Jianjun Wu, and Lingyang Song, *Fellow, IEEE*

Abstract

In the current unmanned aircraft systems (UASs) for sensing services, unmanned aerial vehicles (UAVs) transmit their sensory data to terrestrial mobile devices over the unlicensed spectrum. However, the interference from surrounding terminals is uncontrollable due to the opportunistic channel access. In this paper, we consider a cellular Internet of UAVs to guarantee the Quality-of-Service (QoS), where the sensory data can be transmitted to the mobile devices either by UAV-to-Device (U2D) communications over cellular networks, or directly through the base station (BS). Since UAVs' sensing and transmission may influence their trajectories, we study the trajectory design problem for UAVs in consideration of their sensing and transmission. This is a Markov decision problem (MDP) with a large state-action space, and thus, we utilize multi-agent deep reinforcement learning (DRL) to approximate the state-action space, and then propose a multi-UAV trajectory design algorithm to solve this problem. Simulation results show that our proposed algorithm can achieve a higher total utility than policy gradient algorithm and single-agent algorithm.

I. INTRODUCTION

With high mobility and low operational cost, unmanned aerial vehicle (UAV) is recognized as a powerful facility to provide sensing services [2], [3], which has found use in a wide range of sensing applications including traffic monitoring [4], industrial inspection [5], precision agriculture [6], and fire surveillance [7]. In the current unmanned aircraft systems (UASs) for sensing services, UAVs transmit their sensory data to terrestrial mobile devices¹ over the unlicensed spectrum [8]. However, due to the opportunistic channel access at the media access control (MAC) layer, the interference from surrounding terminals is uncontrollable, and the Quality-of-Service (QoS) for sensing services cannot be guaranteed. Therefore, a more reliable network is necessary.

As an effective solution, terrestrial cellular networks can be utilized to provide UAV sensing services with guaranteed QoS, which we refer to as the cellular Internet of UAVs [9], [10]. In the cellular Internet of UAVs, UAVs first transmit the sensory data to the BS, after which the BS sends the received data to mobile devices. When UAVs fly far from their sensing targets, they may suffer low sensing quality, while if UAVs are far from the BS, it is difficult to transmit their sensory data back to the BS. Therefore, to ensure the QoS, UAVs should jointly take sensing and transmission into consideration in the designing of their trajectories. However, when UAVs are close to their mobile devices, the data rate can be further improved if UAVs can directly transmit the sensory data to proximal mobile devices, namely the UAV-to-Device (U2D) communications, rather than transmit through cellular communications.

In this paper, we propose to enable U2D communications in the cellular Internet of UAVs. We consider a orthogonal frequency division multiple access (OFDMA) cellular Internet of UAVs², where the sensory data can be transmitted to the mobile devices in either the U2D or the cellular mode, and the U2D communications work as an overlay to the cellular network. Since the trajectories of UAVs may influence both sensing and transmission, it is important to design their trajectories. Moreover, UAVs' trajectories are also coupled with their sensing and transmission, and thus, it is challenging to solve the UAV trajectory design problem.

¹These mobile devices can be smartphones, laptops, and dedicated ground-based controllers. Besides, the sensory data are collected by the payloads of UAVs (e.g., cameras or thermometers), which can be further processed on the mobile devices.

²A typical application of this network is traffic monitoring. In the application, UAVs are required to record videos from their target roads to collect the road condition information. To realize real-time monitoring, the recorded videos should be transmitted to their corresponding terrestrial control stations simultaneously, which operates over the cellular spectrum to guarantee the QoS.

To tackle with this challenge, we first design a joint sensing and transmission protocol to enable the joint sensing and transmission for UAVs in different modes. This protocol can be analyzed by nested bi-level Markov chains [11], in which sensing and transmission processes are formulated as the state transitions in the Markov chains. Therefore, the UAV trajectory design problem can be regarded as a Markov decision problem (MDP) [12], [13]. Since the state-action space is very large, we then analyze this problem using multi-agent deep reinforcement learning (DRL) [14], [15], and propose a multi-UAV trajectory design algorithm based on deep Q-networks (DQNs) to obtain the optimal policies for UAVs.

In the literature, several works have investigated the cellular Internet of UAVs, which focus on the UAV-to-Network (U2N) [16] communications that UAVs could set up links with the BS, and UAV-to-UAV (U2U) [17] communications that multiple UAVs could communicate with each other directly. Specifically, authors in [16] investigated a cellular network consisting of one UAV for sensing services, and maximized the energy efficiency in the network by jointly optimizing the UAV's trajectories as well as transmission power. In [17], the authors jointly optimized subchannel allocation and flying speed for a cellular Internet of UAVs, where UAVs could build up U2N links with the BS as well as U2U links with other UAVs. Nevertheless, as an important practical scenario in the cellular Internet of UAVs, the direct links among UAVs and mobile devices, i.e., U2D communications, are lack of investigation in the current works³.

Besides, there also exist works focusing on the configuration of the UAV networks where UAVs are adopted as the moving BSs (UAV-BSs) [21]–[23]. Authors in [21] studied the positioning of UAV-BSs in the urban areas, and proposed an advanced channel model in consideration of the urban environment. In [22], the authors investigated the strategic deployment of UAV-BSs in the presence of a terrestrial network, in which the amount and the locations of UAV-BSs are investigated. A spatial network configuration scheme was proposed in [23] to exploit the mobility for an agile wireless network with UAV-BSs. Different from the above works, in our paper, UAVs are utilized to provide sensing services for terrestrial mobile devices, in which multiple UAVs' sensing and transmission should be jointly analyzed.

³Actually, there still exist several works on the transmission between UAVs and the mobile devices [18], [19]. However, in these works, UAVs are adopted as relays [18] or BSs [19], which are different from our work where UAVs serve as Internet-of-Things (IoT) devices to execute sensing tasks [20]. In our paper, UAV sensing and transmission are jointly investigated, which is more complicated than the UAV networks without the consideration of UAV sensing.

Furthermore, several works have studied the machine learning (ML) [24], [25] in UAV networks. In [24], the authors jointly investigated energy efficiency, wireless latency, and interference management for a UAV networks leveraging dynamic game, and then designed a deep reinforcement learning algorithm based on echo state network to achieve the subgame perfect Nash equilibrium. Authors in [25] jointly investigated cache management and resource allocation for a UAV network over both licensed and unlicensed bands, and then proposed a distributed ML algorithm based on the liquid state machine to solve this problem. Unlike the above works in which UAVs are utilized as flying infrastructures, e.g., base station or relay, which are different from our work where UAVs serve as aerial Internet-of-Things (IoT) devices to execute sensing tasks. In this system, UAV sensing and transmission should be jointly investigated, and thus, the ML methods in the current works cannot be adopted directly in our problem.

The main contributions of this paper can be summarized as follows:

- We propose overlaying U2D communications in the cellular Internet of UAVs to improve the QoS for UAV sensing services, and design a joint sensing and transmission protocol to enable U2D communications.
- We formulate the UAV trajectory design problem using multi-agent DRL, and then propose a DQN-based multi-UAV trajectory design algorithm to solve this problem.
- Simulation results show that our proposed algorithm can achieve a higher utility in the network than policy gradient algorithm and single-agent algorithm.

The rest of the paper is organized as follows. In Section II, we describe the model of the U2D communications overlaying cellular network. In Section III, we design a joint sensing and transmission protocol to coordinate multiple UAVs performing sensing tasks. Then, we analyze the protocol using nested bi-level Markov chains in Section IV. We investigate on the UAV trajectory design problem using multi-agent DRL, and propose a DQN-based multi-UAV trajectory design algorithm in Section V. In Section VI, we analyze the convergence and the complexity of our proposed algorithm, and present some key properties on mode selection and trajectory design for UAVs. Simulation results are presented in Section VII. Finally, Section VIII concludes the paper.

II. SYSTEM MODEL

In this section, we first describe the model for a U2D communications overlaying cellular network. Then, the sensing and the transmission models for UAVs are elaborated on, respectively.

TABLE I
LIST OF NOTATIONS

Notations	Definitions	Notations	Definitions
N	Number of UAVs	\mathcal{T}_i	Trajectory
K	Number of subchannels	Δ	Distance between two adjacent points
P^u	Transmit power of UAVs	v_{max}	Maximum flying speed of UAVs
P^b	Transmit power of the BS	\mathcal{U}_i	Utility
N_0	Noise power	r_i	Reward
f_c	Carrier frequency	π_i	Policy of agent
H_0	Height of the BS	$\mathcal{S} = \{s\}$	State space
$l_i(\mathbf{x}_1, \mathbf{x}_2)$	Distance between \mathbf{x}_1 and \mathbf{x}_2	$\mathcal{A}_i = \{a_i\}$	Action space
λ	UAV sensing factor	\mathcal{P}	State transition function
t_f	Duration of a frame	$\mathcal{R}_i(s, a_i)$	Reward function
$\mathcal{P}_{ss,i}$	Successful sensing probability	ρ	Discount factor
$\gamma_{a,i}, \gamma_{g,i}$	Signal-to-noise ratio in air-to-ground/ground-to-ground link	$p_{ts,i}^u, p_{ts,i}^c$	The probability that transmission succeeds in U2D/cellular mode within a cycle
$\mathcal{L}_{a,i}, \mathcal{L}_{g,i}$	Path loss in air-to-ground/ground-to-ground link	$\mathbb{P}_{ts,i}^u(t), \mathbb{P}_{ts,i}^c(t)$	The probability that transmission succeeds in U2D/cellular mode within the t -th frame
ζ_i, κ_i	Small-scale fading coefficient in air-to-ground/ground-to-ground link	$\mathbb{P}_{ts,i}^u\{t \mathbf{I}(t)\}, \mathbb{P}_{ts,i}^c\{t \mathbf{I}(t)\}$	The probability that transmission succeeds in U2D/cellular mode after the t -th frame, given the state indicator at the t -th frame $\mathbf{I}(t)$
R_i^u, R_i^c	Throughput in U2D/cellular mode	$Q_i(s, a_i)$	Q-value function
R_{th}	QoS requirement	Q_i, Θ_i	Q network and its weight
$\mathcal{P}_{ts,i}^u, \mathcal{P}_{ts,i}^c$	Successful transmission probability in U2D/cellular mode	\hat{Q}_i, Θ_i^-	Target network and its weight
T_s, T_t, T_c	Length of sensing part/transmission part/full cycle	\mathcal{M}, M	Replay memory and its size
$\mathbf{I}(t)$	Transmission state indicator	\mathcal{D}, D	Mini-batch and its size
$\mathbf{v}(t)$	Subchannel allocation vector	τ	Update frequency of target networks

For clarity, we summarize all the following notations and their definitions in Table I.

A. System Description

As illustrated in Fig. 1, we consider an OFDMA cellular network with single BS. The system consists of N UAVs performing sensing tasks, which denoted by $\mathcal{N} = \{1, 2, \dots, N\}$. Each UAV is required to sense its target, and then transmit the sensory data to the corresponding mobile device on the ground. There exist two modes to support the data transmissions from a UAV to its mobile device:

- **U2D Mode:** The UAV transmits the sensory data to its corresponding mobile device directly;
- **Cellular Mode:** The data transmissions include two phases. In the first phase, the UAV sends the sensory data to the BS. In the second phase, the BS transmits the received data

Fig. 1. System model for the U2D communications overlaying cellular network.

to the mobile device.

We define the time unit for the transmission as frame. To be specific, a UAV in the U2D mode takes a whole frame to send the sensory data to its mobile device directly. However, the two phases in the cellular mode are performed in a time division multiplexing (TDM) manner. The UAV in the cellular mode sends the sensory data to the BS in the first half frame, and then the BS transmits the received data to the mobile device in the other half frame.

The network owns K orthogonal subchannels, denoted by $\mathcal{K} = \{1, 2, \dots, K\}$, to support the OFDMA transmissions among UAVs and mobile devices. In order to avoid the mutual interference among UAVs, the BS will allocate orthogonal subchannels to different UAVs⁴. Besides, we assume that the available subchannels are not sufficient to support the data transmissions of all UAVs simultaneously, and thus, we have $K \leq N$.

In the system, the locations of the BS, UAVs, mobile devices and sensing targets are specified by 3D cartesian coordinates. Specifically, the location of the BS is denoted as $\mathbf{x}_0 = (0, 0, H_0)$ with H_0 being its height. The location of the i -th UAV is denoted as $\mathbf{x}_i = (x_i, y_i, h_i)$, and its corresponding mobile device locates at $\mathbf{x}_i^d = (x_i^d, y_i^d, 0)$. Moreover, the coordinates of the sensing target for i -th UAV can be given by $\mathbf{x}_i^t = (x_i^t, y_i^t, 0)$.

⁴For UAVs in the cellular mode, the two phases are operated over the same subchannel.

B. UAV Sensing

We utilize the probabilistic sensing model in [26], [27] to evaluate the sensing qualities of UAVs. Specifically, the successful sensing probability (SSP) for a UAV is an exponential function of the distance between the UAV and its target. When the i -th UAV senses its target for a frame, the SSP can be given as

$$\mathcal{P}_{ss,i} = e^{-\lambda t_f l_i}, \quad (1)$$

where λ is the parameter evaluating the sensing performance, t_f is the duration of a frame, and $l_i = \|\mathbf{x}_i - \mathbf{x}_i^t\|_2$ denotes the distance from the i -th UAV to its target.

Due to the limited computational capability, each UAV cannot figure out whether the sensing is successful or not by itself. Instead, mobile devices can judge whether the sensory data received from UAVs is valid or not. However, we can still evaluate the sensing qualities of UAVs by calculating their SSPs based on equation (1).

C. UAV Transmission

Since UAVs fly at high altitudes, the line-of-sight (LoS) components usually exist in the transmissions from UAVs to their mobile devices and the BS on the ground [28], [29]. Thus, the channel characteristic of the air-to-ground communications is different from that in traditional terrestrial communications. For UAVs in the U2D mode, the sensory data is sent on an air-to-ground channel. However, when UAVs select the cellular mode, the sensory data is transmitted on an air-to-ground channel in the first phase, and then on a terrestrial channel in the second phase. In what follows, we will analyze the transmissions in the U2D and the cellular modes, respectively.

1) *U2D Mode:* We adopt the air-to-ground channel model in [9] to evaluate the direct data transmissions from UAVs to their mobile devices. Then, the received signal-to-noise ratio (SNR) from the i -th UAV to its mobile devices can be expressed as

$$\gamma_{a,i}(\mathbf{x}_i^d, \mathbf{x}_i) = \frac{P^u \zeta_i}{N_0 \cdot 10^{\mathcal{L}_{a,i}/10}} \quad (2)$$

where P^u is the transmit power of UAVs, N_0 denotes the power of noise, $\mathcal{L}_{a,i}$ denotes the air-to-ground path loss, and ζ_i is the small-scale fading coefficient.

To calculate $\mathcal{L}_{a,i}$ and ζ_i , we consider both the LoS and the none LoS (NLoS) components. According to [9], the LoS probability for the i -th UAV can be calculated by

$$\mathcal{P}_{LoS,i} = \begin{cases} 1, & d_{2D,i} \leq d_c, \\ d_c/d_{2D,i} + (1 - d_c/d_{2D,i}) e^{-d_{2D,i}/p_0}, & d_{2D,i} > d_c, \end{cases} \quad (3)$$

where $d_c = \max\{294.05\lg(h_i) - 432.94, 18\}$, $d_{2D,i} = \sqrt{(x_i^d - x_i)^2 + (y_i^d - y_i)^2}$, and $p_0 = 233.98\lg(h_i) - 0.95$. Then, the NLoS probability for the i -th UAV is $\mathcal{P}_{NLoS,i} = 1 - \mathcal{P}_{LoS,i}$. Based on [9], we can calculate the LoS path loss and the NLoS path loss for the i -th UAV, denoted by $\mathcal{L}_{LoS,i}$ and $\mathcal{L}_{NLoS,i}$, respectively. In addition, the LoS small-scale fading coefficient for the i -th UAV $\zeta_{LoS,i}$ obeys Rice distribution, and the NLoS small-scale fading coefficient for the i -th UAV $\zeta_{NLoS,i}$ obeys Rayleigh distribution. More details on the calculations of the path loss and the small-scale fading coefficient are included in [9].

Based on the received SNR, we can calculate the throughput for the i -th UAV in the U2D mode as $R_i^u = \log_2(1 + \gamma_{a,i}(\mathbf{x}_i^d, \mathbf{x}_i))$. Considering the QoS of transmissions, we define that a transmission is *successful* when the throughput exceed a threshold, denoted by R_{th} . Then, the successful transmission probability (STP) for the i -th UAV in the U2D mode can be calculated by $\mathcal{P}_{ts,i}^u = \mathcal{P}_{a,i}(\mathbf{x}_i^d, \mathbf{x}_i, R_{th})$, where $\mathcal{P}_{a,i}(\cdot)$ is given by

$$\mathcal{P}_{a,i}(\mathbf{x}_i^d, \mathbf{x}_i, \beta) = \mathcal{P}_{LoS,i} (1 - F_{ri}(\chi_{LoS,i})) + \mathcal{P}_{NLoS,i} (1 - F_{ra}(\chi_{NLoS,i})), \quad (4)$$

in which $\chi_{LoS,i} = ((2^\beta - 1)N_0 \cdot 10^{0.1\mathcal{L}_{LoS,i}})/P^u$, and $\chi_{NLoS,i} = ((2^\beta - 1)N_0 \cdot 10^{0.1\mathcal{L}_{NLoS,i}})/P^u$. Here, $F_{ri}(x) = 1 - Q_1(\sqrt{2K_{ri}}, x\sqrt{2(K_{ri} + 1)})$ is the cumulative distribution function (CDF) of the Rice distribution with $\Omega = 1$ [30], $F_{ra}(x) = 1 - e^{-x^2/2}$ is the CDF of the Rayleigh distribution with unit variance, and $Q_1(x)$ is the Marcum Q-function of order 1 [31].

2) *Cellular Mode*: In the first phase, the transmissions from the i -th UAV to the BS can also be evaluated by the air-to-ground channel model. Therefore, we can express the received SNR at the BS as $\gamma_{a,i}(\mathbf{x}_0, \mathbf{x}_i)$, where $\gamma_{a,i}(\cdot)$ is given in (2). As for the second phase, we utilize the free space propagation path loss model with Rayleigh fading [32] to characterize the terrestrial transmissions. Thus, the received SNR at the mobile device can be expressed as

$$\gamma_{g,i}(\mathbf{x}_i^d, \mathbf{x}_0) = \frac{P^b \kappa_i}{N_0 \cdot 10^{\mathcal{L}_{g,i}/10}} \quad (5)$$

where P^b is the transmit power of the BS, $\mathcal{L}_{g,i}[\text{dB}] = 20\lg(d_i) + 20\lg(f_c) + 32.45$ is the path loss from the BS to the i -th mobile device, $d_i[\text{m}] = \|\mathbf{x}_i^d - \mathbf{x}_0\|_2$ denotes the distance between

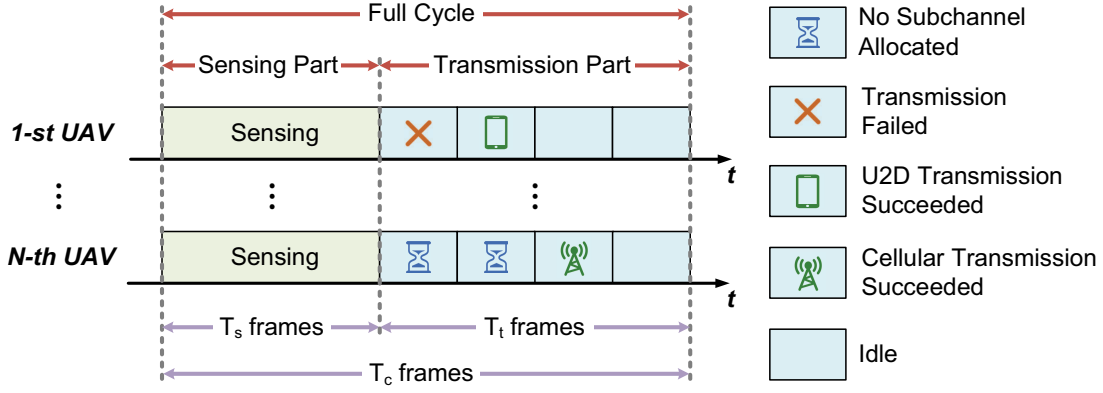

Fig. 2. The joint sensing and transmission protocol.

the BS and the mobile device, $f_c[\text{GHz}]$ is the carrier frequency, and κ_i denotes the small-scale fading following Rayleigh distribution with unit variance.

The throughput of i -th UAV in the cellular mode is given by $R_i^c = \frac{1}{2} \min \{R_{a,i}^c, R_{g,i}^c\}$, in which $R_{a,i}^c = \log_2(1 + \gamma_{a,i}(\mathbf{x}_0, \mathbf{x}_i))$ and $R_{g,i}^c = \log_2(1 + \gamma_{g,i}(\mathbf{x}_i^d, \mathbf{x}_0))$ denote throughput of the transmissions in the first and the second phases. To achieve successful transmissions, R_i^c should exceed the QoS requirement R_{th} , which is equivalent to that both $R_{a,i}^c$ and $R_{g,i}^c$ should be larger than $2R_{th}$. Therefore, we can calculate the STPs for the first and the second phases by $\mathcal{P}_{a,i}(\mathbf{x}_0, \mathbf{x}_i, 2R_{th})$ and $\mathcal{P}_{g,i}(\mathbf{x}_i^d, \mathbf{x}_0, 2R_{th})$, respectively. Here, $\mathcal{P}_{a,i}(\cdot)$ is given in (4), and $\mathcal{P}_{g,i}(\cdot)$ is expressed by

$$\mathcal{P}_{g,i}(\mathbf{x}_i^d, \mathbf{x}_0, \beta) = 1 - F_{ra}(\chi_{g,i}), \quad (6)$$

where $\chi_{g,i} = ((2^\beta - 1)N_0 \cdot 10^{0.1\mathcal{L}_{g,i}})/P^b$, and $F_{ra}(x) = 1 - e^{-x^2/2}$. Since the channel state of these two phases are independent with each other, we can calculate the STP for the i -th UAV in the cellular mode by $\mathcal{P}_{ts,i}^c = \mathcal{P}_{a,i}(\mathbf{x}_0, \mathbf{x}_i, 2R_{th})\mathcal{P}_{g,i}(\mathbf{x}_i^d, \mathbf{x}_0, 2R_{th})$.

III. JOINT SENSING AND TRANSMISSION PROTOCOL

In this section, we design a joint sensing and transmission protocol to coordinate multiple UAVs performing sensing tasks simultaneously. We first show the joint sensing and transmission cycles which consists of sensing parts as well as transmission parts. Then, the subchannel allocation mechanism is presented.

A. Joint Sensing and Transmission Cycle

We assume that the UAVs perform sensing tasks in a synchronized iterative manner, which is characterized by *cycles*. To be specific, in each cycle, UAVs first sense their sensing targets and

then transmit the sensory data to their mobile devices. In Fig. 2, we illustrates a cycle of the joint sensing and transmission protocol, which contains T_c frames. Each cycle is divided into the sensing part with T_s frames and the transmission part with T_t frames. In the sensing part, each UAV should sense its target and collect the sensory data continuously for T_s frames to ensure the sensing quality.

In the transmission part, each UAV attempts to send the sensory data to its mobile device if the BS allocates a subchannel to it. Specifically, at the beginning of each frame, all UAVs should report their locations to the BS, and then the BS preforms the subchannel allocation based on the received information. If a UAV is not allocated to a subchannel, the sensory data cannot be transmitted in this frame. On the other hand, the UAV with allocated subchannel attempts to transmit the sensory data to the mobile device in the transmission mode which satisfies the QoS requirement. When both the U2D and the cellular modes can support successful transmissions, the UAV will select the mode with a higher throughput. However, when neither one of these two modes can satisfy the QoS requirement, the transmission will fail in this frame.

To be specific, there are five possible situations for each UAV in the transmission part:

- **No Subchannel Allocated:** No subchannel is allocated to the UAV, and thus, the UAV cannot transmit data in this frame. It will wait for the BS to assign a subchannel to it in the following frames;
- **Transmission Failed:** A subchannel is allocated to the UAV. However, the transmission is unsuccessful due to the QoS requirement. Thus, the UAV will attempt to transmit the sensory data again in the following frames;
- **U2D Transmission Succeeded:** A subchannel is allocated to the UAV, and the UAV successfully transmits the sensory data in the U2D mode;
- **Cellular Transmission Succeeded:** A subchannel is allocated to the UAV, and the UAV successfully transmits the sensory data in the cellular mode;
- **Idle:** After a successful transmission, the UAV will keep idle until the next cycle begins.

Finally, at the end of the transmission part, the BS broadcasts to inform UAVs of the locations of all the UAVs. By this means, each UAV can obtain the locations of other UAVs, and then decide its trajectory in the next cycle. In practice, the information exchange between UAVs and the BS can be operated through the control channels [8], which is separated from the sensory

data transmission over the data channels⁵.

B. Subchannel Allocation Mechanism

In the transmission part, the available subchannels may not be sufficient to support all the UAVs for data transmission simultaneously. Therefore, the BS will allocate the subchannels to UAVs according to the following mechanism.

In each frame, the BS schedules K subchannels to maximize the sum of STPs of all UAVs. Here, the STP for the i -th UAV is defined by $\mathcal{P}_{ts,i} = 1 - (1 - \mathcal{P}_{ts,i}^u)(1 - \mathcal{P}_{ts,i}^c)$, i.e., the probability that the sensory data can be transmitted successfully in either the U2D or the cellular mode. Besides, when a UAV has already successfully transmitted its sensory data before a frame, the BS is without the need of allocating subchannel to this UAV in the current and future frames any more. Since different UAVs are required to utilize orthogonal subchannels, it is equivalent to that the BS allocates K subchannels to the UAVs with the highest K STPs which have not successfully transmitted their data.

More explicitly, we denote the transmission state indicators of the UAVs in the t -th frame of the c -th cycle as $\mathbf{I}^{(c)}(t) = (I_1^{(c)}(t), I_2^{(c)}(t), \dots, I_N^{(c)}(t))$, in which the value of $I_i^{(c)}(t)$ is given by

$$I_i^{(c)}(t) = \begin{cases} 0, & \text{if the transmission has failed for the } i\text{-th UAV,} \\ 1, & \text{if the U2D transmission has succeeded for the } i\text{-th UAV,} \\ 2, & \text{if the cellular transmission has succeeded for the } i\text{-th UAV.} \end{cases} \quad (7)$$

Based on the above notations, we introduce the subchannel allocation vector in the t -th frame of the c -th cycle as $\mathbf{v}^{(c)}(t) = (v_1^{(c)}(t), v_2^{(c)}(t), \dots, v_N^{(c)}(t))$, where

$$v_i^{(c)}(t) = \begin{cases} 1, & \mathcal{P}_{ts,i}^{(c)}(t) [1 - \text{sgn}(I_i^{(c)}(t))] \geq \left\{ \mathbf{P}_{ts}^{(c)}(t) [1 - \text{sgn}(\mathbf{I}^{(c)}(t))] \right\}_K, \\ 0, & \text{otherwise.} \end{cases} \quad (8)$$

Here, $\text{sgn}(\cdot)$ is the sign function, $\mathcal{P}_{ts,i}^{(c)}(t)$ denotes the STP for the i -th UAV in the t -th frame of the c -th cycle, and $\left\{ \mathbf{P}_{ts}^{(c)}(t) [1 - \text{sgn}(\mathbf{I}^{(c)}(t))] \right\}_K$ denotes the K -th largest STPs among the UAVs which have not succeeded in sending the sensory data before the t -th frame.

⁵The overhead for information exchange is trivial, which can be covered by the control channels owned by the system. We assume that a UAV needs ω messages to describe its location. Thus, the overhead for information exchange is $N\omega$ messages, in which N is the number of UAVs.

Fig. 3. The outer Markov chain.

Under the above subchannel allocation mechanism, each of the UAVs not succeeding in data transmission has the incentive to compete with others by designing its trajectory and selecting its transmission mode. It is worth mentioning that the subchannel allocation result are determined by the *ranking* of all UAVs' STPs, rather than the *absolute values* of them. Therefore, each UAV should take other UAVs' locations into consideration when it optimizes its trajectory and transmission mode.

IV. JOINT SENSING AND TRANSMISSION ANALYSIS

In this section, we analyze the joint sensing and transmission protocol by specifying the state transitions of UAVs in nested bi-level Markov chains. Specifically, the outer and inner Markov chains depict the state transitions in the sensing and transmission processes, respectively. For simplicity, we omit the superscript cycle index c in the following notations.

A. Outer Markov Chain for UAV Sensing

The sensing part in the joint sensing and transmission protocol can be evaluated by an outer Markov chain, where state transitions take place in each cycle. As shown in Fig. 3, a UAV has two sensing states in each cycle, i.e., state H_f denoting that the sensing fails, and state H_s denoting that the sensing succeeds. Define the SSP of the i -th UAV in a cycle as $p_{ss,i}$. Then, the UAV's state transits to H_s with probability $p_{ss,i}$, and transits to H_f with probability $1 - p_{ss,i}$.

Since the location of a UAV changes slightly during each frame, we assume that the location of each UAV is fixed within each frame. Then, we can express the location of the i -th UAV in a cycle as $\mathbf{x}_i(t) = (x_i(t), y_i(t), h_i(t))$, $t \in [1, T_c]$. Likewise, the distance between the i -th UAV and its target in a cycle can be expressed as $l_i(t) = \|\mathbf{x}_i(t) - \mathbf{x}_i^t\|_2$, $t \in [1, T_c]$. Moreover, we

assume that each UAV moves with a uniform speed and direction in each cycle. Based on above assumptions, the location of the i -th UAV at the t -th frame in a cycle can be given by

$$\mathbf{x}_i(t) = \mathbf{x}'_i(T_c) + \frac{t}{T_c}[\mathbf{x}_i(T_c) - \mathbf{x}'_i(T_c)], \quad t \in [1, T_c]. \quad (9)$$

where $\mathbf{x}'_i(T_c)$ denotes the location of the i -th UAV at the last frame in the last cycle. According to the protocol in Section III, a UAV is required to continuously sense its target for T_s frames within a cycle. Thus, we can calculate the SSP of the i -th UAV in a cycle, i.e., $p_{ss,i}$, by

$$p_{ss,i} = \prod_{t=1}^{T_s} \mathcal{P}_{ss,i}(t) = \prod_{t=1}^{T_s} e^{-\lambda_{tf} l_i(t)}. \quad (10)$$

After sensing the target, a UAV may have three possible situations at the end of the transmission part: 1) The transmission has failed; 2) The U2D transmission has succeeded; 3) The cellular transmission has succeeded. The probabilities of these three situations for the i -th UAV are denoted by $p_{tf,i}$, $p_{ts,i}^u$, and $p_{ts,i}^c$, respectively. The values of these probabilities can be calculated by the inner Markov chain, which will be introduced in the next subsection.

We define the data transmission of a UAV is *valid* when the UAV successfully senses its target as well as transmits the sensory data to its mobile device. Then, we can express the valid transmission probability (VTP) for the i -th UAV in the U2D and the cellular modes by $p_{ss,i}p_{ts,i}^u$ and $p_{ss,i}p_{ts,i}^c$, respectively. Besides, the probability that the i -th UAV successfully senses its target but fails to transmit the sensory data to its mobile device can be given by $p_{ss,i}p_{tf,i}$. To characterize whether a transmission is valid or not, we define the output of each state transition, which is denoted on the right side of each transition probability in Fig. 3. The output is one when the data transmission is valid, otherwise, the output is zero.

B. Inner Markov Chain for UAV Transmission

In this part, we introduce an inner Markov chain to formulate the transmission part in the joint sensing and transmission protocol. Since the general state transmission diagram is complicated, we illustrate the inner Markov chain via an example with the number of subchannels $K = 1$, the number of UAVs $N = 3$, and the number of frames in each transmission part $T_t = 2$. We take the 1-st UAV as an example and illustrate its state transition diagram in Fig. 4.

As shown in Fig. 4, in the first frame of the transmission part, i.e., $t = T_s + 1$, none of UAVs has transmitted its sensory data, and thus, we have $\mathbf{I}(T_s + 1) = \{0, 0, 0\}$. During this frame, all UAVs should compete with each other for subchannels. In the next frame, if the 1-st

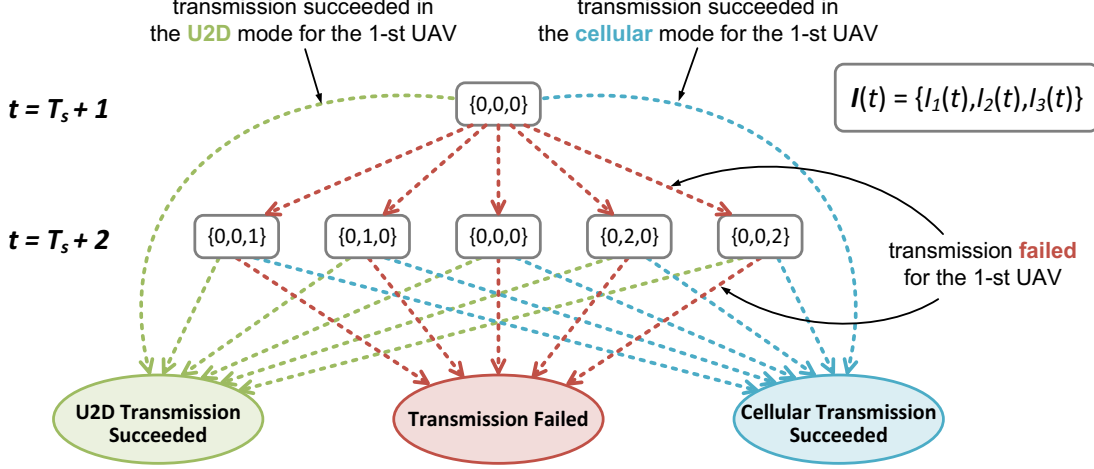

Fig. 4. The inner Markov chain of the 1-st UAV with $K = 1$, $N = 3$ and $T_t = 2$.

UAV successfully transmits its sensory data in the U2D or the cellular mode, the state will transit to *U2D Transmission Succeeded* or *Cellular Transmission Succeeded*, with probability $\mathbb{P}_{ts,1}^u(T_s + 1)v_1(T_s + 1)$ or $\mathbb{P}_{ts,1}^c(T_s + 1)v_1(T_s + 1)$, accordingly. Here, $v_1(\cdot)$ is the subchannel allocation vector for the 1-st UAV, which is given in (8). Besides, $\mathbb{P}_{ts,1}^u(\cdot)$ and $\mathbb{P}_{ts,1}^c(\cdot)$ can be calculated by the following proposition.

Proposition 1. When the i -th UAV is allocated to a subchannel, it will successfully transmit its sensory data in the U2D or the cellular mode with probability $\mathbb{P}_{ts,i}^u$ or $\mathbb{P}_{ts,i}^c$, in which

$$\mathbb{P}_{ts,i}^u = \mathcal{P}_{ts,i}^u (1 - \mathcal{P}_{ts,i}^c) + \mathcal{P}_{ts,i}^u \mathcal{P}_{ts,i}^c \cdot \mathcal{P}\{R_i^u \geq R_i^c\}, \quad (11)$$

$$\mathbb{P}_{ts,i}^c = (1 - \mathcal{P}_{ts,i}^u) \mathcal{P}_{ts,i}^c + \mathcal{P}_{ts,i}^u \mathcal{P}_{ts,i}^c \cdot \mathcal{P}\{R_i^u < R_i^c\}, \quad (12)$$

where $\mathcal{P}\{R_i^u \geq R_i^c\} = 1 - \int_{-\infty}^{\infty} \Psi_i(y) f_{R_i^u}(y) dy$, $\mathcal{P}\{R_i^u < R_i^c\} = \int_{-\infty}^{\infty} \Psi_i(y) f_{R_i^u}(y) dy$, with $\Psi_i(y) = \mathcal{P}_{a,i}(\mathbf{x}_0, \mathbf{x}_i, 2y) \mathcal{P}_{g,i}(\mathbf{x}_i^d, \mathbf{x}_0, 2y)$, $f_{R_i^u}(y) = \mathcal{P}_{LoS,i} \cdot f_{R_{LoS,i}^u}(y) + \mathcal{P}_{NLoS,i} \cdot f_{R_{NLoS,i}^u}(y)$, $f_{R_{LoS,i}^u}(y) = \frac{2 \ln 2 (K_{ri} + 1) (2^y - 1) 2^y}{\xi_{LoS,i}^2} \exp \left\{ -\frac{(K_{ri} + 1) (2^y - 1)^2 + K_{ri} \xi_{LoS,i}^2}{\xi_{LoS,i}^2} \right\} \cdot I_0 \left(\frac{2 \sqrt{(K_{ri} + 1) K_{ri} (2^y - 1)}}{\xi_{LoS,i}} \right)$, $f_{R_{NLoS,i}^u}(y) = \frac{\ln 2 (2^y - 1) 2^y}{\xi_{NLoS,i}^2} \exp \left\{ -\frac{(2^y - 1)^2}{2 \xi_{NLoS,i}^2} \right\}$, $\xi_{LoS,i} = \frac{P^u}{N_0 \cdot 10^{\mathcal{L}_{LoS,i}/10}}$, and $\xi_{NLoS,i} = \frac{P^u}{N_0 \cdot 10^{\mathcal{L}_{NLoS,i}/10}}$.

Proof. See Appendix A. □

However, if the 1-st UAV fails to transmit the sensory data to its mobile device in the first frame, $\mathbf{I}(t)$ will transit into other states in the second frame, which is determined by the transmission states of other UAVs. For instance, when the U2D transmission for the 2-nd UAV succeeds in the first frame, we have $\mathbf{I}(T_s + 2) = \{0, 1, 0\}$. As the 2-nd UAV has succeeded in data transmission, it will quit the competition for subchannels in the following frames. Consequently,

TABLE II
TRANSITION PROBABILITY OF THE i -TH UAV IN THE t -TH FRAME

$\mathcal{P}\{I_i(t+1) I_i(t)\}$ $I_i(t) \backslash I_i(t+1)$	0	1	2
0	$\mathbb{P}_{tf,i}$	$\mathbb{P}_{ts,i}^u$	$\mathbb{P}_{ts,i}^c$
1	0	1	0
2	0	0	1

the 1-st UAV will only face one competitor, namely the 3-rd UAV, in the second frame. In other words, the 1-st UAV will have a larger probability to win a subchannel than before. Finally, in the last frame of the cycle, namely $t = T_c$, the transmission state of the 1-st UAV will transit into *Transmission Failed* if it does not transmit the sensory data successfully.

Based on the above assumptions, we can obtain the values of $p_{tf,i}$, $p_{ts,i}^u$ and $p_{ts,i}^c$ in the outer Markov chain by calculating the absorbing probabilities of the states *Transmission Failed*, *U2D Transmission Succeeded*, and *Cellular Transmission Succeeded* in the inner Markov chain, respectively. Since the absorbing probabilities are difficult to be derived, we adopt the recursive algorithm in [33] to obtain the numerical results.

Specifically, given the state at the t -th frame $\mathbf{I}(t)$, $t \in [T_s + 1, T_c]$, we define the probabilities that the i -th UAV successfully transmits its sensory data *after* the t -th frame as $\mathbb{P}_{ts,i}^u\{t|\mathbf{I}(t)\}$ and $\mathbb{P}_{ts,i}^c\{t|\mathbf{I}(t)\}$, respectively. For these two probabilities, the following two equations hold:

$$\mathbb{P}_{ts,i}^u\{t|\mathbf{I}(t)\} = \mathbb{P}_{ts,i}^u(t)v_i(t) + \sum_{\mathbf{I}(t+1), I_i(t+1)=0} \mathcal{P}\{\mathbf{I}(t+1)|\mathbf{I}(t)\}\mathbb{P}_{ts,i}^u\{t+1|\mathbf{I}(t+1)\}, \quad (13)$$

$$\mathbb{P}_{ts,i}^c\{t|\mathbf{I}(t)\} = \mathbb{P}_{ts,i}^c(t)v_i(t) + \sum_{\mathbf{I}(t+1), I_i(t+1)=0} \mathcal{P}\{\mathbf{I}(t+1)|\mathbf{I}(t)\}\mathbb{P}_{ts,i}^c\{t+1|\mathbf{I}(t+1)\}. \quad (14)$$

Here, the first terms in the righthand of equations (13) and (14) indicate the probabilities that the data transmission of the i -th UAV succeeds within the t -th frame in the U2D and the cellular modes, respectively. Besides, the second terms in the righthand of equations (13) and (14) accordingly imply the probabilities that the data transmission of the i -th UAV fails within the t -th frame and succeeds after the $(t+1)$ -th frame in the U2D and the cellular modes, in which $\mathcal{P}\{\mathbf{I}(t+1)|\mathbf{I}(t)\}$ denotes the state transition probabilities from state $\mathbf{I}(t)$ to state $\mathbf{I}(t+1)$.

Since the STPs of different UAVs are independent with each other, we have $\mathcal{P}\{\mathbf{I}(t+1)|\mathbf{I}(t)\} = \prod_{i=1}^N \mathcal{P}\{I_i(t+1)|I_i(t)\}$, where the values of $\mathcal{P}\{I_i(t+1)|I_i(t)\}$ are shown in Table II. In the first row of Table II, $\mathbb{P}_{ts,i}^u$ and $\mathbb{P}_{ts,i}^c$ are given in Proposition 1, and $\mathbb{P}_{tf,i} = (1 - \mathcal{P}_{ts,i}^u)(1 - \mathcal{P}_{ts,i}^c)$

Fig. 5. Lattice model of available locations that a UAV can select in the next cycle.

denotes the probability that the data transmission of the i -th UAV fails. Besides, the second and third rows of Table II indicate that the transmission state of a UAV will keep unchanged when it has already successfully transmitted the sensory data. According to equations (13) and (14), we can solve $\mathbb{P}_{ts,i}^u\{t|\mathbf{I}(t)\}$ and $\mathbb{P}_{ts,i}^c\{t|\mathbf{I}(t)\}$ via the recursive algorithm in [33], respectively. Thus, the probabilities for the i -th UAV to successfully transmit its sensory data in the U2D and the cellular modes within the transmission part can be given by $p_{ts,i}^u = \mathbb{P}_{ts,i}^u\{T_s + 1|\mathbf{I}(T_s + 1)\}$ and $p_{ts,i}^c = \mathbb{P}_{ts,i}^c\{T_s + 1|\mathbf{I}(T_s + 1)\}$, respectively. Then, the probability that the i -th UAV fails to transmit the sensory data within the transmission part is calculated by $p_{tf,i} = 1 - p_{ts,i}^u - p_{ts,i}^c$.

V. TRAJECTORY DESIGN USING MULTI-AGENT DEEP REINFORCEMENT LEARNING

In the system, UAVs aim to achieve valid data transmissions, i.e., both the sensing and the transmission processes are successful. Since UAVs' sensing and transmission processes have already been formulated as the state transitions in the nested bi-level Markov chains, UAVs can design their trajectories in consideration of their sensing and transmission states at the same time. In this section, we investigate on the trajectory design problem for UAVs using multi-agent DRL, and propose a DQN-based multi-UAV trajectory design algorithm to solve this problem. Before that, we first discrete the space to design the trajectories for UAVs.

A. Space Discretization

We introduce a lattice model to describe the movements of UAVs in Fig. 5. We assume that the space is divided into a finite set of discrete spatial points \mathcal{S} , which can be illustrated as a square lattice pattern. Thus, the trajectory of the i -th UAV starting from the c -th cycle can be represented as the sequence of locations $\mathcal{T}_i^{(c)} = \{\mathbf{x}_i^{(c)}, \mathbf{x}_i^{(c+1)}, \dots\}$, in which $\mathbf{x}_i^{(c)}$ denote the location of the i -th UAV at the beginning of the c -th cycle, with $\mathbf{x}_i^{(c)} \in \mathcal{S}$, and $c \in [1, \infty)$.

As shown in Fig. 5, the set of available locations that a UAV can select in the c -th cycle is a lattice with the center of $\mathbf{x}_i^{(c)}$, consisting of at most 27 available locations. Besides, we define distance between any two adjacent available locations as Δ , and thus, the maximum distance that a UAV can move in a cycle is $\sqrt{3}\Delta$. The value of Δ is determined by the maximum flying speed of a UAV, denoted by v_{max} . Specifically, we have $\Delta = T_c t_f v_{max} / \sqrt{3}$, in which T_c is the number of frames within a cycle, and t_f is the duration of a frame. Further, we introduce the available action set $\mathcal{A}(\mathbf{x})$ to denote the set of all vectors from the current location \mathbf{x} to all available locations in the next cycle.

B. Problem Formulation

In this paper, we define the *utility* of a UAV as the total number of valid data transmissions. Each UAV aims to maximize its utility by designing its trajectory. Besides, considering the time-liness requirements of sensing tasks, we introduce the discounting valuation on the successfully transmitted valid data. To be specific, for UAVs in the c -th cycle, the successfully transmitted valid data in the c' -th cycle ($c' > c$) is worth only $\rho^{c'-c}$ of that in the current cycle. Here, ρ is the discount factor and $\rho \in [0, 1]$. Therefore, the utility of the i -th UAV at the c -th cycle is defined as the total discounted rewards in the future, which is given by $\mathcal{U}_i^{(c)} = \sum_{n=0}^{\infty} \rho^n r_i^{(c+n)}$, in which $r_i^{(c)}$ denotes the reward of the i -th UAV in the c -th cycle. We define the reward of the i -th UAV in the c -th cycle as its sum VTP in both of the transmission modes within this cycle, i.e., $r_i^{(c)} = p_{ss,i} p_{ts,i}^u + p_{ss,i} p_{ts,i}^c$, which is consistent with the output of the outer Markov chain in Fig. 3. Based on the above assumptions, the trajectory design problem in the UAV system can be formulated by

$$\begin{aligned} \max_{\mathcal{T}_i^{(c)}} \quad & \mathcal{U}_i^{(c)} \\ \text{s.t.} \quad & \mathbf{x}_i^{(c'+1)} - \mathbf{x}_i^{(c')} \in \mathcal{A}(\mathbf{x}_i^{(c')}), c' \in [c, \infty). \end{aligned} \tag{15}$$

C. Reinforcement Learning Formulation

Since the rewards of UAVs in the future cycles are determined by the trajectories of all UAVs, the trajectory design problem (15) is difficult to solve. Fortunately, this problem can be regarded as a MDP [13], and thus, we can solve this problem using reinforcement learning (RL). Under the RL framework, each UAV is regarded as an *agent*. The states and the actions of each agent are defined as the locations and the movements of the corresponding UAV, respectively. Based on [14], we can characterize UAVs by a tuple $\langle \mathcal{S}, \mathcal{A}_1, \dots, \mathcal{A}_N, \mathcal{P}, \mathcal{R}_1, \dots, \mathcal{R}_N, \rho \rangle$, where:

- \mathcal{S} denotes the state space including all possible states of UAVs at the beginning of each cycle. The state of the i -th UAV, denoted by s_i , is described by its location, i.e., $= \mathbf{x}_i$;
- $\mathcal{A}_i, i \in \mathcal{N}$ denotes the action space consisting of all available actions of the i -th UAV at the each cycle. The action of the i -th UAV, denoted by \mathbf{a}_i , is defined by its movement at a given state⁶. At state s_i , the available action set of the i -th UAV is expressed as $\mathcal{A}_i = \mathcal{A}(s_i)$;
- $\mathcal{P} : \mathcal{S}^N \times \prod_{i=1}^N \mathcal{A}_i \rightarrow \Pi(\mathcal{S})$ is the state transition function, which maps the state spaces and the action spaces of all UAVs in the current cycle to their state spaces in the next cycle. Here, $\Pi(\mathcal{S})$ is the probability distribution over the state space \mathcal{S} ;
- $\mathcal{R}_i : \mathcal{S}^N \times \mathcal{A}_i \rightarrow \Pi(0, 1), i \in \mathcal{N}$ is the reward function of the i -th UAV, which maps the state spaces and the action spaces of the UAV in the current cycle to its reward. As the reward of each UAV in a cycle equals to its sum VTP in both of the transmission modes, the reward of the i -th UAV taking action \mathbf{a}_i at the state s is given by $\mathcal{R}_i(s, \mathbf{a}_i) = p_{ss,i}p_{ts,i}^u + p_{ss,i}p_{ts,i}^c$;
- $\rho \in [0, 1]$ represents the discount factor, which evaluates the successfully transmitted valid data of UAVs in the future.

At the beginning of each cycle, the i -th UAV observes the state $s = \{s_i\}$, i.e., the states of all UAVs⁷, from state space \mathcal{S}^N . Then, it takes an action \mathbf{a}_i from action space \mathcal{A}_i based on its *policy*, denoted by π_i . Here, the policy is a mapping from the state space to the action space, which can be expressed by $\mathbf{a}_i = \pi_i(s)$. As action \mathbf{a}_i taken by the i -th UAV, it receives a reward $r_i = \mathcal{R}_i(s, \mathbf{a}_i)$ and observes a new state s' , namely the states of all UAVs in the next cycle. Therefore, the trajectory design problem (15) can be transformed into maximizing the total discounted rewards of all UAVs in the system by optimizing their policies.

D. Algorithm Design

In this part, we propose a DQN-based multi-UAV trajectory design algorithm to optimize the policies for all UAVs in the system. Specifically, our proposed algorithm adopts Q-learning for UAVs to learn how to take actions optimally at different states, in which the rewards of state-action pairs are estimated by DQNs.

⁶According to the lattice model shown in Fig. 5, a UAV may have at most 27 available movements at a state, and thus, the cardinality of the action space is up to 27.

⁷Based on the protocol in Section III, the BS is required to inform each UAV of the locations of all UAVs at the end of the last cycle. Thus, all UAVs' locations can be observed by each UAV at the beginning of the current cycle.

Q-learning is a model-free RL algorithm which can effectively optimize the policies for agents [34], [35]. In our system, the Q-value of the i -th UAV, denoted by $Q_i(\mathbf{s}, \mathbf{a}_i)$, is defined as the accumulated discounted rewards when it takes action \mathbf{a}_i at state \mathbf{s} and then follows its policy π_i afterwards. In Q-learning, the i -th UAV at each state will select the action which maximizes its Q-value. Therefore, the policy of the i -th UAV at state \mathbf{s} , i.e., $\pi_i(\mathbf{s})$, is

$$\pi_i(\mathbf{s}) = \arg \max_{\mathbf{a}'_i \in \mathcal{A}_i(\mathbf{s})} Q_i(\mathbf{s}, \mathbf{a}'_i). \quad (16)$$

After taking the action $\mathbf{a}_i = \pi_i(\mathbf{s})$, the i -th UAV receives a reward $r_i = \mathcal{R}_i(\mathbf{s}, \mathbf{a}_i)$, and then observes the next state⁸ \mathbf{s}' . The optimal Q-values of the i -th UAV can be obtained iteratively based on the following update rule:

$$Q_i(\mathbf{s}, \mathbf{a}_i) \leftarrow Q_i(\mathbf{s}, \mathbf{a}_i) + \alpha \left(\mathcal{R}_i(\mathbf{s}, \mathbf{a}_i) + \rho \max_{\mathbf{a}'_i \in \mathcal{A}_i(\mathbf{s}')} Q_i(\mathbf{s}', \mathbf{a}'_i) - Q_i(\mathbf{s}, \mathbf{a}_i) \right), \quad (17)$$

in which α is the learning rate. Once the optimal Q-values of a UAV are obtained, the optimal policy is also determined.

When the state-action space is small, Q-learning can work efficiently by maintaining look-up tables for the update of Q-values [36]. However, in our system, the state-action space of the trajectory design problem is very large, which makes the update of look-up tables infeasible. Fortunately, motivated by the deep neural network (DNN), we can estimate the Q-values by a DNN function approximators, which are known as DQNs [37]. To be specific, DQNs can address the sophisticated mappings between the states of UAVs and their corresponding Q-values based on a large amount of training data. In our system, when a DQN is well-trained for the i -th UAV, given the current state \mathbf{s} as the input of the DQN, we can obtain the Q-values of the i -th UAV taking different actions, i.e., $Q_i(\mathbf{s}, \mathbf{a}_i), \mathbf{a}_i \in \mathcal{A}_i(\mathbf{s})$, from the outputs of the DQN.

In order to train the DQN of the i -th UAV Q_i , we utilize a separate network \hat{Q}_i , namely the target network [37], to generate the target for training. Define the weights of Q_i and \hat{Q}_i as Θ_i and Θ_i^- , respectively. During the training of Q_i , we update its weight Θ_i by minimizing the following loss function:

$$Loss(\Theta_i) = \sum_{m \in \mathcal{D}_i} (y - Q_i(\mathbf{s}, \mathbf{a}_i; \Theta_i))^2, \quad (18)$$

⁸Actually, a UAV does not know the actions of other UAVs in the current cycle by itself. However, it can still observe the next state according to the information from the BS.

Algorithm 1 DQN-based multi-UAV trajectory design algorithm for the i -th UAV.

Input: The structure of the network Q_i and its target network \widehat{Q}_i ; Maximum number of cycles C ; Initial state s .

Output: Policy π_i .

- 1: Initialize replay memory \mathcal{M}_i ;
 - 2: Initialize network Q_i with random weight Θ_i ;
 - 3: Initialize target network \widehat{Q}_i with weight $\Theta_i^- = \Theta_i$;
 - 4: **for** $c = 1 : C$ **do**
 - 5: With probability $1 - \epsilon$ select action $\mathbf{a}_i = \arg \max_{\mathbf{a}'_i} Q_i(s, \mathbf{a}'_i; \Theta_i)$; otherwise, select a random action from $\mathcal{A}_i(s)$;
 - 6: Take action \mathbf{a}_i , and then observe reward r_i and next state s' ;
 - 7: Store the sample $\{s, \mathbf{a}_i, r_i, s'\}$ into replay memory \mathcal{M}_i ;
 - 8: Sample a mini-batch \mathcal{D}_i from replay memory \mathcal{M}_i ;
 - 9: Perform a gradient descend step on the loss function $Loss(\Theta_i)$ with respect to weight Θ_i using data set \mathcal{D}_i ;
 - 10: Set $\Theta_i^- = \Theta_i$ every τ steps;
 - 11: **end for**
 - 12: **return** Policy π_i based on the trained network Q_i .
-

where $y = r_i + \max_{\mathbf{a}'_i} \widehat{Q}_i(s', \mathbf{a}'_i; \Theta_i^-)$ denotes the target for training, and \mathcal{D}_i is the training set with size D . Each sample in the training set, denoted by $m = \{s, \mathbf{a}_i, r_i, s'\}$, contains the current state s , the action taken by the i -th UAV \mathbf{a}_i , the reward received by the i -th UAV r_i , and the next state s' . However, we do not update the weight of the target network Θ_i^- simultaneously with Θ_i . Instead, we set $\Theta_i^- = \Theta_i$ every τ steps of the updating for Θ_i .

The proposed DQN-based multi-UAV trajectory design algorithm is presented in Algorithm 1. In our algorithm, we adopt the *experience replay* to suppress the temporal correlation in the generated training data [36]. Specifically, the training data of the i -th UAV is stored in a replay memory, denoted by \mathcal{M}_i , with size M . During the training of network Q_i , we randomly sample a mini-batch with D samples from the replay memory \mathcal{M}_i as the training set \mathcal{D}_i in each iteration. Besides, we utilize ϵ -greedy policy to balance the exploration and exploitation [37], [38]. Moreover, the *reduced available action set* method is used to accelerate the convergency [33].

VI. PERFORMANCE ANALYSIS

In this section, we first analyze the convergency and the complexity of our proposed algorithm. After that, we present some properties on the mode selection and the trajectory design for UAVs.

A. Algorithm Analysis

1) *Convergency*: In our algorithm, we adopt the gradient descend method to update the weight Θ_i for network Q_i , in which the learning rate exponentially decreases with iterations. Therefore, after a finite number of iterations, the weight Θ_i will converge to a certain value, which ensures the convergency of our proposed algorithm. Actually, the convergency of neural networks is challenging to be theoretically analyzed before training, as referred in [24]. The analytical challenge lies in that the convergence of a neural network is highly dependent on the hyperparameters used during the training process, in which the quantitative relationship between the network convergency and the hyperparameters is complicated. Instead, in our paper, the convergency of our algorithm can be observed by simulation.

2) *Complexity*: The time complexity of a network Q_i is characterized by the number of operations in each iteration during the update of its weight Θ_i . Assume the network Q_i has Z layers, whose numbers of neurons are denoted by q_i , $i = 1, \dots, Z$. Then, the time complexity in each iteration can be expressed as $\mathcal{O}\left(\sum_{i=1}^{Z-1} q_i q_{i+1}\right)$. When all layers in the network have the same amount of neurons, denoted by q , the time complexity can be given by $\mathcal{O}((Z-1)q^2) = \mathcal{O}(q^2)$.

B. UAV Performance Analysis

1) *Mode Selection*: In the system, which transmission mode that a UAV may select is mainly determined by the location of this UAV. To analyze the mode selection of a UAV, we consider a general case that a UAV flies directly from its mobile device to the BS at a fixed altitude⁹, which is illustrated in Fig. 6(a). The locations of the UAV, the mobile device, and the BS are given by \mathbf{x} , \mathbf{x}^d , and \mathbf{x}_0 , respectively. Without loss of generality, we assume $\mathbf{x}^d = (x^d, 0, 0)$. Besides, we define the 2D distance from the BS to the UAV as L_{2D} , which is the distance from the mobile device to the UAV's projection on the ground. Moreover, we denote the STP of the UAV in the

⁹The following analysis can also be applied to the cases where UAV's trajectory is in parallel to the direction from the BS and the mobile device.

Fig. 6. Mode selection for UAV transmissions.

U2D and the cellular modes as \mathcal{P}_{ts}^u and \mathcal{P}_{ts}^c , respectively. Based on these notations, we can show how the UAV-BS distance influences the UAV's STPs in different modes by Proposition 2.

Proposition 2. *As the increase of L_{2D} , \mathcal{P}_{ts}^u monotonously decreases while \mathcal{P}_{ts}^c monotonously increases. Besides, \mathcal{P}_{ts}^c changes more sharply with L_{2D} than \mathcal{P}_{ts}^u .*

Proof. According to subsection II-C, given the QoS requirement R_{th} , we have $\mathcal{P}_{ts}^u = \mathcal{P}_{a,i}(\mathbf{x}^d, \mathbf{x}, R_{th})$ and $\mathcal{P}_{ts}^c = \mathcal{P}_{a,i}(\mathbf{x}_0, \mathbf{x}, 2R_{th})\mathcal{P}_{g,i}(\mathbf{x}^d, \mathbf{x}_0, 2R_{th})$. Since the locations of the mobile device and the BS are fixed, the second term in the expression of \mathcal{P}_{ts}^c , i.e., $\mathcal{P}_{g,i}(\cdot)$, is a constant. With the assumption that the UAV flies at a fixed altitude, as the increase of L_{2D} , $\|\mathbf{x} - \mathbf{x}^d\|_2$ increases, and thus, \mathcal{P}_{ts}^u monotonously decreases. On the other side, \mathcal{P}_{ts}^c monotonously increases with L_{2D} , since a higher value of L_{2D} results in a lower value of $\|\mathbf{x} - \mathbf{x}_0\|_2$. Based on the above analysis, we can illustrate the STPs in both the transmission modes in Fig. 6(b).

Furthermore, due to the TDM property of the cellular mode, the data transmissions in the cellular mode is harder to satisfy the QoS requirement than that of the U2D mode, which can be characterized by the terms R_{th} and $2R_{th}$ in the expressions of \mathcal{P}_{ts}^u and \mathcal{P}_{ts}^c , respectively. Therefore, \mathcal{P}_{ts}^c changes more sharply with L_{2D} than \mathcal{P}_{ts}^u , i.e., the absolute value of the slope of the red curve (cellular) is larger than that of the blue one (U2D) in Fig. 6(b). \square

According to the protocol in Section III, the UAV tends to select the transmission mode with higher throughput. However, in this case, the transmission mode with a higher STP is equivalent to the one with a higher throughput. Therefore, based on Proposition 2, we can further figure out how the UAV select its transmission mode as it flies from its mobile device to the BS by Proposition 3.

Proposition 3. *As the increase of L_{2D} , the UAV first tends to select the U2D mode, after a switching point it prefers the cellular mode. The UAV locating at the switching point is more likely to fail in transmission than that close to the mobile device or the BS.*

Proof. When the UAV is close to the mobile device and far from the BS, i.e., $L_{2D} \rightarrow 0$, the data transmissions are more likely to succeed in the U2D mode, since \mathcal{P}_{ts}^u is higher than \mathcal{P}_{ts}^c . Besides, when the UAV is close to the BS and far from the mobile device, i.e., $L_{2D} \rightarrow x^d$, \mathcal{P}_{ts}^u can reach a high value while \mathcal{P}_{ts}^c is relatively low, and thus, the cellular mode can ensure successful data transmissions. Therefore, as L_{2D} increases from 0 to x^d , the UAV first tends to select the U2D mode, after a *switching point*, denoted by x^* , it prefers the cellular mode.

When the UAV locates at the switching point, neither the U2D nor the cellular mode can guarantee successful data transmissions. Thus, we can conclude that UAV locating at the switching point is more likely to fail in transmission than that close to the mobile device or the BS. Since \mathcal{P}_{ts}^u and \mathcal{P}_{ts}^c are continuous functions of L_{2D} , we can find the location of x^* by setting the derivative of $\mathcal{P}_{ts}^u - \mathcal{P}_{ts}^c$ to zero. Although the analytical solution of x^* is very hard to obtain, we can still get the numerical solution of x^* by simulations. \square

2) *Trajectory Design:* In the system, the trajectory of a UAV can not be characterized by specific system parameters. In other words, even all of the system parameters are given, the trajectory of this UAV can not be determined before simulation. However, we can still find the factors that may influence the trajectories of the UAV. Specifically, we consider the case that a UAV performs sensing task for C cycles at a fixed altitude, whose starting point locates at the above of its mobile device. In this case, the trajectory of the UAV can be limited in finite area determined by the BS, its mobile device, and its sensing target, which is given by Proposition 4.

Proposition 4. *In the top view of the system, the trajectory of a UAV is within a triangular area with the BS, its mobile device and its sensing target as the vertexes.*

Proof. As illustrated in Fig. 7, when the BS, the mobile device and the sensing target are non-collinear, they divide the plane into 7 areas, which can be classified in to three groups: $\mathcal{G}_1 = \{A_1\}$, $\mathcal{G}_2 = \{C_1, C_2, C_3\}$, and $\mathcal{G}_3 = \{E_1, E_2, E_3\}$. For any location in \mathcal{G}_2 or \mathcal{G}_3 , we can find a location in \mathcal{G}_1 where the UAV can obtain a higher utility than that in \mathcal{G}_2 or \mathcal{G}_3 . For instance, given a point U within area C_1 in \mathcal{G}_2 , we can find its foot point U' on the segment BD , i.e., a side of the triangular area A_1 . Since U' is closer to the sensing target T than U , the SSP at U'

Fig. 7. The trajectory of a UAV, where the BS, its mobile device, and its sensing target are denoted by points B , D , and T , respectively.

Fig. 8. The optimal points of a UAV, where the BS, its mobile device, and its sensing target are denoted by points B , D and T , respectively.

is higher. Besides, U' is closer to the BS B as well as the mobile device D than U , and thus, the STPs in both transmission modes at U' are also higher. Therefore, the UAV locating at U' can obtain a higher utility than that of U . Likewise, given a point V within area E_3 in \mathcal{G}_3 , we can conclude that UAV locating at the sensing target T , i.e., a vertex of the triangular area A_1 , can obtain a higher utility than that of V for the same reason.

Since the UAV aims to maximize its utility by designing its trajectory, we can conclude that it will not fly to the areas in \mathcal{G}_2 or \mathcal{G}_3 . Therefore, trajectory of the UAV is within the triangular area A_1 . When the BS, the mobile device and the sensing target are collinear, the trajectory of the UAV is within the longest segment among these three locations. This proposition can be further extended to the 3D case, where the trajectory of the UAV is within a triangular prism area, whose height is determined by the maximum and minimum flying altitudes of the UAV. \square

In addition, since the UAV aims to maximize its utility by designing its trajectory, it is motivated to fly to the locations where it can achieve high utility. Then, the trajectory of the UAV can be further described by Proposition 5.

TABLE III
PARAMETERS FOR SIMULATION

Parameters	Values	Parameters	Values
Number of UAVs N	10	Distance between two adjacent points Δ	25 m
Number of subchannels K	2	UAV sensing factor λ	$0.0005 \text{ (s}\cdot\text{m)}^{-1}$
Transmit power of UAVs P^u	10 dBm	Duration of a frame t_f	2 s
Transmit power of the BS P^b	41 dBm	QoS requirement R_{th}	1 bit/s/Hz
Noise power N_0	-85 dBm	Length of the sensing part T_s	2
Carrier frequency f_c	2 GHz	Length of the transmission part T_t	2
Height of the BS H_0	10 m	Discount factor ρ	0.9
Minimum flying altitude of UAVs h_{min}	50 m	Size of mini-batch D	50
Maximum flying altitude of UAVs h_{max}	150 m	Size of replay memory M	3000
Maximum flying speed of UAVs v_{max}	5.4 m/s	Update frequency of target networks τ	30

Proposition 5. *After performing enough cycles, i.e. $K \rightarrow \infty$, a UAV will keep still at a point or fly to and fro among multiple adjacent points.*

Proof. Since the trajectory of a UAV is within a finite and discrete triangular area, there exists single or multiple optimal points in the area that the UAV can obtain the highest utility. Therefore, a UAV aiming to maximize its utility has the tendency to fly to the optimal points. In the system, there may exist three cases for the optimal points:

- **Single optimal point:** This case is shown in Fig. 8(a). In this case, the UAV will fly to the optimal point P_1 , and then keeps still.
- **Multiple non-adjacent optimal points:** This case is shown in Fig. 8(b). In this case, the UAV flies to one of the optimal point P_2 or P_3 , and then keeps still.
- **Multiple adjacent optimal points:** This case is shown in Fig. 8(c). In this case, the UAV first flies to one of the optimal points P_4 or P_5 , after which it may fly to and fro among these adjacent points.

Therefore, we can conclude that a UAV will keep still at a point or fly to and fro among multiple adjacent points after performing enough cycles. \square

VII. SIMULATION RESULTS

In this section, we present the simulation results on the trajectory design of UAVs in the U2D communications overlaying cellular network. The simulation parameters based on the existing 3rd Generation Partnership Project (3GPP) technical reports [9] are given in Table III.

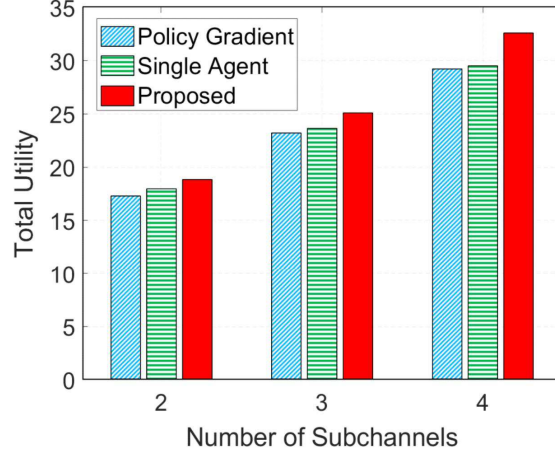

Fig. 9. Performance comparison of three algorithms, given different number of subchannels K .

In the simulation, we model the cell as a circular area with the BS at the center and the radius as 500 m. The sensing targets and mobile devices are randomly distributed within this circular area. The initial position of each UAV is on its corresponding mobile device with the altitude 100 m. Furthermore, during the training of DQNs, the ReLU function, defined by $f_{ReLU}(x) = \max\{0, x\}$, is adopted as the activation function [40]. The learning rate has the initial value of 0.001, and decreases exponentially with performing cycles. The exploration parameter ϵ in the ϵ -greedy policy decreases linearly during updating, whose initial and final value are 1.0 and 0.1, respectively.

In Fig. 9, we compare our proposed algorithm with the following two algorithms:

- **Policy gradient algorithm** [39]: Each UAV directly optimizes its parameterized control policy by a variant of gradient descent.
- **Single-agent Q-learning algorithm** [33]: Each UAV updates its policy considering other UAVs as the environment.

To be specific, Fig. 9 shows the performance comparison on the total utility in the system, given different numbers of subchannels K . We can observe that our proposed algorithm outperforms both policy gradient algorithm and single-agent algorithm in terms of the total utility. Besides, for any algorithm, the total utility increases with the number of subchannels K , since more frequency resources can be utilized by UAVs.

In Fig. 10(a), we present the total utility versus the number of episodes, with different learning rate α . Here, policy gradient algorithm is adopted as the benchmark. As shown in the figure, for all of the cases, our proposed algorithm converges after 100 episodes, which is faster than the

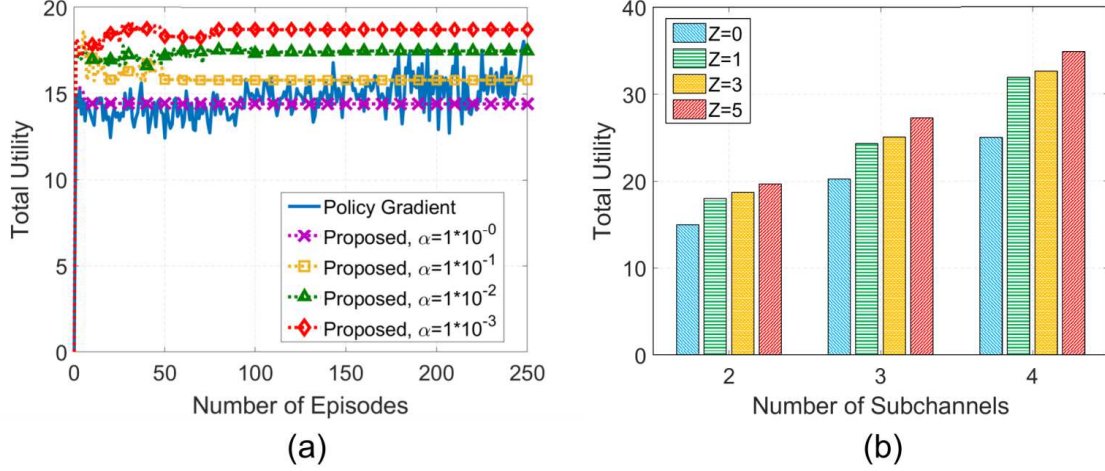

Fig. 10. (a) Total utility versus the number of episodes, with different learning rate α ; (b) Performance comparison of our algorithm given different number of hidden layers Z . The DQN with $Z = 0$ does not have hidden layer. The hidden layer of the DQN with $Z = 1$ contains 250 neurons. The hidden layers of the DQN with $Z = 3$ have 500, 250, and 120 neurons accordingly. The hidden layers of the DQN with $Z = 5$ have 500, 500, 250, 250, and 120 neurons accordingly.

policy gradient algorithm. Besides, the network with a smaller learning rate may achieve a higher total utility in the system, while it may spend a little longer time to converge. In Fig. 10(b), we compare the performance of our algorithm with different number of hidden layers Z . We can observe that the network with larger number of hidden layers can obtain higher total utility in the system. Likewise, for all cases, the total utility increases with the number of subchannels K , as more frequency resources can be utilized.

In Fig. 11(a), we present the trajectory of a UAV after performing 30 cycles, whose sensing target and mobile device are located at $\mathbf{x}^t = (50, -200, 0)$ and $\mathbf{x}^d = (-350, -150, 0)$, respectively. We can observe that the UAV first flies towards to its sensing target, and then flies among multiple adjacent points which are close to the optimal point obtained by simulation. Besides, the UAV's trajectory is within the triangular area whose vertexes are the BS, the mobile device, and the sensing target. This is consistent with Propositions 4 and 5. Moreover, the UAV's altitude is changing during the flight, which is caused by the trade-off between the path loss and the LoS probability. In Fig. 11(b), we show the UAV's STPs at different cycles on its trajectory. Overall, the UAV moves far from its mobile device and close to the BS. Therefore, as the UAV performs cycles, the STP in the U2D mode approximately decreases while that in the cellular mode monotonously increases, and the switching point is at the 9-th cycle. We can conclude that the UAV tends to select the U2D mode before the 9-th cycle, after which it prefers the

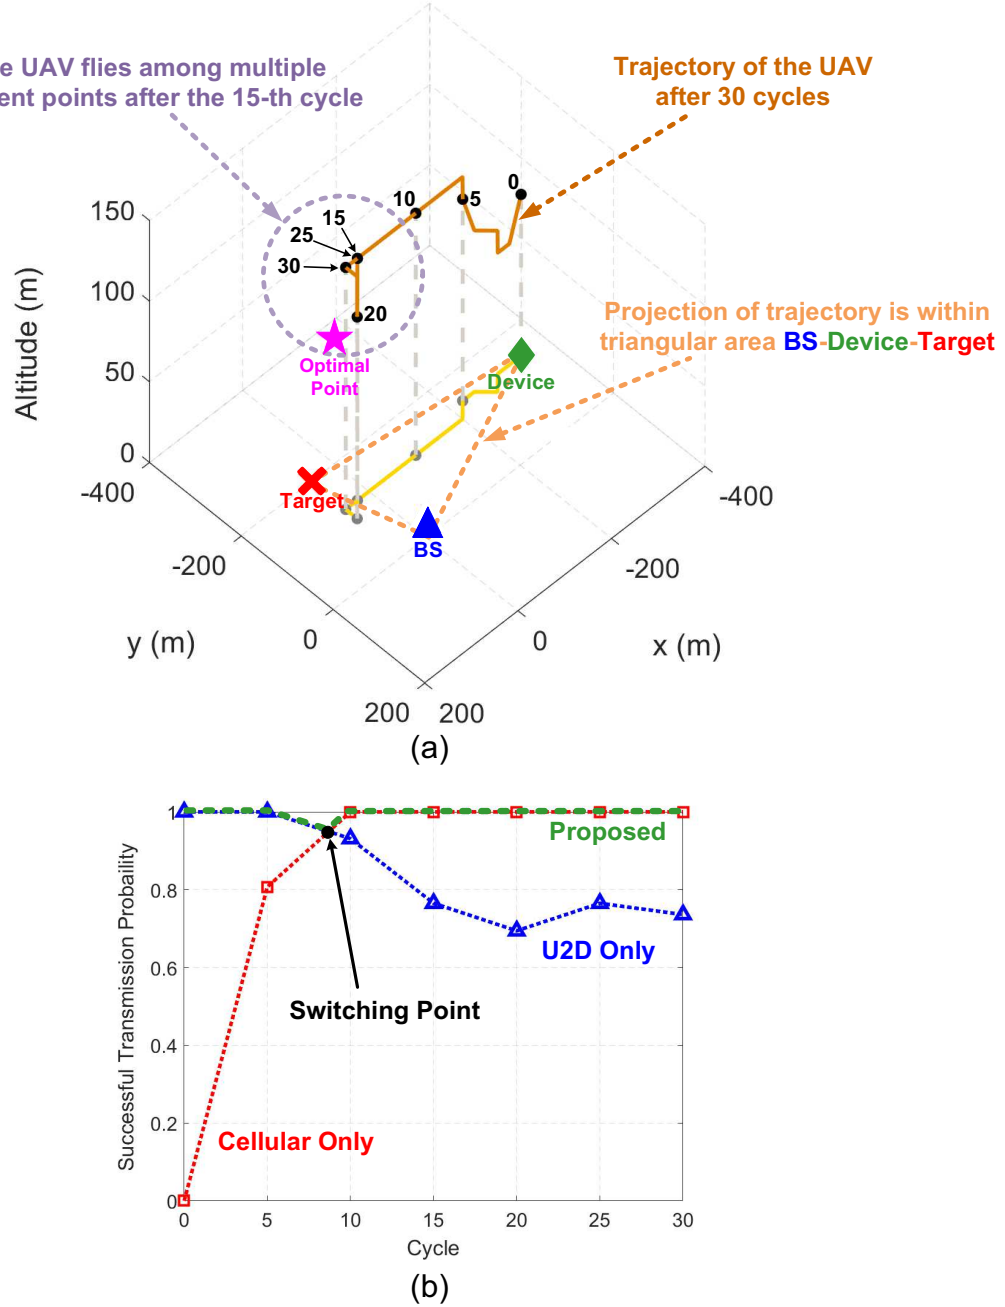

Fig. 11. (a) The trajectory of the UAV; (b) The STPs of the UAV on its trajectory. The UAV's sensing target and mobile device are located at $\mathbf{x}^t = (50, -200, 0)$ and $\mathbf{x}^d = (-350, -150, 0)$, respectively.

cellular mode, which is consistent with Propositions 2 and 3. Besides, by selecting the better transmission mode, the UAV can effectively improve its overall STP during the flight, which is illustrated by the green curve in the figure.

Fig. 12(a) shows the transmission state distribution of a UAV, with sensing target located at $\mathbf{x}^t = (50, -200, 0)$ and mobile device located at $\mathbf{x}^d = (-350, -150, 0)$. Here, we assume that other UAVs locate on their mobile devices with the altitude of 100 m. From the figure,

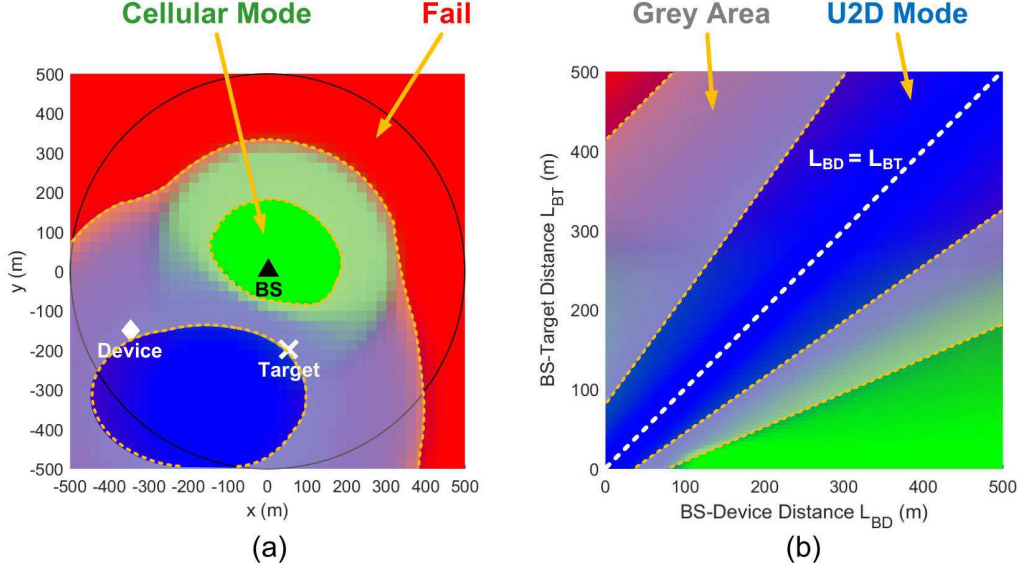

Fig. 12. (a) Transmission state distribution of the UAV, whose sensing target and mobile device are located at $\mathbf{x}^t = (50, -200, 0)$ and $\mathbf{x}^d = (-350, -150, 0)$, respectively; (b) Transmission state distribution given different BS-device distances L_{BD} and BS-target distances L_{BT} .

we can observe that the UAV tends to select the U2D mode for data transmission when it is close to its mobile device. Besides, as the UAV moves away from its mobile device and close to the BS, it prefers to transmit in the cellular mode. Neither of the modes can support valid data transmissions when the UAV flies far from its mobile device as well as the BS. When the UAV flies into the grey area, it may have multiple possible transmission states, i.e., the data transmission may succeed in either of the modes, or fail. In Fig. 12(b), we present the transmission state distribution of a UAV hovering over its sensing target at the altitude of 100 m. We assume that the mobile device, the sensing target, and the BS are collinear. The BS-device distance and BS-target distance are denoted as L_{BD} and L_{BT} , respectively. As shown in the figure, the UAV tends to select the U2D mode when its mobile device and sensing target are close to each other, i.e., the area near the white dash line which implies $L_{BD} = L_{BT}$. In addition, the UAV will transmit the sensory data in the cellular mode when the sensing target is close to the BS while the mobile device is far from the BS. The data transmission may fail when the mobile device is next to the BS while the sensing target is remote from the BS. In the grey areas, the UAV may have more than one possible transmission states.

VIII. CONCLUSION

In this paper, we have proposed overlaying U2D communications in a cellular Internet of UAVs, and investigated the trajectory design problem in this network. We have designed a joint

sensing and transmission protocol to schedule the sensing and transmission processes of multiple UAVs, and analyzed this protocol using nested bi-level Markov chains. Since the trajectory design problem can be regarded as a MDP, we have formulated this problem using multi-agent DRL. Then, we have proposed a DQN-based multi-UAV trajectory design algorithm to solve this problem. Simulation results have shown that our proposed algorithm can achieve a higher utility than policy gradient algorithm and single-agent algorithm.

Three conclusions can be drawn from the simulation results. First, UAVs tend to select the U2D mode when their mobile devices and sensing targets are close to each other. Second, UAVs prefer the cellular mode if the sensing targets are near the BS while the mobile devices are located at the cell edge. Third, UAVs' transmissions are prone to fail when their sensing targets are located at the cell edge while their mobile devices are close to the central BS.

APPENDIX A

PROOF OF PROPOSITION 1

According to the joint sensing and transmission protocol in Section III, a UAV will select the U2D mode in either of the following two cases:

- The data transmissions satisfy the QoS requirement only in the U2D mode;
- The data transmissions satisfy the QoS requirement in both the U2D and the cellular modes, and the throughput in the U2D mode is higher than that in the cellular mode.

We can then express the probability that the i -th UAV selects the U2D mode by $\mathbb{P}_{ts,i}^u = \mathcal{P}_{ts,i}^u (1 - \mathcal{P}_{ts,i}^c) + \mathcal{P}_{ts,i}^u \mathcal{P}_{ts,i}^c \cdot \mathcal{P} \{R_i^u \geq R_i^c\}$. Similarly, the i -th UAV selects the cellular mode with probability $\mathbb{P}_{ts,i}^c = (1 - \mathcal{P}_{ts,i}^u) \mathcal{P}_{ts,i}^c + \mathcal{P}_{ts,i}^u \mathcal{P}_{ts,i}^c \cdot \mathcal{P} \{R_i^u < R_i^c\}$. Given the location of the i -th UAV \mathbf{x}_i , the location of its mobile device \mathbf{x}_i^d and the location of the BS \mathbf{x}_0 , the terms $\mathcal{P} \{R_i^u < R_i^c\}$ and $\mathcal{P} \{R_i^u \geq R_i^c\}$ can be expressed as

$$\begin{aligned} \mathcal{P} \{R_i^u < R_i^c\} &= \mathcal{P} \left\{ R_i^u < \frac{1}{2} \min \{R_{a,i}^c, R_{g,i}^c\} \right\} = \mathcal{P} \{2R_i^u < R_{a,i}^c\} \mathcal{P} \{2R_i^u < R_{g,i}^c\} \\ &= \mathbb{E} \{ \mathcal{P}_{a,i}(\mathbf{x}_0, \mathbf{x}_i, 2R_i^u) \mathcal{P}_{g,i}(\mathbf{x}_i^d, \mathbf{x}_0, 2R_i^u) \} \triangleq \mathbb{E} \{ \Psi_i(R_i^u) \}, \end{aligned} \quad (19)$$

and $\mathcal{P} \{R_i^u \geq R_i^c\} = 1 - \mathcal{P} \{R_i^u < R_i^c\}$. Here, $\mathbb{E} \{\cdot\}$ is the mathematical expectation.

Based on the assumptions in Section II, if the LoS component exists in the link from \mathbf{x}_i to \mathbf{x}_i^d , $\zeta_{LoS,i}$ follows the Rice distribution with probability density function (PDF) $f_{\zeta_{LoS,i}}(x) = \frac{x}{\sigma^2} \exp \left(-\frac{x^2 + A^2}{2\sigma^2} \right) \cdot I_0 \left(\frac{x A}{\sigma^2} \right)$. Here, $I_0(\cdot)$ denote the modified Bessel function of the first kind with

order zero. Besides, A and σ are parameters, which can be obtained through $\Omega = A^2 + 2\sigma^2 = 1$ and $K_{ri} = \frac{A^2}{2\sigma^2}$. Thus, the PDF of R_i^u is $f_{R_{LoS,i}^u}(y) = f_{\zeta_{LoS,i}}\left(\frac{2^y-1}{\xi_{LoS,i}}\right) \frac{2^y \ln 2}{\xi_{LoS,i}}$, where $\xi_{LoS,i} = \frac{P^u}{N_0 \cdot 10^{\mathcal{L}_{LoS,i}/10}}$. Likewise, when the NLoS component exists, $\zeta_{NLoS,i}$ is Rayleigh-distributed with PDF $f_{\zeta_{NLoS,i}}(x) = \frac{x}{\sigma^2} \exp\left(-\frac{x^2}{2\sigma^2}\right)$, where σ is a parameter with the value of one. Then, the PDF of R_i^u is given by $f_{R_{NLoS,i}^u}(y) = f_{\zeta_{NLoS,i}}\left(\frac{2^y-1}{\xi_{NLoS,i}}\right) \frac{2^y \ln 2}{\xi_{NLoS,i}}$, where $\xi_{NLoS,i} = \frac{P^u}{N_0 \cdot 10^{\mathcal{L}_{NLoS,i}/10}}$. Therefore, given probabilities $\mathcal{P}_{LoS,i}$ and $\mathcal{P}_{NLoS,i}$, we can express the PDF of R_i^u as $f_{R_i^u}(y) = \mathcal{P}_{LoS,i} \cdot f_{R_{LoS,i}^u}(y) + \mathcal{P}_{NLoS,i} \cdot f_{R_{NLoS,i}^u}(y)$. Finally, we have $\mathcal{P}\{R_i^u < R_i^c\} = \int_{-\infty}^{\infty} \Psi_i(y) f_{R_i^u}(y) dy$ and $\mathcal{P}\{R_i^u \geq R_i^c\} = 1 - \int_{-\infty}^{\infty} \Psi_i(y) f_{R_i^u}(y) dy$, where $\Psi_i(y)$ is defined in equation (19). Then, $\mathbb{P}_{ts,i}^u$ and $\mathbb{P}_{ts,i}^c$ can be obtained, and the proof ends.
