state is chosen to be completely unentangled. It has been established[8] that following a global quench to the critical point of a one-dimensional free fermionic Hamiltonian, \( S(\ell, t) \) exhibits a ballistic growth, \( S(\ell, t) \sim t \), up to a time \( t^* = \ell/2v_{\text{max}} \). Here, \( v_{\text{max}} = \partial \epsilon(k)/\partial k|_{k_{\text{max}}} \) is the maximum group velocity obtained from the energy dispersion \( \epsilon(k) \) of the quasiparticles with quasi-momentum \( k \). For \( t > t^* \), \( S(\ell, t) \) saturates to a constant value proportional to \( \ell \), and hence the EE satisfies a volume law in the steady state.

We note that this ballistic growth and the volume law scaling have also been verified in other models[9] and also experimentally simulated in integrated photonics quantum circuit[10]. For disordered spin chains[11, 12] or in many body localized (MBL) phases[13, 14] a characteristic logarithmic growth of EE has been observed. This logarithmic growth of the EE has also been observed for local quenches[15, 16]. The initial linear growth and steady state (volume law) scaling of the EE have also been observed both in periodically[17, 18] and aperiodically[19, 20] driven free fermionic systems.

The purpose of this work is to investigate an area unexplored till date, namely how is the dynamical generation of the bipartite entanglement following a global quench influenced when the composite system is coupled to a weak dissipative environment. Notably, a dissipative coupling to an environment is likely to result in a generation of entanglement between the composite system and the bath. This entanglement is quantified by the Von-Neumann entropy \( S(\rho_L) \) of the composite system of size \( L \) (or equivalently the bipartite EE between the composite system and the bath). Since in a dissipative environment, the composite system is no longer a pure state, it is useful to study the mutual information (MI) between a sub-system of size \( \ell \) and the rest of the system[4].

Particularly, we note that a direct calculation of the von Neumann entropy for a subsystem using Eq. (1) will also have contribution from \( S(\rho_L) \). For our analysis, we model the dynamical evolution of our system through a Lindbladian framework within the Born-Markov and secular approximations[21, 22]. Interestingly, as we shall demonstrate below, the contribution from the \( S(\rho_L) \) can be filtered out for some particular choice of Lindblad operators, to restore the direct correspondence with the MI.

In the unitary situation[5], the initial ballistic growth as well as the steady state volume law behavior of the EE (or equivalently the MI) has been phenomenologically explained within a quasi-particle picture. In the dissipative case, we find that the ballistic growth is ex-
ponentially suppressed suggesting a finite life-time of the quasi-particles generated after the quench. Nevertheless, a finite MI persists in the asymptotic steady state which interestingly follows a sub-volume law.

**Mutual information**– Let us recall the definition of MI:

\[ I(\ell : L - \ell) = S(\rho_\ell) + S(\rho_{L-\ell}) - S(\rho_L) \tag{2} \]

where \( S(\rho_\ell), S(\rho_{L-\ell}) \) and \( S(\rho_L) \) are the von-Neumann entropy of the sub-system, rest of the system and the composite system, respectively. For a closed system, \( S(\rho_L) = 0 \) and \( S(\rho_\ell) = S(\rho_{L-\ell}) \); consequently, the MI is equivalent to the bipartite entanglement entropy in the unitary case \([8]\). However, if \( \rho_\ell \) is a mixed state then \( S(\rho_\ell) \neq S(\rho_{L-\ell}) \).

By splitting the quantity \( S(\rho_L) \) into two parts, we can rewrite the Eq. 2 in following way

\[ I(\ell : L - \ell) = S'(\ell) + S'(L - \ell) \tag{3} \]

where

\[ S'(\ell) = S(\rho_\ell) - \frac{\ell}{L} S(\rho_L), \tag{4} \]

\[ S'(L - \ell) = S(\rho_{L-\ell}) - \frac{L - \ell}{L} S(\rho_L). \tag{5} \]

Interestingly, in our case, two quantities \( S'(\ell) \) and \( S'(L - \ell) \) are exactly equal (as shown in the supplemental material (SM)) and such that \( S'(\ell) = S'(L - \ell) = I(\ell : L - \ell)/2 \). This factorization of \( S(\rho_L) \) is meaningful because the Lindbladian operators we consider in this work are independently coupled to each site with uniform coupling strength.

**Model and the bath**– In this work, we consider a transverse field Ising chain (TFIC) globally coupled to a Markovian bath using the Lindblad master equation \([30, 32]\) (see SM for detail): the chain is prepared in the (un-entangled) ground state of the Hamiltonian with a large negative value of the transverse field \( h \) which is instantaneously quenched to the final critical value \( h_f = 1 \).

The TFIC is described by the Hamiltonian

\[ H = -\sum_{n=1}^{L} \sigma_n^z \sigma_{n+1}^z - h \sum_{n=1}^{L} \sigma_n^z, \tag{6} \]

where \( \sigma_n \)'s are the Pauli spin matrices for the \( n \)th site and \( h \) is the transverse magnetic field. This can be mapped to a system of spinless fermions model through a Jordan-Wigner (JW) transformation \([33, 37]\), following a Fourier transformation to the quasi-momentum basis the Hamiltonian decouples to the form: \( H = \sum_{k>0} H_k \).

In the basis spanned by the states \( \{|\phi_1^k\rangle = |0\rangle, |\phi_2^k\rangle = c_k^\dagger |0\rangle, |\phi_3^k\rangle = c_{-k}^\dagger |0\rangle, |\phi_4^k\rangle = c_k^\dagger c_{-k}^\dagger |0\rangle \} \), where \( c_k^\dagger \) is the fermionic creation operator for the mode \( k \) and \( |0\rangle \) refers vacuum of fermions, \( H_k \) assumes the form

\[ H_k = \begin{pmatrix} h - \cos k & 0 & 0 & \sin k \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ \sin k & 0 & 0 & -h + \cos k \end{pmatrix}. \tag{7} \]

We choose a specific Markovian bath where system-bath interaction characterised by a set of site-local Lindblad operators \( L_n = c_n [35, 40] \). The efficacy of such a choice of Lindbladian operator is that in the case of homogenous coupling strength \( (\kappa_n = \kappa, \forall n) \), the Lindblad master equation (with \( h = 1 \)) decouples in the momentum modes as

\[ \frac{d\rho_k(t)}{dt} = -i [H_k, \rho_k(t)] + D_k [\rho_k(t)], \tag{8} \]

with

\[ D_k [\rho_k(t)] = \kappa \left( c_k \rho_k(t) c_k^\dagger - \frac{1}{2} \{ c_k^\dagger c_k, \rho_k(t) \} \right. \]

\[ \left. + c_{-k} \rho_k(t) c_{-k}^\dagger - \frac{1}{2} \{ c_{-k}^\dagger c_{-k}, \rho_k(t) \} \right), \tag{9} \]

evidently retaining the form \( \rho(t) = \otimes_{k>0} \rho_k(t) \) for all \( t \). Since the dissipator breaks the parity conservation of number of fermions in the dynamics unlike the unitary case \([33]\), one needs to retain both the parity sectors leading to a \( 4 \times 4 \) form of the density matrix in the basis \( \{|\phi_j^k\rangle\} \):

\[ \rho_k(t) = \sum_{j=1}^{4} \rho_{kj}^l |\phi_j^k\rangle \langle \phi_j^k|. \tag{10} \]

**Numerical results**– The system is initially prepared in the (unentangled) ground state of the Hamiltonian \( H_k(h) \) with \( h \rightarrow -\infty \), such that \( \rho_k(0) = |\phi_1^k\rangle \langle \phi_1^k|, \forall k \). At \( t = 0^+ \), the field \( h \) is suddenly changed to the critical value \( h_f = 1 \) and the system evolves with the final Hamiltonian \( H(h_f) \) following Eq. (8). Numerically evaluating \( \rho_k(t) \), we arrive at the two point correlations of fermions:

\[ C_{mn}(t) = \text{Tr} [\rho(t), c_m^\dagger c_n] \], \( F_{mn}(t) = \text{Tr} [\rho(t), c_n c_m^\dagger] \tag{11} \]

where \( m, n = 1, 2, \ldots, \ell \). Finally, diagonalizing the \( 2\ell \times 2\ell \) correlation matrix

\[ C = \begin{pmatrix} I - C & F \\ F^\dagger & C \end{pmatrix}. \tag{12} \]

for the sub-system of size \( \ell \), one can calculate \( S(\rho_k, t) \) applicable for a free fermionic model \([39]\) and hence the MI \( S'(\ell, t) \) using Eq. (4) (see SM).

Let us first recall the results for the perfectly unitary situation i.e., \( \kappa = 0 [8] \), as reproduced in the Fig. 1(a).

Indeed, the MI shows a ballistic growth up to a time \( t^* = \ell/2 \) and subsequently saturates to a constant value.
which is proportional to \( \ell \). We note that in the limit

\[ L \to \infty, \ell \to \infty \text{ with } \ell \ll L, \]

the MI is expected to have a ballistic growth in time indefinitely. On the contrary, for any finite \( \ell \), the MI follows the \( \ell \to \infty \) line up to the time \( t = t^* = \ell/2 \). This behaviour of the EE has been explained by a semiclassical description in terms of entangled pair of quasi-particles with equal and opposite group velocity \( v \) with \( v_{\text{max}} = 1 \). so that correlations spread following a light-cone behavior\(^{[44]}\). Further, the steady state behaviour of the MI is an artefact of the infinite life time of the quasi-particles.

We now proceed to the case, \( \kappa \neq 0 \): the temporal variation of \( S'(\ell, t) \), obtained from Eq. (4) using \( p(t) \), is presented in Fig. 1(b) for different sub-system size \( \ell \). Critically inspecting the results, we conclude that the temporal evolution of \( S'(\ell, t) \) is significantly different when compared to that of the MI with \( \kappa = 0 \). For a given \( \ell \), we observe a monotonic non-linear growth of the entanglement and it eventually decays to the steady state

\[ S'(\ell, t) \sim A \left( 1 - e^{-c(\kappa)t} \right) + Bte^{-d(\kappa)t}, \]

(13)

with \( c(\kappa) \gg d(\kappa) \) and the parameter \( B \) is a non-universal constant depending on the group velocity of quasi-particles. Eq. (13) gives a perfect fitting with the numerically obtained results as depicted in Fig. 1(b). The functional form can be interpreted in the following way: in early time limit, \( S'(\ell \to \infty, t) \sim Bte^{-dt} \), which essentially means that the linear growth in the MI observed in the \( \kappa = 0 \) situation is now exponentially suppressed. This suppression can be attributed to the finite life-time of the quasi-particles in the case of finite dissipation. However, a finite MI survives in the asymptotic steady state, \( S'(t \to \infty) = A \), which may be erroneously attributed to the mixed nature of the steady state. We however show below that, most surprisingly, this remanent MI is indeed produced by propagating quasi-particles, a fact that is manifested in two-point correlations.

Following the insight obtained from the \( \kappa = 0 \) situation, it is natural to expect that for a finite \( \ell \), the early time growth of the MI \( (\sim te^{-dt}) \) will continue as long as the quasi-particles originating from the centre of the sub-system do not cross the sub-system boundary, following which the MI will only decay exponentially, i.e.
existence of a finite correlation between the two sites $'m'$ and $'n'$ at a particular instant of time can now be attributed to the arrival of one quasi-particle of an entangled pair at site $m$ and the other at site $n$ at the same time. This evidently ensures that only the quasi-particles originating at the middle of either of the two segments between the two points can contribute to the two point correlations. Since the minimum time taken by these quasi-particles to arrive at the two sites is given by $t^* = \min \{|(m-n)/2|, |L-m+n)/2\}$, no finite correlation is observed for $t < t^*$. The successive peaks occur due to the slower moving quasi-particles ($v(k) < v_{\text{max}}$). The slower moving quasi-particles are less abundant than the faster moving ones, as evident from the progressively decreasing amplitude of the subsequent peaks. A revival of correlation can occur due to the arrival of the quasi-particles from the middle of the longer segment connecting the two points as observed in Fig. 3. We note that in the thermodynamic limit $L \to \infty$ and for a finite $|m-n| \ll L$, this revival can not occur.

Remarkably, even for the case $\kappa \neq 0$, no finite correlation is observed for $t < t^*$. Particularly, we note that the maximum group velocity of the quasi-particles is same as in the unitary case. This validates our conclusion that the maximum group velocity of the quasi-particle is not renormalized in the presence of dissipation. Further, the amplitude of the correlations are smaller as compared to the $\kappa = 0$ case with the amplitude of the revivals significantly diminished. This supports the fact that the quasi-particles originating at $t = 0$ now has a finite life time.

Further, the two point correlation saturates to a finite non-zero value unlike the $\kappa = 0$ case as shown in the Fig. 3. This is manifested also in the non-zero steady state value of the $S'(\ell, \infty)$ as we have analysed in the SM.

Finally, the steady state, reached following a global...
quench to $h = 1$, TPC when plotted as a function of the (shorter) intermediate distance $|m - n|$, (as shown in Fig. 4 for different values of $\kappa$) shows an exponential decay of the form,

$$C_{mn}(\infty) \sim \exp \left\{ \frac{-\kappa(m - n)}{2} \right\}. \quad (15)$$

This implies that when the $|n - m|$ exceeds $2/\kappa$, the quasi-particles generate exponentially small correlations, thereby pointing to a finite life-time of the quasi-particles generated in the dissipative environment.

The above analysis of the TPCs have following bearing on the behaviour of $S'(\ell, t)$ discussed earlier. Since the group velocity of the entangled pair of quasi-particles remain unaltered for $\kappa \neq 0$, we observe that the deviation in $S'(\ell, t)$ from the $\ell \to \infty$ curve occurs at $t^* = \ell/2$ as for $\kappa = 0$. The remanent TPC in the steady state is reflected in the non-zero steady state value of $S'(\ell, t)$. This steady state MI , however, results from the collective contribution of remanent TPCs between sites that are located within a finite distance from either end of the sub-system. We note that this is significantly different from the $\kappa = 0$ case where the finite MI at large time is maintained collectively by TPCs between all sites of the system.

Further, the finite life time of quasi-particles results in an exponential suppression of the MI at all instances of time. Remarkably, the no-quench analysis of the TPC (elaborated in SM) establishes that perpetual coupling to the bath also generates quasi-particles at all instants apart from imparting the quasi-particles a finite life time.

In summary, we study the influence of a weak dissipative coupling on the generation and growth of the MI in a quenched one-dimensional integrable model. As in the unitary ($\kappa = 0$) case, the MI acquires a finite steady value at long times; in this case however, the steady value is determined by both the post-quench Hamiltonian as well as the coupling strength with the bath and does not follow a volume law. Further, the ballistic growth due to the quench induced propagating correlations is exponentially damped due to the bath induced dissipation.

MODEL AND THE BATH

In this work, the subsequent dissipative dynamics of the transverse Ising chain following a quench of the transversal field (from $h = -\infty$ and $h = 1$) is assumed to be described by a Lindblad master equation of the form

$$\frac{d\rho(t)}{dt} = -i[H, \rho(t)] + D[\rho(t)];$$  \hspace{1cm} (S1)

we have set $\hbar = 1$ throughout. The first term on the right-hand side describes the unitary time evolution of the system’s density matrix $\rho(t)$ while the dissipator $D[\rho(t)]$ encapsulates the dissipative dynamics and assumes a form:

$$D[\rho(t)] = \sum_n \kappa_n \left( L_n \rho(t) L_n^\dagger - \frac{1}{2} \{ L_n^\dagger L_n, \rho(t) \} \right),$$  \hspace{1cm} (S2)

where $L_n$ are the Lindblad operators with $\kappa_n (\geq 0)$’s being the corresponding dissipation strengths.

The transverse field Ising chain is described by the Hamiltonian

$$H = -\sum_{n=1}^L \sigma^x_n \sigma^x_{n+1} - h \sum_{n=1}^L \sigma^z_n,$$  \hspace{1cm} (S3)

where $\sigma^x$’s are the Pauli spin matrices for the $n$th site and $h$ is the transverse magnetic field. Considering anti-periodic boundary condition, the Eq. (S3) can be mapped to a system of spinless fermions model through a Jordan-Wigner (JW) transformation, to arrive at the following quadratic form:

$$H = -\sum_{n=1}^L \left( c_n^\dagger c^\dagger_{n+1} + c_n^\dagger c^\dagger_{-n+1} + \text{h.c.} \right) + 2h \left( c_n^\dagger c_n \right),$$  \hspace{1cm} (S4)

where $c_n$ (c^\dagger_n) are Fermionic annihilation (creation) operators residing on the $n$-th site. Further, in the quasi-momentum basis, the Hamiltonian decouples as $H = \sum_{k>0} H_k$, with $k = [2\pi(n + 1/2)] / L$ where $n \in \{0, 1, 2 \ldots (L - 1)\}$. In the basis spanned by the states $\{ | \phi^k_1 \rangle = |0\rangle, | \phi^k_2 \rangle = c^\dagger_k |0\rangle, | \phi^k_3 \rangle = c^\dagger_{-k} |0\rangle, | \phi^k_4 \rangle = c^\dagger_k c^\dagger_{-k} |0\rangle \}$, $H_k$ assumes the form

$$H_k = \begin{pmatrix}
    h - \cos k & 0 & 0 & \sin k \\
    0 & 0 & 0 & 0 \\
    0 & 0 & 0 & 0 \\
    \sin k & 0 & 0 & -h + \cos k
  \end{pmatrix}. $$  \hspace{1cm} (S5)

For a specific system-bath interaction, as used in this work, characterised by a set of local Lindblad operators $L_n = c_n$ \cite{41, 42}, the Lindblad master equation given in Eq. (S1) decouples in the momentum modes as

$$\frac{d\rho_k(t)}{dt} = -i[H_k, \rho_k(t)] + D_k[\rho_k(t)],$$  \hspace{1cm} (S6)
with
\[ D_k [\rho_k(t)] = \kappa \left( c_k \rho_k(t) c_k^\dagger - \frac{1}{2} \left\{ c_k^\dagger c_k, \rho_k(t) \right\} + c_{-k} \rho_k(t) c_{-k}^\dagger - \frac{1}{2} \left\{ c_{-k}^\dagger c_{-k}, \rho_k(t) \right\} \right) \] (S7)

GENERAL SOLUTION OF \( \rho(t) \)

In this section, we will briefly elaborate the calculation of the density matrix \( \rho_k(t) \) for each momenta mode using the Lindblad equation (Eq. [10] in the main text)\[S3, S4\]. Let us recall the basis which we considered here,

\[ |\phi^k_0\rangle \equiv |0,0\rangle, \quad (S8) \]
\[ |\phi^k_1\rangle \equiv c_k^\dagger |0,0\rangle = |k,0\rangle, \quad (S9) \]
\[ |\phi^k_2\rangle \equiv c_{-k}^\dagger |0,0\rangle = |0,-k\rangle, \quad (S10) \]
\[ |\phi^k_3\rangle \equiv c_k^\dagger c_{-k}^\dagger |0,0\rangle = |k,-k\rangle, \quad (S11) \]

where \( |0,0\rangle \) and \( |k, -k\rangle \) refer both the fermionic states for \( c_k \) and \( c_{-k} \) are occupied and unoccupied, respectively. In the above basis, we have the following matrix forms of \( c_k \), \( c_{-k} \) and \( H_k(\hbar) \) for each \( k \) mode

\[ c_k = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad c_{-k} = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad \text{and} \quad H_k(\hbar) = \begin{pmatrix} h - \cos k & 0 & \sin k \\ 0 & 0 & 0 \\ \sin k & 0 & -h + \cos k \end{pmatrix}. \] (S12)

Using the above equations, the Lindblad equation (Eq. [10] in the main text) for each \( k \) mode contains sixteen coupled first order linear differential equations of which only ten are independent, those are

\[ \dot{\rho}_{11}(t) = -i \Delta (\rho_{12}^*(t) - \rho_{14}(t)) + \kappa (\rho_{22}(t) + \rho_{33}(t)), \]
\[ \dot{\rho}_{12}(t) = -i (\epsilon \rho_{12}(t) + \Delta \rho_{24}^*(t)) - \kappa \left( \frac{1}{2} \rho_{12}(t) - \rho_{24}(t) \right), \]
\[ \dot{\rho}_{13}(t) = -i (\epsilon \rho_{13}(t) + \Delta \rho_{34}^*(t)) - \kappa \left( \frac{1}{2} \rho_{13}(t) - \rho_{24}(t) \right), \]
\[ \dot{\rho}_{14}(t) = -i (2\epsilon \rho_{14}(t) + \Delta \rho_{11}(t) + \Delta \rho_{44}(t)) - \kappa \rho_{14}(t), \]
\[ \dot{\rho}_{22}(t) = -\kappa \rho_{22}(t), \quad \dot{\rho}_{23}(t) = -\kappa \rho_{23}(t), \]
\[ \dot{\rho}_{24}(t) = -i (\epsilon \rho_{24}(t) - \Delta \rho_{12}^*(t)) - \frac{3\kappa}{2} \rho_{24}(t), \]
\[ \dot{\rho}_{33}(t) = -\kappa \rho_{33}(t) + \kappa \rho_{44}(t), \]
\[ \dot{\rho}_{34}(t) = -i (\epsilon \rho_{34}(t) - \Delta \rho_{13}^*(t)) - \frac{3\kappa}{2} \rho_{34}(t), \]
\[ \dot{\rho}_{44}(t) = -i \Delta (\rho_{14}(t) - \rho_{14}(t)) - 2\kappa \rho_{44}(t). \] (S13)

where \( \epsilon = h - \cos k \), \( \Delta = \sin k \) and \( \dot{\rho}_{ij} = d\rho_{ij}/dt \). Solving the above equations we can obtain \( \rho_k(t) \). It is evident from the above equations that if we consider the initial state prepared at \( \hbar_i = -\infty \) i.e., \( \rho_k(0) = |0,0\rangle \langle 0,0| \), the density matrix \( \rho_k(t) \) has only five non-zero elements, \( \rho_{11}(t), \rho_{22}(t), \rho_{33}(t), \rho_{44}(t) \), and \( \rho_{14}(t) \). Thus, at any instant of time \( t \), the density matrix for each \( k \) mode takes the following form

\[ \rho_k(t) = \begin{pmatrix} \rho_{11}(t) & 0 & 0 & \rho_{14}(t) \\ 0 & \rho_{22}(t) & 0 & 0 \\ 0 & 0 & \rho_{33}(t) & 0 \\ \rho_{14}^*(t) & 0 & 0 & \rho_{44}(t) \end{pmatrix}. \] (S14)

STEADY STATE SOLUTION OF \( \rho_k(t) \)

In the presence of the dissipative environment, following a sudden quench the system reaches a steady state in the asymptotic limit of time \( t \to \infty \). In the present scenario, analytical form of the steady state density matrix \( \rho_k(\infty) \)
for each $k$ mode can be exactly calculated by putting $d\rho_k(t)/dt = 0$ in the Lindblad master equation. The non-zero elements of the density matrix $\rho_k(\infty)$ assume the following form:

$$\rho_{11}(\infty) = \frac{\Delta^2 + 4\epsilon^2 + \kappa^2}{4(\Delta^2 + \epsilon^2 + \kappa^2)},$$  
(S15)

$$\rho_{22}(\infty) = \rho_{33}(\infty) = \rho_{44}(\infty) = \frac{\Delta^2}{4(\Delta^2 + \epsilon^2 + \kappa^2)},$$  
(S16)

$$\rho_{14}(\infty) = \frac{\Delta (2\epsilon - i\kappa)}{4(\Delta^2 + \epsilon^2 + \kappa^2)},$$  
(S17)

where $\epsilon = h_f - \cos k$ and $\Delta = \sin k$. These solutions enable us to calculate the steady state two point correlation functions $C_{mn}(\infty)$, $F_{mn}(\infty)$ and thus the steady state von Neumann entropy $S(\ell, \infty)$.

**CALCULATION OF FERMIONIC TWO POINT CORRELATIONS**

In this section, we will present the calculation of fermionic two point correlation functions. Let us first write the Fourier transform of the JW fermion $c_n$ for the momenta $k > 0$

$$c_n = \frac{1}{\sqrt{L}} \sum_{k > 0} (e^{-ikn}c_k + e^{ikn}c_{-k}) .$$  
(S18)

The two point correlation functions in real space can be calculated from the correlation functions in the momentum space as

$$\langle c^\dagger_{m,n} c_{m,n} \rangle = \frac{1}{L} \sum_{k_1, k_2 > 0} \left( e^{i(k_1 m - k_2 n)} \langle c^\dagger_{k_1} c_{k_2} \rangle + e^{i(k_1 m + k_2 n)} \langle c^\dagger_{-k_1} c_{-k_2} \rangle + e^{-i(k_1 m + k_2 n)} \langle c_{-k_1} c_{-k_2} \rangle + e^{-i(k_1 m - k_2 n)} \langle c_{k_1} c_{k_2} \rangle \right),$$

$$\langle c^\dagger_{m,n} c^\dagger_{m,n} \rangle = \frac{1}{L} \sum_{k_1, k_2 > 0} \left( e^{i(k_1 m + k_2 n)} \langle c^\dagger_{k_1} c^\dagger_{k_2} \rangle + e^{i(k_1 m - k_2 n)} \langle c^\dagger_{-k_1} c^\dagger_{-k_2} \rangle + e^{-i(k_1 m + k_2 n)} \langle c^\dagger_{-k_1} c^\dagger_{-k_2} \rangle + e^{-i(k_1 m - k_2 n)} \langle c^\dagger_{k_1} c^\dagger_{k_2} \rangle \right),$$

where all the expectation values on the right hand side are taken over the momentum space density matrix $\rho(t) = \otimes_{k > 0} \rho_k(t)$ i.e. for a general operator $\hat{O}$:

$$\langle \hat{O}(t) \rangle = Tr \left[ \rho(t) \hat{O} \right] = \sum_{k > 0} \sum_{i, j = 1}^4 \rho_{ij,k}^k(t) \langle \phi_i^k | \hat{O} | \phi_j^k \rangle .$$  
(S19)

Using Eqs. S8-S11 one can calculate the following correlations in momentum space;

$$\langle c^\dagger_{k_1} c_{k_2} \rangle = \sum_{k > 0} \sum_{i, j = 1}^4 \rho_{ij,k}^k \delta_{k_1, k_2} \delta_{k_1, k} ,$$  
(S20)

$$\langle c^\dagger_{-k_1} c_{-k_2} \rangle = \sum_{k > 0} \left( \rho_{33,k}^k + \rho_{44,k}^k \right) \delta_{k_1, k_2} \delta_{k_1, k} ,$$  
(S21)

$$\langle c^\dagger_{k_1} c_{-k_2} \rangle = \sum_{k > 0} \left( \rho_{32,k}^k \right) \delta_{k_2,k} \delta_{k_1, k} ,$$  
(S22)

$$\langle c^\dagger_{-k_1} c_{k_2} \rangle = \sum_{k > 0} \left( \rho_{23,k}^k \right) \delta_{k_2,k} \delta_{k_1, k} ,$$  
(S23)

and

$$\langle c^\dagger_{k_1} c^\dagger_{k_2} \rangle = 0 ,$$  
(S24)

$$\langle c^\dagger_{-k_1} c^\dagger_{-k_2} \rangle = 0 ,$$  
(S25)

$$\langle c^\dagger_{k_1} c_{-k_2} \rangle = \sum_{k > 0} \left( \rho_{14,k}^k \right) \delta_{k_2,k} \delta_{k_1, k} ,$$  
(S26)

$$\langle c^\dagger_{-k_1} c_{k_2} \rangle = -\sum_{k > 0} \left( \rho_{14,k}^k \right) \delta_{k_2,k} \delta_{k_1, k} .$$  
(S27)
valid for the present choice of initial conditions (see Eq. S14). In the unitary case (matrix \( \rho_{mn} \)) where the composite system size \( \kappa \) for all instants of time. We have chosen two values of the coupling strength \( \kappa = 0.05 \) and 0.1, the sub-system size \( \ell = 30 \) and the composite system size \( L = 100 \).

Interestingly, for the bath chosen in the present work, the two quantity \( S'(\ell, t) \) and \( S'(L - \ell, t) \) for all instants of time. We have chosen two values of the coupling strength \( \kappa = 0.05 \) and 0.1, the sub-system size \( \ell = 30 \) and the composite system size \( L = 100 \).

that in the last equation the negative sign comes from fermionic anti-commutation relations i.e. using the fact \( e_{-k}^\dagger e_{-k}^\dagger |0, 0\rangle = -|k, -k\rangle \). Finally, using the above correlation functions in Eqs. S20, S27 and Eq. S19, the elements in the correlation matrix \( \mathcal{C} \) for the sub-system of size \( \ell \) can be found as

\[
C_{mn}(t) = \frac{1}{L} \sum_{k > 0} (\rho_{22}^k + \rho_{44}^k) e^{ik(m-n)} + \rho_{32}^k e^{ik(m+n)} + \rho_{23}^k e^{-ik(m+n)} + (\rho_{33}^k + \rho_{44}^k) e^{-ik(m-n)}
\]

\[
F_{mn}(t) = \frac{2}{L} \sum_{k > 0} \rho_{14}^k \cos(k(m-n)) + \frac{1}{L} \sum_{k > 0} \{ \rho_{22}^k e^{ik(m-n)} + \rho_{33}^k e^{-ik(m-n)} \}
\]

where \( m, n = 1, 2, 3, \ldots, \ell \) and the time dependence comes from the time dependent matrix elements \( \rho_{ij}^k(t) \) of the density matrix \( \rho_k(t) \). Note that in arriving at the final form of the Eq. S28 we have used the fact that \( \rho_{23}^k(t) = \rho_{32}^k(t) = 0 \) valid for the present choice of initial conditions (see Eq. S14). In the unitary case (\( \kappa = 0 \)), \( \rho_{22}^k(t) \) and \( \rho_{33}^k(t) \) vanish, rendering a simpler form of the \( C_{mn}(t) \).

In our numerical scheme, by solving Eqs. S13, we shall construct the density matrix given in the Eq. S14 and hence evaluate Eq. S28 and Eq. S28. Having the values of TPCs \( C_{mn}(t) \) and \( F_{mn}(t) \), we construct the correlation (or covariance) matrix (Eq. [15]) and proceed to calculate the von-Neumann entropy of a reduced density matrix of any sub-system [S7].

**NUMERICAL VERIFICATION OF S′(ℓ, t) = S′(L − ℓ, t) FOR ALL t**

Let us recall, the definition of the mutual information (MI)

\[
I(\ell : L - \ell) = S(\rho_\ell) + S(\rho_{L-\ell}) - S(\rho_L),
\]

where \( S(\rho_\ell), S(\rho_{L-\ell}) \) and \( S(\rho_L) \) are the von-Neumann entropy of the sub-system, rest of the system and the composite system, respectively. By splitting the quantity \( S(\rho_L) \) into two parts, we can rewrite the above equation in following way

\[
I(\ell : L - \ell) = S'(\ell) + S'(L - \ell)
\]

where

\[
S'(\ell) = S(\rho_\ell) - \frac{\ell}{L} S(\rho_L), \quad \text{and} \quad S'(L - \ell) = S(\rho_{L-\ell}) - \frac{L - \ell}{L} S(\rho_L).
\]

Interestingly, for the bath chosen in the present work, the two quantity \( S'(\ell) \) and \( S'(L - \ell) \) are exactly equal in all time as shown in the Fig. S1.
STEADY STATE MI FROM TWO-POINT CORRELATIONS:

In this section, we study the dynamics of two-point correlations (TPCs) \( C_{mn}(t) = \langle c_m^\dagger c_n \rangle \) further to understand the origin of finite non-zero value of the steady state MI for the dissipative case. Here, we calculate the equal-time two-point correlations between pairwise points equidistant from a fixed site (denoted by \( m \)):

\[
C_{m-n, m+n} = \langle c_{m-n}^\dagger(t)c_{m+n}(t) \rangle
\]  
(S33)

by varying \( n \) (\( \geq 1 \)). In the Fig. S2, we plot \( C_{m-n, m+n}(t) \) with the distance \( n \) from the mid point \( m \) for different instants of time. The two points \( m+n \) and \( m-n \) become correlated only when entangled quasi-particles originating from the mid point \( m \) of the segment reach them simultaneously. Since the mid point \( (m) \) is kept fixed, at all times \( t > 0 \), the quantity \( C_{m-n, m+n}(t) \) has contribution only from the originated quasi-particles from the same point \( m \). We ignored the other possibility that the two-point correlations might have contribution from the mid-point of the other segment \( (L-2n) \) due to the circular geometry of the chain; this is a valid approximation as \( L \gg 2n \). Thus, it is clear that in both the unitary and dissipative case, at a time \( t \), the TPCs can only have non-zero value up to a length \( (n-m) = v_g t = t \) as is shown in the Fig S2. We observe that the wave packet like correlation profile propagates through the system and it spreads behind the first peak i.e., in the region \( (m-n) \leq t \), due to the presence of the slow moving quasi-particles. Unlike the unitary case, as the correlation profile evolves in time, in the dissipative case, the correlation profile leaves a non-zero two point correlations in the system. This remaining two point correlations in the steady state is an exponentially decaying function with the intermediate distance \( (n-m) \) between them and a finite correlation length \( \xi_k = 2/\kappa \) emerges in the system as we have discussed in the main text.

We also observe that as system evolves, the amplitude of oscillations of TPCs decreases rapidly in the dissipative case unlike the unitary case. To capture this difference in a more compact way, we calculate the following quantity

\[
P_m(t) = \sum_{n=m}^{m+t} |\langle c_{m-n}^\dagger(t)c_{m+n}(t) \rangle|^2,
\]
(S34)

which is the area under the correlation profile \( |\langle c_{m-n}^\dagger(t)c_{m+n}(t) \rangle|^2 \) at a time \( t \). Physically the quantity \( P_m(t) \) is a measure of the total number of quasi-particles originated from the point \( m \). In the Fig. S3, we have shown the behaviour of \( P_m(t) \) with time for different values of \( \kappa \). For the unitary case (\( \kappa = 0 \)), it remains constant with time which indicates that total number of quasi-particles remains constant for all time. However, in the dissipative case (\( \kappa \neq 0 \)), \( P_m(t) \) shows an exponential decay to a constant non-zero steady state value. Therefore, in the presence of bath, the quasi-particles generated by the sudden quench of the field has a finite life time. The finite steady value may be interpreted as the consequence of perpetual coupling to the bath which may result in generation and destruction of quasi-particles as we shall discuss in the next section.
FIG. S3: (Color online) Here, we plot the quantity $P_m(t)$ with time $t$ for different values of $\kappa$. We have chosen the total system size $L = 1000$.

FIG. S4: This figure shows the time evolution of the two point correlation $C_{mn}(t)$ for different values of $\kappa$ under no quench situation for different values of $(m - n)$. This figure should be compared with Fig. [3] of the main text.

**ROLE OF BATH**

To comprehend the role played by the bath, we investigate TPCs, defined as $C_{mn}(t)$ with $m$ and $n$ fixed as a function of time in the *no-quench* situation. This implies that there is no quenching of the field and the Ising chain is initially prepared in the ground state of Hamiltonian $H_k(h)$ with field $h = 1$, which thereafter evolves with the same Hamiltonian. After the decay of the (small) initial correlation of the critical ground state, we once again observe that a finite correlation starts developing for $t > t^* = \ell/2$ as depicted in Fig. S4. This, in hindsight, suggests that the action of attaching the bath is similar to a global quench that results in the generation of quasi-particles throughout the system.
