A lower bound for the modulus of the Dirichlet eta function when $\Re(s) \geq \frac{1}{2}$ using 2-D principal component analysis

Yuri Heymann

Abstract The aim of the present manuscript is to derive an expression for the lower bound of the modulus of the Dirichlet eta function on vertical lines $\Re(s) = \alpha$. An approach based on a two-dimensional principal component analysis matching the dimensions of the complex plane, which is built on a parametric ellipsoidal shape, has been undertaken to achieve this result. This lower bound, which is expressed as $\forall s \in \mathbb{C}$ s.t. $\Re(s) \geq \frac{1}{2}$, $|\eta(s)| \geq 1 - \frac{2}{\pi^2}$ where $\eta$ is the Dirichlet eta function, has implications for the Riemann hypothesis as $|\eta(s)| > 0$ for any $s \in \mathbb{C}$ such that $\Re(s) \in [\frac{1}{2}, 1]$.

Keywords Riemann hypothesis, principal component analysis

1 Introduction

The Riemann zeta function is an extension of the zeta function introduced by Bernhard Riemann to study the distribution of prime numbers [7]. The location of the zeros of the Riemann zeta function in the critical strip $\Re(s) \in [0, 1]$, which are also called the non-trivial zeros, is key information in number theory. For example, the Riemann-von Mangoldt explicit formula, which is an asymptotic expansion of the prime-counting function, involves a sum over the non-trivial zeros of the Riemann zeta function [5]. The Riemann hypothesis, which states that all non-trivial zeros lie on the critical line $\Re(s) = 1/2$, has many implications including for the accuracy of the error estimate of the prime-number theorem and also for a number of conjectures such as the Lindelöf hypothesis [2], the study of L-functions [6], and the inverse spectral problem for fractal strings [3].

Let us introduce below the Riemann zeta function and its extension to the critical strip with the Dirichlet eta function. The Riemann zeta function is expressed as follows:

\[ \zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s}, \quad (1) \]

where \( s \) is a complex number and \( \Re(s) > 1 \).

The extension of the Riemann zeta function to the critical strip \( \Re(s) \in ]0, 1[ \) is accomplished by multiplying \( \zeta(s) \) by the factor \( \left(1 - \frac{2}{n^2}\right) \), leading to the Dirichlet eta function:

\[ \eta(s) = \left(1 - \frac{2}{2^s}\right) \zeta(s) = \sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n^s}, \quad (2) \]

where \( \Re(s) > 0 \).

The factor \( \left(1 - \frac{2}{n^2}\right) \) has an infinity of zeros on the line \( \Re(s) = 1 \) given by \( s_k = 1 + \frac{2k\pi i}{\ln 2} \) where \( k \in \mathbb{Z}^* \). As \( \left(1 - \frac{2}{n^2}\right) \) has no poles nor zeros in the critical strip \( \Re(s) \in ]0, 1[ \), the Dirichlet eta function can be used as a proxy of the Riemann zeta function for zero finding in the critical strip.

The Dirichlet eta function can also be expressed as follows:

\[ \eta(s) = \sum_{n=1}^{\infty} \frac{(-1)^{n+1} e^{-i\beta \ln(n)}}{n^s}, \quad (3) \]

where \( s = \alpha + i\beta \) is a complex number and \( \alpha \) and \( \beta \) are real numbers.

Eq. (3) follows from \( \frac{1}{n^s} = \frac{1}{n^\alpha \exp(i\beta \ln(n))} = \frac{1}{n^\alpha \cos(\beta \ln(n)) + i\sin(\beta \ln(n))} \). We then multiply both the numerator and denominator by \( \cos(\beta \ln(n)) - i\sin(\beta \ln(n)) \) and after a few simplifications we get \( \eta(s) = \sum_{n=1}^{\infty} \frac{(-1)^{n+1} \cos(\beta \ln(n)) - i\sin(\beta \ln(n))}{n^s} \).

In the remaining sections of the manuscript, whenever \( \Re(s) \leq 1 \), the Riemann zeta function refers to its analytic continuation.

2 Mathematicalcs

2.1 Elementary propositions

**Proposition 1** Given \( z_1 \) and \( z_2 \) two complex numbers, we have:

\[ |z_1 + z_2| \geq |z_1| - |z_2|, \quad (4) \]

where \( |z| \) denotes the modulus of the complex number \( z \).
Proof Let us write the complex numbers in polar form and set \( z_1 = r_1 e^{i\theta_1} \) and \( z_2 = r_2 e^{i\theta_2} \). We get:

\[
|z_1 + z_2| = |r_1 e^{i\theta_1} + r_2 e^{i\theta_2}|
\]

\[
= \sqrt{(r_1 \cos(\theta_1) + r_2 \cos(\theta_2))^2 + (r_1 \sin(\theta_1) + r_2 \sin(\theta_2))^2}
\]

\[
= \sqrt{r_1^2 + r_2^2 + 2r_1 r_2 \cos(\theta_1) \cos(\theta_2) + 2r_1 r_2 \sin(\theta_1) \sin(\theta_2)}
\]

\[
= \sqrt{r_1^2 + r_2^2 + 2r_1 r_2 \cos(\theta_1 + \theta_2)}.
\]  

(5)

The trigonometric identities \( 2 \cos(a) \cos(b) = \cos(a - b) + \cos(a + b) \) and \( 2 \sin(a) \sin(b) = \cos(a - b) - \cos(a + b) \) were used in (5), see [1] formulas 4.3.31 and 4.3.32, page 72. In addition, we have:

\[
|z_1| - |z_2| = |r_1 + r_2 e^{i\pi}|
\]

\[
= \sqrt{r_1^2 + r_2^2 - 2r_1 r_2}.
\]  

(6)

Eq. (4) follows from (5) and (6).

**Proposition 2** Let us apply a rotation by an angle \( \theta \in \mathbb{R} \) to a given complex number \( z_1 \) leading to the complex number \( z_2 = z_1 e^{i\theta} \) where \( u = \Re(z_2) \) and \( v = \Im(z_2) \). By choosing \( \theta \) to maximize the objective function \( u + v \), we get:

\[
|z_1| \leq \max(u + v),
\]  

(7)

where \( |z_1| \) is the modulus of the complex number \( z_1 \) and \( \max(u + v) \) is the maximum value of the objective function.

Proof Principal component analysis is a statistical method for reducing the dimensionality of the variable space by representing it with a few orthogonal variables that capture most of its variability. In our context, the rationale is to use a two-dimensional principal component analysis matching the dimensions of the complex plane on a parametric ellipsoidal shape. An ellipse centered at the origin of the coordinate system can be parametrized as follows: \( (x, y) = [a \cos(t), b \sin(t)] \) where \( a \) and \( b \) are respectively positive real numbers corresponding to the semi-major and semi-minor axis of the ellipse \( (a \geq b) \) and \( t \in \mathbb{R} \) is the angle between the vector \( (x, y) \) and the x-axis. Let us consider the rotation of the coordinate system by an angle \( t \). As the directions of the x-axis and y-axis are orthogonal, the objective function \( x + y \) is maximized with respect to \( t \) when the major axis is aligned with either of the rotated x or y-axis. When \( x + y \) is at its maximum value, we get \( x + y = a \) where \( a \) is the semi-major axis. The modulus of \( X = (x, y) \) is as follows:

\[
|X| = \sqrt{a^2 \cos^2(t) + b^2 \sin^2(t)} \leq a, \forall t \in \mathbb{R}.
\]
Proposition 3 Let us consider an alternating series $S^m$ constructed on a sequence $\{a_n\}$ where $n \in \mathbb{N}^*$ decreasing monotonically with respect to the index $n$ with $a_n > 0$ and $\lim_{n \to \infty} a_n = 0$:

$$S^m = \sum_{n=m}^{\infty} (-1)^{n+1} a_n,$$

where $a_n > 0$ and $m$ is an integer. Hence, we have the below upper bound inequality on the absolute value of the series:

$$\left| \sum_{n=m}^{\infty} (-1)^{n+1} a_n \right| \leq a_m.$$  \hfill (9)

Proof According to Leibniz’s rule, the series $S^m$ is convergent as $\{a_n\}$ decreases monotonically and $\lim_{n \to \infty} a_n = 0$. Let us define the series $L = \sum_{n=1}^{\infty} (-1)^{n+1} a_n$ and its partial sum $S_k = \sum_{n=1}^{k} (-1)^{n+1} a_n$. The odd partial sums decrease monotonically as $S_{2(m+1)+1} = S_{2m+1} - a_{2m+2} + a_{2m+3} \leq S_{2m+1}$. The even partial sums increase monotonically as $S_{2(m+1)} = S_{2m} + a_{2m+1} - a_{2m+2} \geq S_{2m}$. As the odd and even partial sums converge to the same value we have $S_{2m} \leq L \leq S_{2m+1}$ for any $m \in \mathbb{N}$.

When $m$ is odd:

$$S^m = a_m + \sum_{n=m+1}^{\infty} (-1)^n a_n = a_m + (L - S_m) \leq a_m.$$ \hfill (10)

When $m$ is even:

$$S^m = -a_m + \sum_{n=m+1}^{\infty} (-1)^n a_n = -a_m + (L - S_m) \geq -a_m.$$ \hfill (11)

Hence:

$$|S^m| \leq a_m.$$ \hfill (12)

2.2 The lower bound of the Dirichlet eta function

Let us set the complex number $s = \alpha + i \beta$ where $\alpha$ and $\beta$ are real numbers.

Note the zeros of the Dirichlet eta function are also the zeros of its complex conjugate. For convenience, let us use the conjugate of the Dirichlet eta function which is expressed as follows:

$$\tilde{\eta}(s) = \sum_{n=1}^{\infty} (-1)^{n+1} e^{i \beta \ln n} n^{-\alpha},$$ \hfill (13)

where $\Re(s) > 0$. By applying proposition 1 to (13), we get:
\[ |\hat{\eta}(s)| \geq 1 - \left| \sum_{n=2}^{\infty} (-1)^{n+1} \frac{e^{i \beta \ln n}}{n^\alpha} \right|. \tag{14} \]

For notation purposes \([z]\) denotes the modulus of the complex number \(z\). The square brackets are used to make it easier to read.

First, let us analyze the expression \[ \sum_{n=2}^{\infty} (-1)^{n+1} \frac{e^{i \beta \ln n}}{n^\alpha}. \] The components \(z_n = \frac{(-1)^{n+1}}{n^\alpha} e^{i \beta \ln n}\) can be represented as vectors where \(\beta \ln n + (n + 1)\pi\) is the angle between the real axis and the orientation of the vector and \(\frac{1}{n^\alpha}\) is the modulus of the vector. The idea is to apply a rotation by the angle \(\theta\) to all the component vectors simultaneously, resulting in a rotation of the vector of their sum. The resulting vector of their sum after applying the rotation \(\theta\) expressed as a complex number is \(v = \sum_{n=2}^{\infty} (-1)^{n+1} \frac{e^{i (\beta \ln n + \theta)}}{n^\alpha}\). Let us denote by \(v_0 = \sum_{n=2}^{\infty} (-1)^{n+1} \frac{e^{i (\beta \ln n)}}{n^\alpha}\) the resulting vector expressed as a complex number before rotation \(\theta\) is applied.

Let us introduce the objective function \(w\), defined as the sum of the real and imaginary parts of \(v\), i.e. \(w = v_x + v_y\) where \(v_x = \Re(v)\) and \(v_y = \Im(v)\). We get:

\[
\begin{align*}
  w &= \sum_{n=2}^{\infty} (-1)^{n+1} \frac{\cos(\beta \ln n + \theta) + \sin(\beta \ln n + \theta)}{n^\alpha} \\
  &= \sum_{n=2}^{\infty} (-1)^{n+1} \frac{\sqrt{2}}{n^\alpha} \cos \left( \beta \ln n + \theta - \frac{\pi}{4} \right). \tag{15}
\end{align*}
\]

The trigonometric identity \(\cos(x) + \sin(x) = \sqrt{2} \cos \left( x - \frac{\pi}{4} \right)\) which follows from \(\cos(a) \cos(b) + \sin(a) \sin(b) = \cos(a-b)\) with \(b = \frac{\pi}{4}\) is used in (15), see [1] formulas 4.3.31 and 4.3.32, page 72.

In the remaining portion of the manuscript, orthogonality between functions has to be defined. While orthogonality between two vectors is defined such that the scalar product between the vectors is equal to zero, for functions we usually define an inner product. Let us say we have two functions \(f\) and \(g\) defined on \(\mathbb{R} \rightarrow \mathbb{R}\) which are square integrable on \((a, b)\) where the inner product between \(f\) and \(g\) is given by:

\[
\langle f, g \rangle = \int_a^b f(x) g(x) dx. \tag{16}
\]

For sinusoidal functions such as \(\sin\) and \(\cos\), it is common to set \([a, b] = [0, 2\pi]\), which interval corresponds to one period. The condition for the functions \(f\)
and $g$ to be orthogonal is that the inner product as defined in (16) is equal to zero.

The objective function $w$ was constructed by adding together the real and imaginary parts of $v$. We note that the real and imaginary parts of $v$ are orthogonal due to the Euler formula. Hence, $\Re(v_0)$ is maximized in absolute value when $\Im(v_0) = 0$, which occurs when $\beta = 0$. As $w = \sqrt{2} \Re(v_0)$ when $\theta = \frac{\pi}{4}$, the objective function is maximized when $\theta = \frac{\pi}{4}$ and $\beta = 0$. We get:

$$\max |w| = \left| \sum_{n=2}^{\infty} (-1)^{n+1} \frac{\sqrt{2}}{n^{\alpha}} \right|, \quad (17)$$

which is the maximum value of the objective function.

By applying proposition 3 on (17), we get:

$$\max |w| \leq \frac{\sqrt{2}}{2^{\alpha}}. \quad (18)$$

By applying proposition 2 using (14) and (18), we get:

$$\forall s \in \mathbb{C} \text{ s.t. } \Re(s) > 0, \quad \left| \sum_{n=2}^{\infty} (-1)^{n} \frac{e^{i \beta \ln n}}{n^{\alpha}} \right| \leq \frac{\sqrt{2}}{2^{\alpha}}. \quad (19)$$

We note that the two principal components of the objective function $w$ can be expressed as $(w_1, w_2) = [a \cos(t), b \sin(t)]$ where $a$ and $b$ are positive real numbers describing an ellipse under the rotation by $t \in \mathbb{R}$. This is a consequence of the orthogonality between the principal components $w_1$ and $w_2$. If $w_1$ and $w_2$ were not orthogonal, there would be a phase shift $\varphi$ between the components, i.e. $w_1 = a \cos(t)$ and $w_2 = b \sin(t + \varphi)$. A further observation is that the m-th term of the Dirichlet eta function is orthogonal with the function comprised of the remaining terms of the series of index larger than $m$.

Let us suppose that most of the variance of $w$ comes from the first component:

$$w_1 = -\frac{\sqrt{2}}{2^{\alpha}} \cos \left( \beta \ln(2) + \theta - \frac{\pi}{4} \right), \quad (20)$$

where the second component is:

$$w_2 = \sum_{n=3}^{\infty} (-1)^{n+1} \frac{\sqrt{2}}{n^{\alpha}} \cos \left( \beta \ln n + \theta - \frac{\pi}{4} \right). \quad (21)$$

We now apply a rotation by an angle $\theta$ to maximize the objective function $w$. As we suppose that $w_1$ carries most of the variance of $w$ where $w_1$ and $w_2$ are orthogonal, at the maximum value of $w$, $w_1 = \frac{\sqrt{2}}{2^{\alpha}}$ and $w_2 = 0$. Hence,
we get $\max(|u|) \leq \sqrt{2}$. This is the value we obtained in (18), meaning that $w_1$ and $w_2$ are truly orthogonal. If we suppose that $w_2$ carries most of the variance of $w$, at the maximum value of $w$, $w_1 = 0$ and $w_2 = b > \sqrt{2}$, and in (22) below, the modulus of the Dirichlet eta function on the critical line is strictly larger than zero, which we know is not possible as there are some zeros on the critical line $\Re(s) = 1/2$.

When $\alpha \geq \frac{1}{2}$, (14) and (19) imply that:

$$|\eta(s)| \geq 1 - \frac{\sqrt{2}}{2^\alpha}.$$  \hspace{1cm} (22)

When $\alpha = 1/2$, $|\eta(s)| \geq 0$ means the Dirichlet eta function can have some zeros on the critical line $\Re(s) = 1/2$, which we know is true.

$\forall \alpha \in \left[\frac{1}{2}, 1]\right[, |\eta(s)| > 0$ means the Dirichlet eta function has no zeros in the strip $\Re(s) \in \left[\frac{1}{2}, 1]\right[$. As the Dirichlet eta function and the Riemann zeta function share the same zeros in the critical strip, the Riemann zeta function has no zeros in the strip $\Re(s) \in \left[\frac{1}{2}, 1]\right[$.

Let us recall Proposition 8 in [3]: Given a complex number and $\bar{s}$ its complex conjugate, if $s$ is a complex zero of the Riemann zeta function in the strip $\Re(s) \in [0, 1[$, then we have: $\zeta(s) = \zeta(1 - \bar{s})$.

By reflection with respect to the axis $\Re(s) = \frac{1}{2}$ (cf. proposition 8), there are no zeros in the strip $\Re(s) \in [0, \frac{1}{2}]$. It follows that all non-trivial zeros of the Riemann zeta function lie on the critical line $\Re(s) = 1/2$.

3 Conclusion

The lower bound of the modulus of the Dirichlet eta function of the present manuscript was derived with a two-dimensional principal component analysis built on a parametric ellipsoidal shape. We obtained that $\forall s \in \mathbb{C}$ s.t. $\Re(s) \geq \frac{1}{2}$, $|\eta(s)| \geq 1 - \frac{\sqrt{2}}{2^\alpha}$ on any given line $\Re(s) = \alpha \geq 1/2$ where $\eta$ is the Dirichlet eta function. As the Dirichlet eta function is a proxy of the Riemann zeta function for zero finding in the critical strip $\Re(s) \in [0, 1[$, it follows that all non-trivial zeros of the Riemann zeta function lie on the critical line $\Re(s) = 1/2$.

Further observations are made, such as the orthogonality between the m-th component of the Dirichlet eta function and the function comprised of the remaining elements of the series of index larger than $m$.
